By definition, the difference in latitude $L_2 - L_1$ can be expressed directly in **nautical** miles by calling one minute of arc a nautical mile. However, the difference of longitude $Lo_2 - L_1$ cannot be expressed in nautical miles of **departure** (easting or westing) without making use of the relation departure $= (Lo_2 - Lo_1)' \cos L$, in which $Lo_2 - Lo_1$ is expressed in minutes of arc and L is the latitude of operation. From the figure it is evident that the value of the computed departure would differ, depending upon what value of L between L_1 and L_2 is used. For distances under 600 miles and in latitudes lower than 60° a sufficiently close approximation to the departure distance can be obtained by using for L the value $\frac{L_1 + L_2}{2}$ or the "middle latitude." Outside the limits stated for latitude and distance, other methods, such as **Mercator sailing** will yield more accurate results. Graphical solutions of the middle-latitude problem may be made on **small-area plotting sheets.** (W.K.G.)

MIDGE. Insecta, Diptera. **Insects** resembling mosquitoes but with strong veins only near the anterior margin of the wing and without scales along the veins. Only a few can bite. Family Chironomidae. Insects of the family Dixidae, called dixa midges, also resemble mosquitoes but differ in the lack of scales on the wings and in the venation. (A.W.L.)

MIDRIB. Leaf.

MIGMATITE. The term proposed by Sederholm, in 1907, for composite gneiss, the result of **lit-par-lit** injection of granitic **magma** between the thin, closely spaced **foliation** planes of **schistose** rocks. Migmatites are closely related to **injection gneisses** and probably represent a form of **contact metamorphism** in the wall rock, or roof, of a granitic **batholith.** (R.M.F.)

MIGRAINE. Severe paroxysmal headache frequently associated with vomiting and visual disturbances.

The cause of this disorder is unknown. **Heredity** is a strong factor in many cases. Neurotic and mentally active individuals are more apt to be affected than phlegmatic and dull ones. Women are 2–3 times more commonly affected than are men.

Many theories are advanced for its causation: 1. Transient spasm of the cerebral arteries with or without pressure disturbance of the cerebrospinal fluid in the cavities of the brain. 2. Disturbances of the sympathetic nervous system brought on by toxic, psychic, emotional, or fatigue states. These disturbances of the sympathetic nervous system could cause the vascular disturbances cited above in (1). 3. Various allergic states with sensitivity to food or other allergens. 4. Disturbances in the function of the endocrine glands, particularly the pituitary and the ovaries.

Migraine attacks occur as paroxysms which come at more or less regular intervals. Most often they begin during or after puberty and in some cases disappear in both sexes at the menopause or climacteric. In women, the attacks often occur with the menstrual periods. The attack may last one, two, or three days and utterly prostrate the patient. Many patients can tell when the attack is coming on. The headache is usually on one side, and is of a boring, intense type difficult to bear. Most often it is located around the eyeball, temporal region, or forehead, later spreading to involve a larger area. Flashes of light, or scintillating zigzag lights before the eyes are common. Jarring movements, bright lights and noise all accentuate the headache. Dizziness, nausea, and vomiting are frequent.

The treatment of migraine is varied, and different measures are effective in different patients. Gynergen (ergotamine tartrate) is the most effective drug now in use. The inhalation of 100% oxygen, sedation with **barbital** compounds, and desensitization with histamine are also employed. (D.M.H.)

MIGRATION. Movement from one region to another over greater distances than are covered by the incidental wanderings of the individual.

The most familiar example is the seasonal migration of birds from their nesting grounds at higher latitudes to regions nearer the equator and back. Some species cover thousands of miles in these semiannual flights, while others winter only a few hundreds of miles from their summer homes.

The underlying causes of bird migration have been the subject of too extensive discussion to be reviewed here. They are undoubtedly closely correlated with the

ability to migrate, which results from specialization for flight. Birds are able to see long distances from the altitudes at which they fly, sometimes thousands of feet above the ground, and are able to proceed far more rapidly than any running animal. The advantages of wintering in a region of plenty are obvious, and the release of pressure during the breeding season by removal to less crowded regions is scarcely less so. At that time not only hungry adults must be fed but voracious young as well. Recent experimental work has emphasized the role of the endocrine glands and of seasonal changes in the environment in stimulating them as factors partially explaining the mechanism of bird migration.

Migrations of other animals are less common, but the movements of the great herds of bison on the western plains were a similar adjustment to seasonal food supply. The migrations of the European **lemming**, ending in the destruction of great numbers, are less easily understood. It has been suggested that they originate in a scarcity of food.

Many species of fish also migrate, either from one part of the ocean to another or between fresh and salt water. Two of the most noteworthy migrations are those of the salmon and the eel. Eels grow up in fresh water and migrate to the Atlantic Ocean in the neighborhood of Bermuda to spawn. Their young gradually work their way back to the rivers to develop. Salmon, on the other hand, are chiefly ocean fish, but during the breeding season they migrate far up the coastal rivers to spawn in fresh water.

Migrations of invertebrates have also been noted, but as a result of the small size and slow locomotion of most species they are usually mass movement over relatively short distances. Flying insects, however, often cover hundreds of miles, and in the case of some species of butterflies great hordes of individuals may take part in the migration. The southward flights of the North American milkweed butterfly are the most common example. Occasionally these butterflies move in such hordes that they cover large trees when they come to rest at night. The northward flight of the cotton moth in the summer is also noteworthy. This species is abundant in Ohio, far beyond the nearest cotton, which is its sole food plant. (A.W.L.)

MILDEW. **Fungi.**

MILE. The English or statute mile of 5280′ is that most commonly used by English-speaking people. This distance is supposed to be equivalent to 1000 paces of the Roman Legions stationed in Britain. Navigators and geographers prefer to use the nautical mile and the geographic mile respectively. (See **Nautical Mile.**) (W.K.G.)

MILK FACTOR. Cancer.

MILKWEEDS. Asclepiadaceae. A family of some 325 genera with over 1700 species of shrubs, woody vines, and perennial herbs. All contain a milky juice from which **rubber** may be made. The family is particularly abundant in the tropics, especially in Africa. The forms are extreme: many are **lianas** of great length; others have leaves modified into **pitcher**-like forms; some are **epiphytes**; while many, especially in Africa, are very much like **Cacti** in appearance. Indeed, many species are sold under the name of cactus. The uses made of various milkweeds are many and varied. The young shoots of many species are eaten as greens; other species yield dyes. The juices of several are violent poisons, as *Gonolobus*, from which an arrow-poison is obtained, and *Cynanchum*, which is used to stupefy fish. Many are grown for their weird shape, or because of their beauty, as the **Wax-plant**, *Hoya carnosa.* (R.M.W.)

MILKY WAY. The milky way, or galaxy, appears to the naked eye as a broad irregular band of misty light which encircles the sky. The telescope shows that it is in reality made up of myriads of faint stars interspersed with gaseous **nebulae.** Its light is due to these faint stars, and if all of the stars which can be distinguished as individuals with the unaided eye were blotted out, the milky way would still remain undiminished in intensity against the otherwise dark sky. A mere casual examination of the milky way on a dark night will reveal that its intensity varies from point to point, which is an indication that the faint stars are not uniformly distributed.

For many years the milky way itself, and the clustering of faint stars in the general direction of its plane, have been taken to indicate, not that the stars were actually closer together in that direction, but rather that the volume of space which contains all of the stars is more extensive in that direction. The first line of attack on the general problem of the distribution of matter in space was made by Sir William Herschel, in 1784. His method, which is essentially that of the modern methods of star counting, consisted in counting the number of stars visible in his telescope when it was directed to various directions in the sky. As a result of his observations he announced that all of the stars were contained in a volume of space shaped like a "grindstone," with the plane of the grindstone in the direction of the plane of the milky way. The relative dimensions of this grindstone-shaped volume of space were 850 to 155.

With the application of photography to astronomy and the construction of telescopes of greater light-gathering power the limiting brightness at which stars could be counted was extended down to about the 19th magnitude. It was immediately recognized that to cover the entire sky to such limits of faintness would be a hopelessly long task, and the plan of **selected areas** was proposed by Kapteyn and adopted by most astronomers.

The details of the methods of star counting and the results of the various counts are far too involved to be discussed in a work of this type, but the general results are of tremendous interest. For the purpose of interpretation a system of **spherical coordinates** known as **galactic coordinates** was devised. It should be remembered that all of the results are based on a statistical examination of a definitely limited amount of space and that the stars are counted only to an arbitrarily selected limit of faintness. It is believed that for every star which can be observed with the 100-in. telescope (the largest used at present) there are 29 stars which cannot be observed, and hence the results are based upon a statistical study of less than 5% of the stars in the selected areas.

In addition to the study of the milky way structure by star counts, many other methods of investigation have been developed and research is going forward. The existence of absorbing material in "empty space" has been confirmed from a variety of observations. We have even been able to make approximate determinations of the character and density of this "cosmic dust" or "cosmic haze," to mention merely two of the various descriptive terms applied to it. We are confident that it is not uniformly distributed and that there exist large, and relatively dense, clouds of dark material known as dark **nebulae.** Until the effects of this material on star counts and other data, in all directions and distances from our sun, have been established, we cannot do much more than guess as to the size and detailed structure of the milky way. All that we are justified in stating is that the original hypothesis of Herschel still remains and we believe that our milky way, or galaxy, occupies a more or less lens-shaped volume of space with the maximum diameter of the order of magnitude of one hundred thousand **light years.** The sun is not far from the central plane of the lens, and is of the order of magnitude of thirty thousand light years from the

center. The total mass of this galactic system is probably as high as two hundred billion (2×10^{11}) times the mass of our **sun**.

The problems relating to the dynamics and evolution of this galactic system are far from definitive solution. We have an abundance of evidence, from an analysis of the observed stellar motions, that the milky way is in general rotation with a period of the order of two hundred million years. Questions as to whether or not this motion is uniform, the location of the axis of rotation, etc., are far from being definitely answered.

It is interesting to speculate upon whether or not there are other galactic systems in space, and, if so, how they compare in size with our own. It is confidently believed that the extra-galactic spirals represent other galactic systems. When we attempt to compare the masses and dimensions of these outer objects with those of our own galaxy we are faced with two practically insurmountable problems: the dimensions of our own are very imperfectly determined, and the dimensions for the others are equally uncertain. At one time we believed that our own system was by far the largest of all. That statement must be modified now, and the best that we are entitled to state is that our own system probably has much in common with the Great Spiral in Andromeda. (W.K G)

MILLER INDEX. Crystallography.

MILLERITE (CAPILLARY PYRITES). The mineral millerite is **nickel** sulfide, NiS, whose slender **hexagonal** interwoven crystals so suggestive of hairs has led to the application of the name "capillary pyrites." It occurs also as radiated masses and coatings. It is brittle; hardness, 3–3.5; specific gravity, 5.3–5.6; luster, metallic; color, brass-yellow, often with an iridescent tarnish. Millerite is found in association with other nickel-bearing minerals and other sulfides. European localities are Bohemia, Westphalia, Wales, etc.; and in the United States at Antwerp, New York; with **pyrrhotite** in Lancaster County, Pennsylvania; at St. Louis, Missouri; Keokuk, Iowa; and Milwaukee, Wisconsin. In Canada millerite occurs in Oxford, Quebec, and in the famous Sudbury District, Ontario. It is used as an ore of nickel. Millerite was named for the English mineralogist, W. H. Miller. (E.S.C.S.)

MILLER'S THUMB. Pisces, Teleostei. A small fish (**Pisces**), *Cottus bairdi*, with very large pectoral fins and the head and anterior part of the body large and somewhat flattened. Common in the northeast quarter of the United States and southward in the mountains. In clear streams and lakes. One of the fresh-water sculpins. (A.W.L.)

MILLET. Gramineae. Cereal and forage grasses of several different genera are included in the term millet. All have a fibrous root system, ample foliage, and rather small grains. They are grown extensively in Occidental countries as forage crops and in many Oriental countries for human food as well as for forage.

Pearl millet, or *Pennisetum glaucum*, is an erect grass with solid stems 3–8′ tall. The **inflorescence** is a dense cylindrical spike 6″–1′ long. The **spikelets** are 2-flowered, the lower floret being staminate (see **Stamen**), the upper pistillate (see **Pistil**). Cross-pollination normally occurs. This plant is very variable in the structure of its inflorescence and has been given a number of names, such as African millet, Japanese millet, and Indian millet.

Panicum miliaceum is an erect grass 2–3′ in height and with frequent branching from the basal portion of the stem. The inflorescence is a **panicle** from 4–12″ long and variable in appearance in different varieties.

Foxtail millet, *Chaetochloa italica*, is an erect grass 2–5′ tall, with occasional branches from the base of the stem. The leaves are long, rather broad and tapering to a sharp point. The inflorescence is a narrow spike 4–8″ long. The elliptical spikelets are subtended by a group of long bristles and are 2-flowered. Cross-pollination occurs in this grass, as is also the case in the preceding species. Hungarian, German, Siberian, and Common Millet are varieties of this plant, an Old World native which is now widely distributed in North America.

Barnyard millet *Echinochloa Crus-galli*, is a coarse branching annual from 2–4′ tall. The inflorescence is a branched panicle with 2-flowered spikelets densely crowded on one side of the branches. This grass is another European native which has become a widely distributed weed in both cultivated and waste land in North America.

Millets as a group are drought-resistant plants widely distributed as forage or pasture grasses and for hay. The seeds are a valuable poultry food. A valuable feature of the group is their very rapid growth, which allows them to be used at times when other crops have failed; about 6 weeks after planting the seed, the plant is ready to cut for hay. (R.M.W.)

MILLIBAR. The unit of pressure used in meteorology is the millibar, which is 1/1000 part of a bar. A bar is 1,000,000 dynes per sq. cm. A millibar, therefore, is 1000 dynes per sq. cm. "Bar" is often used by physicists and acoustic engineers to denote 1 dyne per sq. cm. Also spelled barye. (P.E.K., L.D.W.)

MILLING. The process of removing material by multitoothed rotating cutters. Milling machines may be roughly classified into four groups: column and knee type, bed type, planer type, and rotary type.

Column and knee type milling machines are made in three styles: universal, plain, and vertical spindle. They are used for both toolroom and manufacturing work because of their adaptability and because of the ease with which they may be handled. Figure 1 shows the essential features of a modern motor-driven or

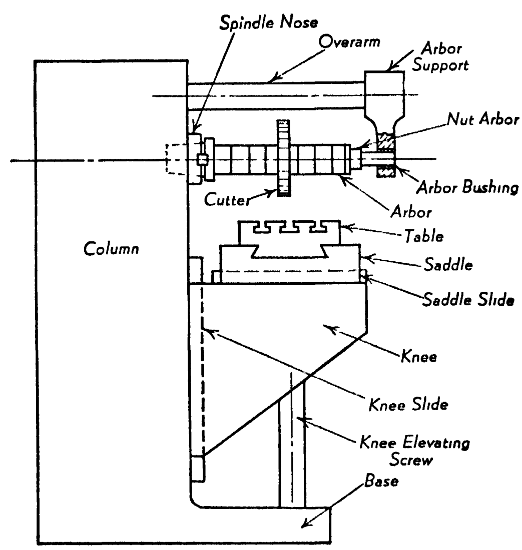

Fig. 1.

constant-speed plain milling machine. The machine has a horizontal spindle rotating in anti-friction bearings in the column. The table is mounted on and slides in dovetail guides on the saddle. The saddle is mounted on and slides in dovetail guides on the knee, which is free to move up and down on the face of the column, and is supported by a screw within a telescoping

cover. In operation, the milling cutters are either attached to the spindle nose or carried on an arbor or shaft which is driven from it. All three elements, table, saddle, and knee, may be either power- or hand-fed by screws turning in fixed nuts.

Universal milling machines are similar to plain milling machines, but the saddle is mounted on and swivels on a clamp bed which in turn slides on the knee, thus permitting the saddle to swing at an angle, and permitting table motion at other angles than 90° to the spindle axis. Vertical milling machines are similar to plain milling machines, but the spindle is vertical.

Modern heavy-duty milling machines are equipped with a standardized spindle end which has a locating taper hole in the spindle. The arbor is seated by turning a draw-in-bolt which extends through a hole in the spindle, and screws into a threaded hole in the arbor. The arbor is driven by a driving key on the spindle nose which fits into slots in the arbor shoulder. The arbor support provides a cylindrical bearing for the pilot of the arbor, and in many instances, an intermediate arbor support, serving as a bearing for an oversize collar, is employed. The arbor support is often connected to the knee by overarm braces for additional rigidity.

There are three types of milling cutters: hole type cutters which are mounted on the milling machine arbor; shank type cutters which have an integral arbor or shank and are mounted in the hole in the spindle nose, or in an adapter or collet that fits the spindle nose; and face type cutters which are fastened directly to the spindle nose by screws in the body of the cutter. Milling cutters may have teeth on the periphery only, on the ends only, or on the periphery and ends. Peripheral teeth may be straight or parallel to the cutter axis, or they may be helical, in which case they are usually, although incorrectly, referred to as spiral teeth. Spiral teeth give the cut a shearing action, which reduces the stress on each individual tooth and prevents the shock that occurs as each tooth of a straight tooth cutter meets the work. Spiral cutters produce much smoother surfaces and require less power to operate than straight-tooth cutters.

Plain milling cutters are used for machining plane surfaces, and are of cylindrical form with teeth on the periphery only. Cutters under ¾" in width are made with straight teeth, those with a wider face have spiral teeth. Helical milling cutters are plain mills with very few teeth and a very short helical lead. They are particularly efficient on surfacing or slabbing operations of considerable width and depth of cut. Helical mills are also used for light cuts where a very smooth finish is desired, and for frail, light work.

Metal slitting saws are essentially thin plain milling cutters. Most of the standard saws are made thinner at the center than at the outer edge to provide clearance in milling deep slots.

Side milling cutters are used for slotting, straddle milling and general side or face milling operations. Side milling cutters are similar to plain milling cutters, but have teeth on both sides as well as on the periphery. Half side milling cutters are similar to side milling cutters, but have teeth on the periphery and on one side only, and are used for straddle milling operations. Side milling cutters are also made in interlocking pairs as interlocking cutters so that slots of standard width may be milled in one operation even after the side teeth are resharpened. The slot width is regulated by shims or washers placed between the hubs of the two parts of the cutter.

Shank type cutters with an integral shank may be held directly in the hole in a taper nose spindle, or held in an adapter or collet which fits in the spindle nose hole in standardized spindle ends. Fig. 2 illustrates three extensively used shank type cutters which have Brown and Sharpe taper shanks with tang ends. Circular ends with a threaded hole for a milling machine draw-in-bolt are also obtainable. Slotting or two-lipped end mills have two cutting lips and are somewhat similar

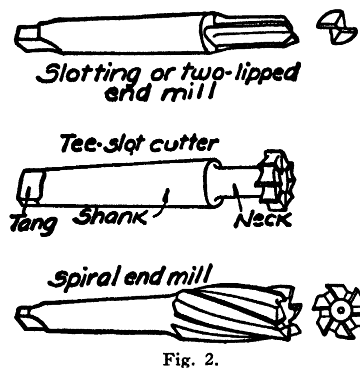

Fig. 2.

in action to twist drills. They may be used for milling slots with semicircular ends by first feeding to depth and then moving laterally. The depth of cut in solid stock is generally limited to one-half the diameter of the cutters, but deep slots can be produced by successive cuts.

Spiral end mills are similar to plain milling cutters but have teeth on the end face as well as on the periphery. End mills are used for a variety of surfacing operations, particularly for surfaces that cannot be conveniently reached with hole type cutters. The cutter is made with a deep center hole to permit many resharpenings, but cannot be used for originating blind end slots from the solid metal since the teeth do not extend to the center. In machining slots by end milling, it is necessary to drill a starting hole whose diameter is at least equal to the mill diameter. Spiral end mills with straight shanks are extensively used for die-sinking and other similar operations. Straight shank mills are either held in an arbor with a straight hole by a set screw, or held in a spring collet. Tee-slot cutters are used for milling the base groove or portion of a tee-slot. The body slot must be cut before the tee-slot cutter can be used, and the neck of this cutter must be smaller than the body slot width.

Shell end mills are used in conjunction with an arbor and are more economical than solid end mills of the same size, since one arbor will serve for several cutters and need not be discarded when a cutter is worn out or broken. Face milling cutters are essentially shell end mills with inserted teeth. Each tooth is held by a taper bushing and a screw which wedges it tightly in place, but will permit adjustment for sharpening. Face type cutters are used for surfacing operations, and consist of a body of cylindrical form with inserted teeth that have cutting edges on the periphery and on one face. The back of the cutter has a cylindrical recess that fits over the spindle nose to locate the cutter. The cutter is held to the spindle nose by four fillister head screws passing through holes in the body of the cutter and screwing into tapped holes in the spindle nose. The cutter has a key slot in the back that fits the driving keys on the spindle. Fly cutters are single-toothed form cutters. Since one tooth does all the cutting, it reproduces its shape very accurately in the work, but a very fine feed is required. The cutter can be easily ground from tool bit stock, and often serves as a means of milling intricate shapes that will not warrant the expense of special formed cutters.

Cutting speeds on the milling machine depend upon the character of the work, the type of cutter, the condition of the machine and, in many instances, upon the experience and ability of the machine operator. A reasonable basis for surface cutting speeds, in ft. per min., for high-speed steel cutters, is as follows:

annealed tool steel, 60 to 80; machinery steel and cast iron, 80 to 100; and brass, 150 to 200. Carbon steel cutters should operate at approximately half these speeds.

Feed rates in milling are expressed in two ways: in. per min., or thousandths of an inch per revolution of the spindle. Delicate or fragile work requiring an accurate finish will need fine feeds, while heavy work, from which a considerable amount of metal is to be removed, can be subjected to coarse feeds. The type of cutter employed also has a definite bearing on the feeds.

A good commercial finish can usually be obtained by using a feed rate of from .030" to .050" per revolution of the cutter. Finer feeds, such as .015" per revolution, will result in an excellent finish.

Milling machine work is held in a vise whenever possible, since work may be set up more quickly than by using clamps or bolting the work to the table. Hole type cutters are used in preference to end milling cutters, although face mills will afford production rates that compare favorably with those attained by peripheral cutters. Milling machine spindle attachments are employed for milling, drilling and boring operations on column and knee type milling machines. The attachment may be used for machining angles, undercuts, and other surfaces that are difficult or impossible to reach with standard equipment. It is also used in place of a vertical milling machine on small and medium sized work. A rotary milling attachment consists of a circular table which is supported by and rotates on a base which is bolted to the milling machine table. The rotary table is driven by a worm gear and worm, which is in turn rotated by a handwheel and crank in hand attachments, or by a universal shaft drive from the table in power attachments. The rotary attachment is used for circular milling and for indexing, for which graduations are provided at the edge of the table.

Indexing is one of the most important applications of the milling machine. A set of universal index centers consists of a headstock and a footstock. The headstock has a hollow head in which a spindle carrying a 40-tooth worm wheel is mounted. A single-threaded worm, which may be rotated by a crank, is in mesh with the worm wheel. The nose of the spindle is threaded to carry a chuck if desired, and has a taper hole for a center or an arbor. It is possible to swing the head in its bearings so that the nose of the spindle can be set to any angle from 10° below the horizontal to 5° beyond the perpendicular.

The work to be indexed can be held on a mandrel or arbor in the spindle nose of the headstock, or it can be held in a chuck which is screwed to the spindle. Many parts, however, are held between the headstock and footstock center or on a mandrel between these centers. The footstock is bolted to the milling machine table, and carries a sleeve which holds the footstock center. The sleeve may be adjusted axially by a crank. The center can be adjusted vertically, and can be set at an angle out of parallelism with the base when it is desired to mill tapered work.

Plain indexing makes use of index plates mounted on the bearing for the worm shaft and locked in place by a pin. Each index plate has six series of holes, and the crank arm, fastened to the worm shaft, is adjustable so that the locking pin in the crank handle can fit any of the series of holes in a particular plate.

To illustrate plain indexing, suppose it is desired to cut 60 slots in a cylindrical bar that is mounted between the headstock and footstock centers. The plate with a 15-hole circle is used and the crank is set to fit this circle. If the crank is turned from one hole on this circle to the next hole, the crank will have made $1/15$ of a revolution. Since the worm and worm gear ratio is 40:1, the spindle will therefore make $1/15 \times 1/40$ of a turn, or $1/600$ of a turn. In order for the spindle to index $1/60$ of a turn, it is therefore necessary to move the crank 10 spaces at a time. The crank will be moved from hole No. 1 to hole No. 11, to hole No. 21, etc. With the three index plates usually supplied, plain indexing can be used for all divisions up to 50; even numbers, except 96, up to 100; and many others. Two methods of indexing, compound and differential, are used for divisions that cannot be obtained by plain indexing. In compound indexing, the crank is turned as in plain indexing and locked in place in the plate, but the plate locking pin is then withdrawn and the plate rotated a definite amount to give a combination of motions that will afford the desired division. The method is tedious and time-consuming, and is rarely employed except when differential indexing equipment is not available.

In differential indexing, the index plate is not fixed, but is geared to the crank in such a manner that it moves a small fraction of a turn for every revolution of the crank. In this way, all indexing between 2 and 382 divisions may be handled; data for plate selection and necessary gearing may be found in shop handbooks.

Spiral milling is the process of cutting helices on a universal milling machine by connecting a universal dividing head by change gears to the table lead screw, so that the dividing head spindle rotates in conjunction with the movement of the table.

The profiler is a vertical milling machine with two spindles, one of which carries a tracer or guide point, and the other an end mill whose cutting end is a duplicate of the tracer end. The operator follows a master template with the tracer and the end mill cuts a similar contour in the work. (H.C.H.)

MILLIPEDE. **Diplopoda.**

MILLON'S REAGENT. **Aminoacids, Polypeptides, and Proteins.**

MIMETITE. The mineral mimetite is a **chloro-arsenate of lead** corresponding to the formula $(PbCl)Pb_4(AsO_4)_3$. It is **hexagonal**; brittle; hardness 3.5; specific gravity, 7.0–7.25; luster, resinous; color, usually yellow to brown but may be colorless or white; translucent. Mimetite is a rather rare secondary mineral occurring in altered lead deposits. Found in Bohemia; Saxony; Cornwall and Cumberland, England; South West Africa; Mexico; and in the United States in Pennsylvania and Utah. The name mimetite is derived from the Greek word meaning imitator, because of the similarity of mimetite and **pyromorphite.** (R.M.F.)

MIMICRY. The resemblance of an animal to some other living thing or inanimate object. Mimicry may involve both color and form, hence it is closely related to **coloration.** It is supposed to benefit the mimic either by concealing it from its enemies, by causing them to mistake it for something undesirable, or by enabling it to approach its prey without giving alarm.

Some cases of mimicry are probably incidental, though it is easy to imagine value in all of them. The brightly colored king snakes, for example, may be avoided because of their resemblance to the poisonous coral snake, but it is difficult to know that this is true. On the other hand, some butterflies are distasteful to monkeys, and by actual experiment it has been shown that after one unpleasant taste the monkey avoids both the unpalatable species and others that resemble it closely. Here there can be no question of the value of the mimicry.

Mimicry of inanimate or inmovable objects is shown by many insects. Tree hoppers may look like stout thorns, some caterpillars resemble stubby dead twigs, leaf insects and leaf butterflies are much like leaves, and some moths that rest on the trunks of trees are scarcely distinguishable from bark. One of the most remarkable examples is that of a little North American moth which

resembles a bird-dropping. Its front wings are chalky white with mottled gray markings. When at rest they are folded close about the body and hind wings and the tip of one overlaps the other, thus concealing the symmetry of the insect. Most moths found near the ground in the woods perch among dry leaves or on the under side of leaves or on stems of low plants, but this one remains in full view on the upper surface of a leaf, where a bird-dropping would naturally fall.

Aggressive mimicry occurs in the **ambush bugs** and some of the **robber flies.** The ambush bugs hide in flowers, where their color and markings make them nearly invisible. They pounce on insects which visit the flowers for nectar. Some robber flies capture bees for food, and in one genus differ greatly from the usual form and resemble bumblebees very closely. (A.W.L.)

MINE SURVEYING. Surveying.

MINERAL. A natural inorganic substance having a characteristic range of chemical composition, usually a definite **crystal form,** and exhibiting other specific, physical characteristics such as **cleavage, fracture, hardness, color, luster,** and **heft** (specific gravity). The study of minerals is called mineralogy. One who studies minerals is called a mineralogist. (R.M.F.)

MINERAL OIL. Petroleum.

MINERALIZERS. The term applied by petrologists to magmatic gases such as water vapor, **hydrogen,** and compounds of the rarer elements and volatile substances which are retained in solution under varying degrees of pressure and temperature, but which tend to escape from the effusive **lavas** under atmospheric pressure alone. These original constituents of **magmas** are essential to the origin of all types of intrusive and relatively coarsely crystalline **igneous rocks,** as they tend to:

1. Lower **viscosity** and thus lower the temperature at which certain minerals crystallize.
2. Act as **catalyzers** in aiding the formation of compounds and crystals.
3. Combine with other elements and compounds to form minerals which require mineralizers.
4. Concentrate metallic and other compounds which otherwise would tend to remain dispersed. (R.M.F.)

MINERALOGIST. Mineral.

MINERALOGY. Mineral.

MINETTE. The term proposed by Voltz, in 1822, for "ironstones" of **Jurassic** age in the Briey basin and Lorraine, France. A **lamprophyric dike** rock whose principal minerals are **orthoclase** and **biotite.** (R.M.F.)

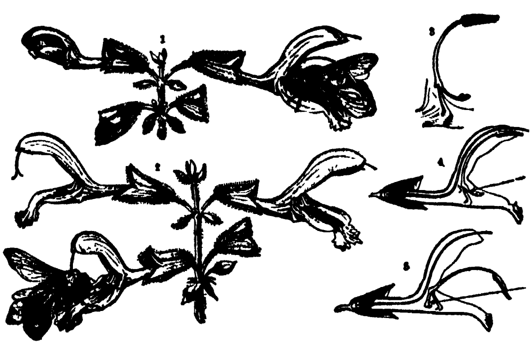
MINIVET. Aves, Passeriformes. A brightly colored **shrike.** The several species inhabit eastern Asia and India. (A.W.L.)

MINK. Mammalia, Carnivora. A slender semiaquatic animal with short legs, partially webbed toes, and a short, moderately bushy tail. Related to the polecats. One species, *Mustela sibiricus,* occurs in Siberia, one, *M. lutreola,* in eastern Europe, and one, *M. vison,* throughout North America. The fur varies from light to very dark brown and is thick and soft, mixed with long glossy hairs. It is among the more valuable furs commercially. (A.W.L.)

MINNOW. A small fish (**Pisces**), especially certain species related to the carp, dace, and chubs, which never exceed a few inches in length. The members of the genus *Hybopsis* are the typical minnows but the name is not limited to this genus. (A.W.L.)

MINOR OF A DETERMINANT. Determinants.

MINT FAMILY. Labiatae. The greater number of the 3000 species of this family are herbaceous plants, widely distributed in the temperate regions. The family also includes a few small trees and shrubs, found mostly in the American tropics. The characters distinguishing these plants are so outstanding as to make identification easy. Commonly the stem is 4-angled, appearing square in cross-section, with the leaves opposite, simple, and without **stipules.** The flowers are borne in **racemes** or more frequently in dense axillary **cymes.** The flowers are irregular, with the **calyx** composed of five **sepals** united to form a tube, and the **corolla** composed of fused petals which form a 2-lipped tube, the upper lip of three, the lower of two lobes. The **stamens,** either two or four in number, are inserted on the corolla tube. The **pistil** is composed of a bicarpellate **ovary,** each of whose **carpels** becomes constricted early in development to form a 4-parted ovary, from which a 2-lobed style arises. The fruit is commonly composed of four



Pollination by insects of sage, *Salvia glutinosa.* The flower is visited by a bee which pushes the stamen in such a way that its pollen-covered anther strikes the insect on the back (1). The anther (3) is hinged and has a projecting appendage which the bee touches with its head, thus tilting the anther over (see 4 and 5). When the bee visits another and older flower (2) in which the style and stigma project, cross pollination is effected. (*Kerner, Natural History of Plants, Henry Holt & Co.*)

achenes or nutlets. The flowers of this family are mainly cross-pollinated by insects: in some species the corolla tube is short enough to allow bees to obtain the nectar located in a disk at the base of the ovary. Pushing into the corolla tube to reach this nectar causes the pollen in the anthers to be shaken onto the insect's back, where it will be carried to the stigmas of another flower. Other species having longer corolla tubes are cross-pollinated by butterflies.

Many members of this family have **volatile oils** located in epidermal glands on the leaves, giving to the plants characteristic odors. Because of these volatile oils many of them are useful to man, some as condiments, some as **perfumes,** and some as **drugs.** Food products are rare in this family, the genus *Stachys* having species which form tubers, eaten in some European countries. *Salvia* species are widely grown because of the showy scarlet flowers, often accompanied by brightly colored bracts. The leaves of the garden sage, *Salvia officinalis,* are used as flavoring for poultry dressing. The stamens of *Salvia* species are interestingly modified to insure pollination. The filaments are long and arching under the upper lip of the corolla, and so attached that a downward projecting portion stands across the corolla tube. Any insect pushing against this projection in order to reach the nectar at the base of the flower causes the filaments to swing down, bringing the anthers against his back, on which the pollen is dusted. After discharge of the pollen from the anther, the style

elongates so that the forked stigma is in a position to touch the back of a pollen-laden insect and thus receive pollen, insuring cross-pollination. This stamen structure of *Salvia* is almost unique. Several species of *Monarda*, native plants of North America, are cultivated for their showy red or pink flowers. These plants are variously known as Bee Balm, Horse Balm, Oswego Tea. The leaves of some of them are used medicinally.

The leaves of *Ocimum Basilicum* (basil), *Thymus vulgaris* (thyme), and *Origanum vulgare* (marjoram), as well as *Salvia*, are used for flavoring. *Rosamarinus officinalis* gives rosemary oil; *Lavandula vera* and other species, oil of lavender; and *Pogostemon Patchouly*, oil of Patchouli—all these oils being used in making perfumes.

Many species of *Mentha* yield valuable **volatile oils**, used in medicine and as flavoring. *Mentha Pulegium* is pennyroyal. American pennyroyal is another mint, *Hedeoma pulegioides*, yielding a similar oil used as a stimulant and an emmenogogue. *Scutellaria lateriflora* contains a volatile oil used as a tonic and anti-spasmodic. *Marrubium vulgare*, or horehound, contains a volatile oil used as a treatment for catarrh and chronic infections of the lungs.

Certain species of Mints, commonly called nettles, are troublesome weeds, often with strong rank odors. Of these two species of *Nepeta* are worthy of note. One is *Nepeta Glechoma*, the Gill-over-the-ground, or Ground-ivy, a prostrate trailing vine, freely rooting at the nodes and bearing small deep blue flowers. It is often a persistent weed in lawns and gardens. The other is *Nepeta Cataria*, Catnip or Catmint, an erect, branching plant with pale bluish flowers and hairy leaves. It has a stimulating effect on cats; the dried leaves and stems, sometimes put up in cloth bags, are frequently sold to cat owners. (R.M.W.)

MIOCENE. Next to the last **period** in the **Tertiary** subdivision of the **geologic time-scale.** Type locality, the Paris Basin. The term Miocene was first proposed by Lyell in 1832. Miocene sedimentation started approximately 20,000,000 years ago and continued for about 12,000,000 years. In the United States the marine formations are best developed on the Pacific Coast, where they reach a maximum thickness of some 21,000′. There is no distinct evidence of an unconformity between the **Oligocene** and Miocene, but the **paleontological** record shows that the plants and animals of the Miocene are distinctly modern, especially those occurring in the terrestrial deposits which cover a wide area of the Great Plains. There was considerable volcanic activity during this period, as disclosed by beds of volcanic ashes and **andesitic** and **basaltic** lava flows in the John Day Basin and Columbia River Plateau. Volcanic **agglomerates** also occur interbedded with ashes and conglomerates in the Yellowstone Park Region. The Miocene is also an important period of mountain building, especially in the Alps, Apennines, and Himalayas. The plants of this period were similar to modern types, including the grasses, pines, and hard woods (Sumach, Elm, Oak). Most of the **fossil** marine **invertebrates** belong to the same genera living at the present time. During the Miocene there was a great development of modern mammals, especially in North and South America. The principal and peculiar South American types are: Cladosictis (carnivorous **marsupial**), Stegotherium (giant **armadillo**), Propalaeohoplophorus (glyptodont) Hapalops (giant ground **sloth**). The principal North American forms are the primitive types of dogs, horses, camels, antelope, elephants, and rodents. The development of grass-covered plains formed a suitable environment for the grazing instead of browsing **herbivores.** Mammalian adaptation is shown in both the tooth and limb structure, as well as in the increased size of the brain. For a description of the mineral resources of this period see the **Tertiary.** (R.M.F.)

MIRA. Mira (omicron Ceti) has the distinction of being the first **variable** star ever announced as such. In 1596 the Dutch astronomer Fabricius noticed a star of about the third **magnitude** which had not previously been recorded. The star faded within a few weeks, but was again seen and recorded by Bayer in 1603. In 1638 Holwarda, another Dutch astronomer, again observed the star and found that after disappearing it returned to visibility about 11 months later. At maximum brightness the star is easily visible to the naked eye, having a magnitude of about 3.5, but at minimum it can be seen only with a telescope of aperture greater than 1″, for its magnitude is only about 9.

Many determinations of the period of variability have been made, the time from maximum to maximum averaging about 330 days, with variations between times of successive maxima amounting to as much as one month. The diameter of the star is of the order of magnitude of 260,000,000 miles, or large enough to contain the sun and all the members of the **solar system** in their **orbits** out to beyond the planet **Mars.** Coupled with the variation in brightness there is also a variation in diameter amounting to about 32,000,000 miles, together with a temperature variation of roughly 500° K. (900° F.). (W.K.G.)

MIRACIDIUM. Larva.

MIRAGE. A curious atmospheric phenomenon caused by the **total reflection** of light at a layer of rarefied air. The most familiar manifestation is observed in warm weather on paved highways. The air next the pavement becomes heated and rarefied in comparison with that above it, so that at a sufficient angle of incidence, objects beyond the area are mirrored as if by polished silver, giving the almost irresistible impression that one is looking at a layer of water. Travelers in hot desert regions are sometimes thus deceived. Much more rarely the phenomenon appears in the air at a higher level than the observer. In either case the images are inverted; and because of the irregular contour of the air layer, they are usually distorted. A somewhat different effect, known as "looming," is produced by the refraction of light passing from rarefied air to a lower and denser layer. This results in distortion, making distant objects appear grotesquely elongated vertically, or in lifting into view objects beyond the horizon. It is most frequently observed at sea. (L.D.W.)

MIRRORS AND LENSES. We shall here be chiefly concerned with spherical or plane reflecting and refracting surfaces. A spherical mirror may be treated as a 1-base zone of a spherical surface, the axis of which is the straight line passing through the center of curvature and the pole of the zone. When the diameter of the mirror is small compared with its **radius of curvature,** and when the rays make only small angles with the axis, so that **spherical aberration** may be neglected, such a mirror produces fairly sharp images which are easily calculated from the laws of **reflection.** Taking the pole O as origin and the mirror axis as X-axis (Fig. 1), and representing the radius OC by r, the image of a point $P_1(x_1, y_1)$ in the plane XY is the

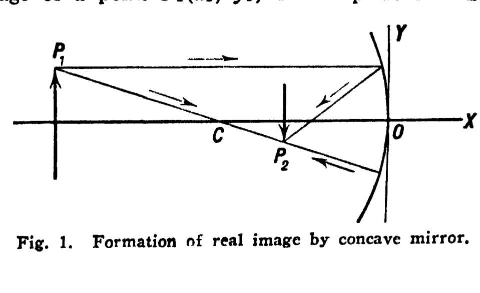


Fig. 1. Formation of real image by concave mirror.

point P_2 whose coordinates, for either a concave or a convex mirror, are

$$\left.\begin{aligned} x_2 &= \frac{rx_1}{2x_1 - r}, \\ y_2 &= \frac{-ry_1}{2x_1 - r}. \end{aligned}\right\} \quad (1)$$

r is + or − according as the mirror is convex or concave. If x_2 turns out positive, it means that the image is virtual. In Figure 1, r, x_1, and x_2 are all *negative*, as is y_2, so that the image is real and inverted. If the incident rays are parallel to the axis, the focus of the reflected rays, called the "focal point" of the mirror, is on the axis at $x = r/2$. For a plane mirror, $r = \infty$ and $x_2 = -x_1$, $y_2 = y_1$.

Spherical lenses have various combinations of convex, concave, or plane surfaces. There is always a point on the axis, called the "optical center," such that if a ray in traversing the lens is in line with this point, the entering and emerging parts of the ray are parallel. For a very thin lens this point may be considered at the center of the lens and is a suitable origin (O, Fig. 2). If

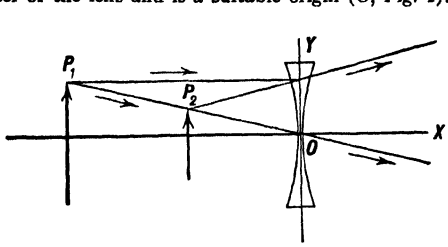

Fig. 2. Formation of virtual image by "negative" lens.

the radii of curvature r_1, r_2 are large compared with the diameter of the lens, and if the refractive index of the lens is n, the equations giving the image of the point x_1, y_1 made by a thin lens are

$$\left.\begin{aligned} x_2 &= \frac{r_1r_2x_1}{r_1r_2 + (n-1)(r_2 - r_1)x_1}, \\ y_2 &= \frac{r_1r_2y_1}{r_1r_2 + (n-1)(r_2 - r_1)x_1}. \end{aligned}\right\} \quad (2)$$

r_1 and r_2 refer to the left and right surfaces, respectively, which is the order in which the light encounters them. P_1 and P_2 in either figure are called conjugate points of the system. The "focal length" is obtained by letting $x_1 = \infty$ and calculating x_2 from (2), which gives

$$f = \frac{r_1r_2}{(n-1)(r_2 - r_1)}. \quad (3)$$

This enables us to write (2) in simpler form:

$$\left.\begin{aligned} x_2 &= \frac{fx_1}{f + x_1}, \\ y_2 &= \frac{fy_1}{f + x_1}. \end{aligned}\right\} \quad (4)$$

If x_2 turns out negative, the image is virtual; if y_2 is negative, it is inverted. For lenses of appreciable thickness or of strong curvature, the calculations are not so simple, and in general there are two unequal focal lengths, depending upon which way the rays pass through the lens.

The reciprocal of the focal length of a lens, called its "focal power," is a measure of the converging or diverging effect of the lens. It is commonly expressed in "diopters" or reciprocal meters; thus if the focal length is 50 cm. or ½ meter, the focal power is 2 diopters. (L.D.W.)

MISCEGENATION. Reproduction by parents of different races. A form of intraspecific **hybridization.** (A.W.L.)

MISFIT STREAM. U-Valley.

MISPICKEL. Arsenopyrite.

"MISSING LINK." Paleontology of Man.

MISSISSIPPIAN PERIOD. A geologic period in the **Paleozoic** Era. Term first proposed by H. S. Williams in 1891. Type locality, Mississippi Valley. The period began about 280 million years ago and lasted for about 25 million years. The term Mississippian is roughly equivalent to the more general term, Lower **Carboniferous.** In Britain, the formations of this system are grouped under the terms **Culm** and **Mountain Limestones,** which, as in the United States, immediately succeed the **Devonian** and are followed by the upper Carboniferous, or **Pennsylvania** System (U. S.), and Coal Measures (Britain). The formations of this system are chiefly sandstones and shales in the **Appalachian Geosyncline,** representing **delta** and **estuarine** deposits of considerable thickness which pass Westward into thinner **facies** of marine **shales** and **limestones.** In the Rocky Mountain region occur a great thickness of marine Mississippian called, locally, the **Madison Limestone.** The marine life of the Mississippian is chiefly characterized by **echinoderms** and **foraminifera.** Petroleum occurs in the Mississippian formations of Southeastern Ohio, West Virginia, Southeastern Pennsylvania and Eastern Kentucky. (R.M.F.)

MISSOURITE. The term proposed by Weed and Pirsson, in 1896, for a **basic, intrusive igneous** rock of **granitic texture** containing an abundance of **pyroxene, olivine** and **leucite.** This rock is the deep-seated equivalent of leucite **basalt.** Type locality, Highwood Mts., Montana. (R.M.F.)

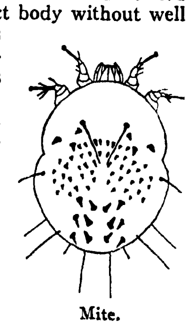
MIST. Suspended, very small water droplets with a grayish appearance are internationally recognized as mist. This type of phenomena is known as damp haze in the United States. (P.E.K.)

MISTLETOE. Parasitic Plants.

MITE. Arachnida, Acarina. Minute animals related to the spiders. They have a compact body without well marked regions. The many species include scavengers and external parasites, many of them serious pests of domestic animals and man.

The group includes the harvest mites, also called the **chigger** or jigger in the United States, the red **spider,** and numerous species known as mites. Among the latter are the scab mites, mange mites, and itch mites which attack animals and man, and the gall mites which live on plants.

The forms called fresh-water and salt-water mites are ticks. (A.W.L.)



Mite.

MITER GEARING. Bevel Gearing.

MITOCHONDRIA. Cell.

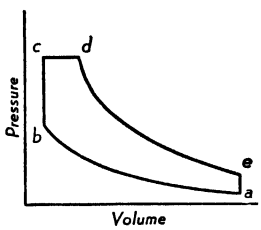
MITOSIS. Cell Division.

MIXED ACID. Mixtures of **nitric acid** and **sulfuric acid** used for nitrating organic substances, such as **glycerol, toluene, phenol,** in the manufacture of **explosives** and **plastics.** A standard acid consists of 36% nitric acid, 61% sulfuric acid and 3% water. Different strengths are used for various purposes, for example,

Nitration of	Mixed Acid Used		
	H_2SO_4	HNO_3	H_2O
Cellulose, for military nitrocellulose	74	18	8
Glycerol, for nitroglycerin	50	50	—
Toluene, for mononitrotoluene	58	24	18
Dinitrotoluene, for T.N.T.	68	24	8

The price of mixed acid is based on the "N unit" (the price of 1 lb. of contained HNO_3) and on the "S unit" (the price of 1 lb. of contained H_2SO_4) in the quantity of acid involved. (R.K.S.)

MIXED CYCLE. High-speed internal combustion engines perform their thermodynamic cycles of operation so rapidly that, whether originally intended to operate on the **Diesel** or the **Otto** principle, the actual cycle has a combustion that exhibits both constant volume and constant pressure phases. Spark ignition engines must receive the timed spark in advance of piston dead center position. Compression ignition engines must have the injector timed to begin the fuel spray also ahead of dead center position. In either case, on account of high rotative engine speed the combustion is only partially completed before the piston begins the expansion stroke. The remaining fuel is burned approximately at constant



pressure. A conventionalized cycle is shown in Fig. 1. Combustion extends from b to d. The air standard efficiency expression is:

$$E = 1 - \frac{1}{r^{\gamma-1}}\left[\frac{ZR^{\gamma} - 1}{(Z-1) + Z\gamma(R-1)}\right]$$

where r = Ratio of compression along ab.
γ = Adiabatic gas constant (specific heat ratio).
R = Cutoff ratio V_d/V_c.
Z = Combustion pressure ratio P_c/P_b.

All factors which influence either Otto or Diesel cycle efficiency appear here, and in addition a factor introducing characteristics of the constant volume phase of combustion. (F.T.M.)

MIXER. **Superheterodyne.**

MIXING. Mixers for agitating mobile liquids can be divided into two general types, namely (1) propeller, which gives a flow parallel to the axis of rotation, and (2) radial, which gives a flow perpendicular to the axis of rotation. The most common radial types are paddles and turbines.

The power required to drive an impeller can be found by use of the following formula:

$$P = KN^{3-a}D^{5-2a}\rho^{1-a}\mu^{a}$$

where P = Power input to the shaft.
K = A constant characteristic of the tank geometry.
N = Shaft speed.
D = Impeller diameter.
ρ = Density of the fluid.
μ = Viscosity of the fluid.
a = A number varying from one to zero and dependent on the value of the modified Reynolds number, $\frac{ND^2\rho}{\mu}$, "a" has a value of one at low values of the Reynolds number.

Once the constant K and the variation of "a" with the Reynolds number have been established in a laboratory scale tank the equation can be used to "scale up" to other geometrically similar systems. Both tank and impeller must be kept similar.

Mixers may be used wherever agitation of a liquid is desired. Such cases may include blending of liquids, solution of solids, crystallization, gas absorption, suspension of a solid, e.g., a catalyst, or for **heat transfer** from tank walls or from a coil in the tank. The problem of anticipating the size, shape and speed of an impeller to do a specific job is still for the most part unsolved and recourse must be made to trial and error testing Among the various criteria used as a measure of agitation intensity are: power input to the stirrer, periferal velocity, shaft speed, and Reynolds number. No one criterion has been found to hold for all cases.

The mixing impeller is usually mounted on a vertical shaft concentric with the tank, although side entering shafts or tilted shafts are used, the shaft usually having no bottom bearing because of lubrication and corrosion difficulties. The drive may be either direct or by pulley.

To gain increased turbulence and to break up the vortex caused by the swirling liquid, *baffles* are frequently put into the tank. These are usually placed vertically at or near the outside wall of the tank, and causing the liquid swirling around the edge of the tank to be deflected into the center.

Thin liquids are usually stirred by small high-speed mixers, and thick liquids by large slow-speed types. When the mix becomes semisolid or doughy, a ***kneading machine*** is required. These machines consist of two Z-shaped knives which rotate slowly in a trough, and which lift, press, cut, and mix the materials. (D.E.M.)

MIXING OF AIR. **Condensation in the Atmosphere.**

MIZAR. Mizar (ζ **Ursae Majoris**) is, perhaps, the most interesting star in the "big dipper." It is probably the first **double star** ever observed. The fourth **magnitude** star Alcor forms with it a naked-eye double, and Mizar itself has a close companion which is telescopically visible. It was the first star observed as double by Riccioli in 1650. Tradition says that observation of the pair Mizar-Alcor was considered a good test of eyesight among the American Indians. If this was a difficult pair for them to separate, their eyesight could not have compared very favorably with that of modern times, for it is an easy double for most people.

As well as being the first visual double star to be discovered, Mizar also has the distinction of being the first **spectroscopic binary** discovered. In 1889 E. C. Pickering discovered that the **spectral lines** of this star were alternately double and single, a phenomenon which can only be adequately explained if the star is a close binary. In 1908 the fainter companion of Mizar and also the more distant, bright companion Alcor were both found to be spectroscopic binaries. (W.K.G.)

M.K.S. SYSTEM. That view of the **metric system**, in which it is thought of as based directly upon the present-day metric fundamental standards, the meter, the kilogram, and the mean solar second; whereas the **c.g.s. system** is based on the centimeter, gram and second. For example, the m.k.s. unit of work or energy, the joule, is equal to 1 kg. meter²/sec.² or 1 meter-new-

ton, while the corresponding c.g.s. unit, the erg, is 1 gram cm.^{2}/sec.^{2} or 1 centimeter-dyne.

Many writers prefer the m.k.s. system because the units are in general more convenient for practical purposes. The whole intricate array of electrical and magnetic units used by engineers, for example, is on the m.k.s. basis. While the demonstration of this fact would in many cases involve quite technical applications of the theory of physical dimensions, a single, comparatively simple example will serve to illustrate it.

In the article on **Electromagnetism** is mentioned the lateral force or thrust experienced by a conductor carrying a current across a magnetic field, as in an electric motor. If the current is denoted by I, the magnetic field intensity by H, and the length of the current's path, at right angles to the field, by l, then this force f is proportional to the product IHl. Electrical and magnetic units may be so defined that the force is numerically equal to that product:

$$f = IHl. \tag{1}$$

For our present purpose, the relation is more conveniently written

$$I = \frac{f}{Hl}. \tag{2}$$

In the c.g.s system the unit of force is the dyne, that of length is the centimeter, and that of magnetic intensity is the oersted, or maxwell per sq. cm. The above equation (2) now serves to define the c.g.s. absolute electromagnetic unit current. This unit, called the abampere, is that current which, flowing across a magnetic field of 1 oersted magnetic intensity, would experience a lateral force of 1 dyne per cm. length of wire. Thus, using Eq. 2,

$$I = 1 \text{ abampere} = \frac{1 \text{ dyne}}{1 \dfrac{\text{maxwell}}{\text{cm.}^2} \times 1 \text{ cm.}} = 1 \frac{\text{dyne cm.}}{\text{maxwell}}. \tag{3}$$

Now let us use m.k.s. units and take $f = 1$ newton $=$ 100,000 dynes, $l = 1$ meter $= 100$ cm., and $H =$ 1 weber/meter^2 $= 10^8$ maxwells/10,000 cm.^{2} $= 10{,}000 \dfrac{\text{maxwells}}{\text{cm.}^2}$. Using these values in Eq. 2, we have

$$I = \frac{100{,}000 \text{ dynes}}{10{,}000 \dfrac{\text{maxwell}}{\text{cm.}^2} \times 100 \text{ cm.}} = \frac{1}{10} \frac{\text{dyne cm.}}{\text{maxwell}}$$

$$= \tfrac{1}{10} \text{ abampere.} \tag{4}$$

But this current, $\frac{1}{10}$ abampere, is called the ampere. The ampere might thus be defined as that current which, flowing across a magnetic field of intensity 1 weber/meter^2, would experience a lateral force of 1 newton per meter length of wire. Clearly, therefore, the ampere is the m.k.s. absolute electromagnetic unit current.

Similarly, the absolute coulomb, volt, ohm, henry, farad, etc., that is, the so-called "practical" units of electrical engineering, all belong to the m.k.s. system, and fit in with the m.k.s. absolute joule and watt in the solution of the practical problems of electromechanics. (L.D.W.)

MOA. Aves, Apterygiformes. Giant flightless birds (**Aves**) of New Zealand. Now extinct, although they probably existed until about 500 years ago. They are known from skeletons, feathers, dried remains of soft parts, and egg shells. The largest moas, *Dinornis maximus,* were about 12′ tall. (A.W.L.)

MOCCASIN. Reptilia, Sauria. A name applied to two poisonous snakes of North America, the **copperhead** and the **cottonmouth.** (A.W.L.)

MODAL CLASS. The modal class in a **frequency distribution** is the class which has the greatest frequency. (L.A.A.)

MODE. The mode, one of the common **measures of central tendency,** is the value of that **variate** which occurs most frequently in a distribution. In a **serial distribution** it is found by observation. In a **frequency distribution** an empirical formula for the mode is $l + c \dfrac{\Delta_1}{\Delta_1 + \Delta_2}$ where l is the lower closed **class limit** of the **modal class,** c is the **class interval,** Δ_1 is the **absolute value** of the difference of the frequency of the modal class and the class preceding the modal class, and Δ_2 is the absolute value of the difference between the frequency of the modal class and the class succeeding the modal class. In a **probability function,** the mode is the value of x which determines the maximum value of the function. Usually distributions are unimodal.

A term used in Iddings and Washington's classification of the **igneous rocks** (1902) for the actual mineral composition expressed quantitatively in percentages by weight. As opposed to the chemical composition, expressed in the standard mineral molecules in terms of **oxides,** and called the **norm.** (L.A.A., R.M.F.)

MODEL ANALYSIS. Similitude.

MODULATION. Modulation is the process of impressing the intelligence to be transmitted upon the higher frequency radio or telephone carrier wave. The **carrier** may be altered in accordance with the intelligence (speech, music, television picture signal, etc.) in three fundamental ways, by varying the amplitude of the carrier giving amplitude modulation, by varying the frequency of the carrier giving frequency modulation, or by varying the phase of the carrier, thereby producing

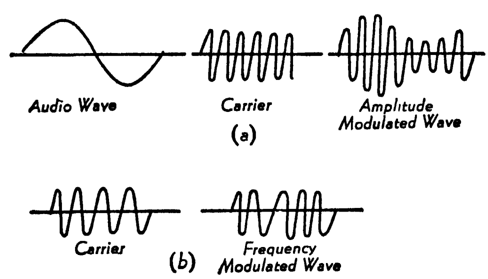


Fig. 1. Modulated waves.

phase modulation. Until fairly recently amplitude modulation was used almost exclusively for radio and is still used exclusively for telephone carrier work. Reference to Fig. 1*a* will indicate the principal characteristics of an amplitude-modulated wave. The amplitude of the carrier wave is caused to vary in accordance with the audio-frequency wave, i.e., the envelope of the carrier is identical with the audio wave. While the figure shows the carrier modulated with a single tone, the usual case involves a very complex sound wave, but even here the envelope is the same as the sound wave. Such a modulated wave may be analyzed and is found to be really several constant amplitude waves of different frequency. These frequencies are the original carrier and the original carrier frequency plus and minus every audio frequency. Thus for ordinary speech which is a continuous band of frequencies the modulated wave will consist of a band of frequencies from the carrier plus the highest audio to the carrier minus the highest audio. These extra, or side, frequencies constitute the sidebands. This is the reason a definite channel width is required to transmit a modulated signal and why the receiver must pass a band of frequencies in order to reproduce the original sound. The degree of modulation is known as the modu-

lation factor and for amplitude modulation is the increase (or decrease) of amplitude under modulation divided by the original amplitude. It is thus limited to 1 or 100%, since the wave cannot be reduced below zero. Frequency modulation, which has undergone very rapid development in the last few years, is obtained by varying the frequency of the carrier in accordance with the audio wave. The degree of modulation is often expressed by the deviation ratio which is the frequency modulation factor divided by the audio frequency. Fig. 1*b* indicates this type of modulation. It will be noted that while the carrier wave crosses the axis at equal intervals the modulated wave crosses at varying intervals as its frequency is changed. This wave is the combination of a much wider band of frequency components than the amplitude-modulated wave. Primarily for this reason frequency modulation is used only on very high frequencies. One of the major advantages of a system using this type modulation is its freedom from noise and interference. This inherent freedom from noise makes it possible to transmit a wider range of audio frequencies than is ordinarily possible with amplitude modulation. FM has thus become known as the high-fidelity system although the real distinction is the difference in noise, since, if noise could be eliminated, amplitude modulation could give just as wide response. The use of very high frequencies limits the coverage range of the frequency modulation stations, but since they have low interference characteristics the stations may be located closer together and thus produce the desired complete coverage. Phase modulation is used to a limited extent only. Modulation may be produced by several methods but **vacuum tubes** are used in all modern radio installations while vacuum tubes and oxide rectifier units are widely used in **telephony**. (L.R.Q.)

MODULUS. A ratio; see **Bearing Modulus, Section Modulus, Modulus of Elasticity.**

MODULUS OF ELASTICITY. The ratio of the unit **stress** to the unit **deformation** of a structural material is a constant, as long as the unit stress is below the **proportional limit**, and is called the modulus of elasticity. The shearing modulus of elasticity is frequently called the modulus of ridigity. (See **Ultimate Strength, Proportional Limit, Tension Test.**) (C.W.C.)

MODULUS OF RIGIDITY. Modulus of Elasticity.

MODULUS OF RUPTURE. The modulus of rupture in bending of a material is found by testing a transversely loaded beam of constant cross-section to failure and substituting the maximum **bending moment, moment of inertia** of the cross-section and the distance from the **neutral axis** to the extreme fiber in the **flexure** formula:

$$p = \frac{My}{I}.$$

The torsional modulus of rupture is obtained by testing a shaft of constant, circular cross-section to failure and then substituting the maximum **torque**, polar moment of inertia of the cross-section and the radius in the torsion formula:

$$s_s = \frac{Tc}{J}. \quad \text{(See Torsional Stress.)}$$

The bending or torsional modulus of rupture may be used to predict the maximum bending or torsional moment which a member can resist. (C.W.C.)

MODULUS OF RESILIENCE. Resilience.

MOERITHERIUM. Fossil Mammals.

MOHS SCALE. Hardness.

MOISTURE CONTENT OF THE AIR. Humidity.

MOLAR. The broad grinding teeth of mammals, located at the back of each jaw. (A.W.L.)

MOLAR SOLUTION. Concentration.

MOLASSES. Sugar.

MOLD. Casting; Phycomycetes.

MOLE. Mammalia. Burrowing animals of small size, highly specialized for life underground. They have short legs but the front pair are powerful with broad feet and strong claws. The eyes are rudimentary and there are no external ears.

The true moles of the Palaearctic region belong to the order Insectivora, which also contains the closely related shrew moles and web-footed moles. All of these forms are related to the shrews. The golden moles of Africa, *Chrysochloris,* are animals of similar form and habits, related to the **tenrecs.**

In the order Marsupialia a single rare Australian animal adapted for subterranean life is called the pouched mole or **marsupial mole.**

The name appears also in the mole voles, **mole rat,** and Cape mole rats, all burrowing animals of the Old World belonging to the order Rodentia. They are much less extremely adapted than the moles.

Mole (or mol) is also a common name for gram molecule. (A.W.L.)

MOLE CRICKET. Insecta, Orthoptera. Burrowing **crickets** whose large fore legs give them a superficial resemblance to moles. (A.W.L.)

MOLECULAR EXCITATION. In physics, excitation usually refers to the process of putting an atom or a molecule into a condition in which the total energy of its interior mechanism is greater than it is in the normal or "ground" state. (This does not refer to energy of translational motion of the particle as a whole.) According to the **quantum theory,** the energy required to accomplish such a change must be supplied in certain definite amounts or quanta. A less amount than this "excitation limit" apparently cannot be received by the atom or molecule. The necessary energy may be supplied by a **collision** with another atom or with an electron (as a cathode particle), or by the advent of a radiation quantum. In the former case the impinging atom or electron must have at least a certain speed (see **Critical Potential**); in the latter, the frequency of the radiation must be sufficient to give its quanta the necessary energy (see **Planck's Law**).

Upon returning to the normal state, or to a state of lower excitation, the atom or molecule yields up this extra energy; ordinarily by emitting a radiation quantum of this amount and of corresponding frequency, as in the emission of **light** or **x-rays,** by imparting the energy, in a "second-class" collision, to another atom or molecule, or by hurling off particles of itself, as in induced radioactivity. Familiar examples of excitation are the production of incandescence by heating, and the glowing of phosphorescent substances after exposure to light or x-rays. (L.D.W.)

MOLECULAR PUMP. Air Pumps.

MOLECULAR RAYS. If a narrow opening or slit is made in the wall of an enclosure containing a gas or a vapor, surrounded by a vacuum, those molecules which chance to encounter the opening pass out through it—a process known as effusion. The escaped molecules move in a wide variety of directions. But if, instead

of a simple slit, we have a succession of similar, parallel slits in plates set one in front of the other, the only molecules finally emerging will be those whose directions of motion are nearly parallel with the common axis of the slits. Such an emergent stream is a beam of "molecular rays." Much study has been devoted in recent years to such beams. By heating the enclosure, the vapors of metals may be studied in this way. To detect a beam of metallic molecular rays, a "target" of very cold glass or porcelain may be interposed for it to condense upon in the form of a visible spot. The motions of the molecules are unidirectional (few collisions) and their speeds should be in accord with the **Maxwell distribution law**; a point which has been ingeniously verified by Eldridge. Many studies have been made possible regarding the properties and behavior of individual molecules; the **Stern-Gerlach experiment** is a notable example. The importance of this field is just beginning to be realized. (L.D.W.)

MOLECULAR SPECTRA. The spectra of substances in the molecular state, like **atomic spectra,** are really made up of lines, though they are much more complicated. The transitions in a molecule which release the most energy (largest quanta) are due to electron changes, as in atoms, and the results of these changes are observed as lines in the **ultra-violet** region. But there are other ways in which a molecule can release or absorb energy. Thus the component atoms oscillate with reference to each other within the molecule, and this motion apparently is "quantized," i.e., changes abruptly from one state to another of different energy. (See **Quantum Theory.**) But these "vibrational" energy changes are much less than the electronic, so that the resulting quanta and spectrum lines are of much lower frequency, and appear in the extreme red or near **infra-red.** Again, the molecule rotates, and the quantization of its rotational energy results in the emission of quanta of still lower frequency, appearing as lines in the far infra-red.

Atomic spectra (due to electronic transitions) are characterized by series of lines progressively crowded together toward a "series limit." This is due to a variety of possible transitions of successively greater energy. The same is true of the changes in molecular rotational energy, but here the differences between the successive quantum energies are so very small and the lines are thus crowded so close together that a whole series of them appears merely as a "band," coming to a sharply defined edge on the low-frequency side and fading away gradually on the other side, or vice versa. Not only this, but the vibrational and electronic transitions are accompanied by rotational transitions, giving combined spectra which, on account of the close-grained character contributed by the rotational component, is composed of bands like the rotational bands themselves.

Thus a molecular spectrum appears as an array of bands instead of distinct lines, but arranged, like lines, in groups and series. The study of these bands and their groupings has furnished a surprising amount of information as to the structure and internal mechanism of molecules. (L.D.W.)

MOLECULAR WEIGHTS. **Chemical Composition.**

MOLECULES. **Chemical Composition.**

MOLLIER DIAGRAM. The properties of a vapor, as recorded in vapor tables, may be displayed graphically in a number of ways, among which the most used, and probably the most valuable, is the charting upon a plane whose coordinates are enthalpy or total heat and **entropy.** Generally, the total heat is made the ordinate, and entropy the abscissa. This chart of the properties of vapor is named the Mollier Diagram, and is of considerable use in tracing both theoretical and actual **expansions** of vapor. A throttled expansion on the Mollier Diagram is parallel to the constant heat lines, and **adiabatic** expansion is parallel to the constant entropy lines. Pressure, quality or superheat, and total temperature are shown on the Mollier Diagram as series of lines curved and inclined to the axes. Thus all characteristics of a vapor except volume may be displayed on the Mollier Diagram. (F.T.M.)

MOLLUSCA. A major division of the animal kingdom containing the **snails, oysters, clams, mussels, squids, octopus, nautilus** and related forms. **Mollusks** are the most highly developed of the unsegmented invertebrates and are both diverse in form and numerous in species.

The phylum is characterized by the following structures: 1. The body is unsegmented. 2. A well-developed head is found in most species. 3. The body bears a ventral muscular protuberance, the foot. 4. A fold extends in most species from the dorsal wall, enclosing a cavity associated with respiration. The fold is the **mantle** and the cavity, the mantle cavity. 5. In many species the mantle secretes a shell. 6. The **circulatory system** consists of tubular vessels and open spaces, with a **heart** made up of a ventricle and two auricles.

Some mollusks are important as food. Clams, oysters, and scallops are the most familiar of the edible species but others are eaten. Pearls and mother-of-pearl are also molluscan products.

The phylum is divided into the following classes:

Class **Amphineura.** Without a distinct head. Shell absent or composed of a series of plates. **Chitons.**

Class **Gasteropoda.** With a distinct head. Shell absent, conical, or spiral. **Snails** and related forms.

Class **Scaphopoda.** Head indistinct. Shell cylindrical.

Class **Lamellibranchiata** (Pelecypoda). Head indistinct. Shell of two lateral parts (bivalve). **Clams, mussels, oysters,** etc.

Class **Cephalopoda.** Head distinct, with long tentacles. **Squids, octopus, nautilus,** etc.

See also **Invertebrate Paleontology.** (A.W.L.)

MOLLUSCOIDEA. A name originally applied to a major group of animals including the **Bryozoa** and **Tunicata** and now used by some biologists to include the Bryozoa and the **Brachiopoda.** (See also **Invertebrate Paleontology.**) (A.W.L.)

MOLOCH. Reptilia, Sauria. An Australian **lizard** found in arid country. It is about 8″ long and resembles the horned toads of the southwestern United States in form, but is covered with stout spines which give it a forbidding appearance Like the horned toads it does not eat readily in captivity. (A.W.L.)

MOLPADONIA. **Holothuroidea.**

MOLYBDENITE. The mineral molybdenite is **sulfide of molybdenum,** MoS_2. Its **hexagonal** crystals are usually tabular to short prismatic, but if in massive form it may be **foliated** or granular. Has a perfect basal cleavage; is sectile; hardness, 1–1.5; specific gravity, 4.7–4.8; luster, metallic; color, very slightly bluish, lead gray; streak, greenish-gray; opaque. Molybdenite is one of the few minerals soft enough to give a distinctly greasy feel. Molybdenite is found as a contact mineral with **cassiterite** and **wolframite,** in **granite pegmatites** and sometimes in granites, **syenites,** or **gneisses.** It is found associated with tin ore in Saxony and Bohemia; in Norway, England, Australia; and in the United States in Washington County and Oxford County, Maine; in New Hampshire, Connecticut, Pennsylvania, and Washington. Its name is derived from

the Greek meaning lead, was formerly applied to minerals containing lead, to graphite and to molybdenite as well. Later the term was restricted to the latter mineral. It is an ore of molybdenum, and the chief commercial source in the United States is the Climax mine, Colorado. (E.S.C.S.)

MOLYBDENUM. Symbol: Mo. Atomic number: 42. Atomic weight: 95.5. Density: 10.2. Melting point: 2622° C. (**Isotopes**, page 290.)

Molybdenum is a silver-white, tough, malleable metal softer than glass, not oxidized by air at ordinary temperatures but above 600° C. burns to form white molybdenum oxide; dissolved by dilute **nitric acid**, and by **aqua regia;** made passive by concentrated nitric acid, and attacked by fused **alkalis**. Chemically related to **chromium, tungsten** and **uranium** elements. Discovered by Scheele in 1778.

The principal use of molybdenum metal is in the production of alloy steels, 0.15 to 0.35% molybdenum in steel for heat-treated machine parts and for some structural grades, up to 1.5% for *tool steel* and heat-resistant grades, up to 4% for *stainless steel* (especially corrosion-resistant), and up to 8.5% for high-speed tool steel. A certain molybdenum high-speed cutting tool steel contains 8.0 to 9.5% Mo, 3.5 to 4.0% chromium, 1.3 to 1.8% tungsten, and 0.9 to 1.3% vanadium. Molybdenum steel is extensively used in the automotive, airplane, and petroleum refining industries.

Molybednum occurs as **molybdenite** (molybednum sulfide, MoS_2), and **wulfenite** (lead molybdate, $PbMoO_4$). Roasting of molybdenite in a current of air yields white crystalline sublimate of trioxide, from which the metal is obtained by reduction with **aluminum** or **carbon** at high temperatures. Fusion of the ore with carbon and **sodium** carbonate in a blast furnace yields a sodium molybdate matte from which ferro-molybdenum is made in an electric furnace.

Hydroxide: Molybdenum trihydroxide ($Mo(OH)_3$), brownish black solid: molybdenum tetrahydroxide ($Mo(OH)_4$, possible $MoO(OH)_2$).

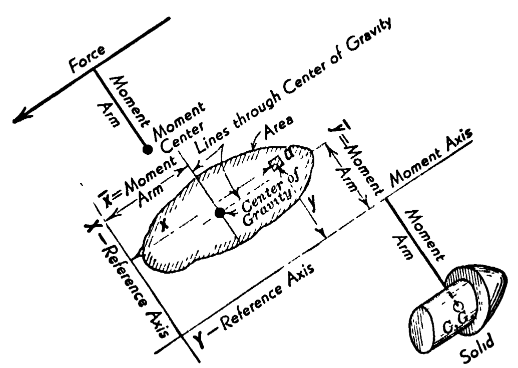
Oxides: Molybednum dioxide (MoO_2), brown and sometimes blue solid by reduction of the trioxide or ignition of ammonium molybdate $(NH_4)_2MoO_4$; molybdenum sesquioxide (Mo_2O_3), black solid by the reduction of the trioxide with zinc metal; molybdenum trioxide (MoO_3), white, somewhat volatile, solid, yellow when hot, greenish-yellow after ignition, soluble in alkalis to form molybdates, which form complex compounds with excess trioxide. The trioxide is the source to most molybdenum compounds.

Many reducing agents, e.g., **hydrogen, zinc** metal, **tin** metal, **ferrous** salts, **sulfurous acid,** sucrose react with molybdates usually forming a mixture known as "Molybdenum blue." Lower valence forms are readily oxidized to molybdate by ignition or by nitric acid.

Ammonium phosphomolybdate, yellow precipitate, of variable composition, and ammonium arsenomolybdate, similar, are important compounds in the identification of **phosphates** and **arsenates** respectively. A common test for molybdenum is as follows: **ammonium** phosphate added to a molybdate solution strongly acidified with **nitric acid,** produces a yellow crystalline precipitate. Arsenates give the same type of precipitate but arsenic can be eliminated by other tests. (See **Arsenic.**) (R.K.S.)

MOMENT. Moment consists of the product of a quantity and a distance to some significant point connected with that quantity. The principal moments are moments of forces, moments of lines, moments of areas, and moments of masses. Two types of moments are statical moment and the **moment of inertia.** Unless specifically stated to be otherwise (see **Statics**), the word moment would be taken to mean statical moment. A physical picture of moment may be obtained by considering the moment of a **force** (called torque). It is the magnitude of the force multiplied by the moment arm which is a perpendicular dropped from the moment center to the line of action of the force. This moment is the turning effect on a body against which the force is applied. The moment of an area is the magnitude of the area multiplied by the perpendicular distance from the centroid of the area to the axis of moments. Similarly the moment of a solid is its weight multiplied by the distance from its center of mass to the axis of moments.

The summation of moments of a force enters into one of the three equations of statical equilibrium (see **Statics**). In a case of equilibrium, this summation must always equal zero about any chosen moment center. The moment of an area about a line is of use in finding the centroid of an area, since the magnitude of the area multiplied by the distance to a parallel line through the centroid must equal the summation of all the incremental areas multiplied by the perpendicular distances from the centers of these areas to this reference line. Thus in the irregular figure shown the distance from the Y-reference axis (any convenient line) to a



Moments of force, area and mass

parallel line through the centroid of the figure is determined by summing the elementary moments, i.e., ay, and equating the summation to the product of the total area, A, and the centroidal distance $\bar{y}$.

$$\bar{y} = \frac{\text{Summation of } ay}{A}.$$

In a similar manner the location of a line, through the center of gravity, may be obtained in relation to the X-reference axis (any other convenient line not parallel to the Y-reference line). That is

$$\bar{x} = \frac{\text{Summation of } ax}{A}.$$

The intersection of these two lines, whose location is given by $\bar{x}$ and $\bar{y}$, is the center of gravity of the area. The center of gravity of a solid may be found in a similar manner by the use of three reference axes.

The use of the statical moment in finding centroid of areas or masses extends to areas and shapes which are made up of a number of elementary areas or masses whose centroids are common knowledge. Thus a trapezoid could be considered as made up of two triangles; a rivet, of a hemisphere and a cylinder. This method is also useful in computing centroids when the outline of the figure is expressed by a mathematical equation, since then the summation of ax and ay may be obtained as definite integrals. Cases of irregular figures which would not be analyzable by either of these methods can be treated by graphical means.

In the case of ***statistical*** moment, let us consider a variate x with either a **probability function** P_x, or a

frequency distribution f_x; then we define the nth moment about any point a as

$$\mu'_{n.x-a} = \frac{\Sigma(x-a)^n P_x}{\Sigma P_x} \quad \text{or} \quad \frac{\Sigma(x-a)^n f_x}{\Sigma f_x}$$

and for the case of a continuous probability function by

$$\mu'_{n:x-a} = \int_{x=x_1}^{x=x_2} (x-a)^n P_x dx$$

where $\int_{x=x_1}^{x=x_2} P_x dx = 1$.

We note $\mu'_{1:x} = \bar{X}$, and $\mu'_{1:x-a} = \mu'_{1:x} - a$. If $a = \bar{X}$, the **mean,** we obtain in all cases the central moments $\mu_{n:x} = \mu'_{n:x-\bar{x}}$. Some formulas for obtaining the central moments are

$$\mu_{0:x} = 1, \quad \mu_{1:x} = 0,$$

$$\mu_{2:x} = \text{the } \mathbf{variance} = \sigma_x^2,$$

$$\mu_{2:x} = \mu'_2 - \mu'^2_1,$$

$$\mu_{3:x} = \mu'_3 - 3\mu'_2\mu'_1 + 2\mu'^3_1,$$

$$\mu_{4:x} = \mu'_4 - 4\mu'_3\mu'_1 + 6\mu'_2\mu'^2_1 - 3\mu'^4_1;$$

all these formulas are valid for either subscript x or $x - a$ for the primed moment. These formulas are very useful in computations. A similar set serves as a check

$$\mu'_3 = \mu_3 + 3\mu_2\mu'_1 + \mu'^3_1,$$

$$\mu'_4 = \mu_4 + 4\mu_3\mu'_1 + 6\mu_2\mu'^2_1 + \mu'^4_1.$$

If x is replaced by bx we call this a change of scale. In this case we have the relationships $\mu'_{n:bx} = b^n\mu'_{n:x}$, and $\mu_{n:bx} = b^n\mu_{n:x}$. If we let x be the original units and $d' = \frac{x-a}{c}$, then we have $\bar{X} = a + c\mu'_{1:d'}$, and $\mu_{n:x} = c^n\mu_{n:d'}$; these relationships are used in finding the central moments in a frequency distribution where c is the **class interval,** x is the class mark in original units, and d' is the class mark in **class interval** units about an arbitrary origin a. The **higher moments** $\mu_{3:x}$ and $\mu_{4:x}$ are used to define $\alpha_{3:x} = \frac{\mu_{3:x}}{\sigma_x^3}$, a measure of **skewness,** and $\alpha_{4:x} = \mu_{4:x}/\sigma_x^4$ a measure of **kurtosis.** The notion of moments may be extended to any number of **variables.** (L.A.A., F.T.M.)

MOMENT COEFFICIENT. The reaction of air upon an **airfoil** varies with the **angle of attack** both in magnitude and position of its result. The moment of the air reaction about some moment center located on the chord and the airfoil is, to a fair degree of approximation, at least, equal to the lift multiplied by the distance to the center of pressure. A coefficient which will bear the same relationship to moments as do coefficients of lift and drag to the lift and drag forces, is obtained by dividing the moment by $\frac{\rho}{2}SV^2c$. ρ is the mass density of air, S wing area, V air speed, c wing chord. The moment coefficient so defined is nearly a constant if the moment center used coincides with the aerodynamic center of the airfoil. On most airfoils, this is about one-quarter of the chord back of the leading edge. It is this quality of the aerodynamic center that causes its frequent use as a reference point in aerodynamic analyses of airplanes. (F.T.M.)

MOMENT OF INERTIA. The moment of inertia of a body with respect to any straight line as an axis has reference to the opposition which the body would offer, by reason of its **inertia,** to being set rotating about that axis if the body were rigid and free to rotate. It represents the **torque** or force moment required, per unit angular acceleration about the axis (in radian measure, e.g., radians per sec. per sec.). Thus if the moment of inertia is I and the angular acceleration is α, the required torque is $T = I\alpha$, which equation corresponds to the familiar $f = ma$ in the dynamics of linear motion.

If the body is divided into elements of mass dm, each at its respective distance r from the axis, it is easy to show that the moment of inertia is expressed by the summation or integral

$$I = \int r^2 dm. \tag{1}$$

Following are formulae for the moments of inertia of certain homogeneous solids with respect to the axes specified (M is the total mass of the body in each case):

Particle distant r from axis	Mr^2
Sphere of radius R, with respect to any diameter	$\frac{2}{5}MR^2$
Cube of edge L, with respect to axis through center parallel to edge	$\frac{1}{6}ML^2$
Rectangular plate, dimensions $A \times B$, with respect to axis perpendicular to it at center	$\frac{M}{12}(A^2 + B^2)$
Cylinder of length L and radius R, with respect to axis perpendicular to its length at center	$M\left(\frac{L^2}{12} + \frac{R^2}{4}\right)$
Cylinder of radius R, with respect to its own longitudinal axis	$\frac{1}{2}MR^2$
Any body with respect to any axis distant r from the center of mass, the value for a parallel axis through that point being I_0	$I_0 + Mr^2$

Experimental methods of obtaining moments of inertia by the use of a **torsion pendulum** are explained in any laboratory manual of elementary dynamics.

For certain purposes it may be desirable to know at what one distance from the axis all the particles of the body of mass M would have to be placed to give it the same moment of inertia I that it actually has. This distance is the radius of gyration, and is expressed by the formula

$$R = \sqrt{\frac{I}{M}}. \tag{2}$$

The "principal axes" of a body through a given point are axes of maximum or minimum moment of inertia. (See **Dynamics of Rotation.**)

By reason of its mathematical analogy to Eq. 1, the quantity expressed by

$$I = \int r^2 da, \tag{3}$$

in reference to any plane figure, is called the areal moment of inertia of the figure with respect to a given straight line in its plane. The figure is divided into elements of area da, each element multiplied by the square of its distance r from the axis, and the products summed as indicated in (3) to get the areal moment of inertia. This quantity is purely geometric and has of course no actual connection with inertia or mass. One of its important applications is in the theory of **flexure** of elastic rods or beams. If E is the (Young's) elastic modulus of the material and I the areal moment of inertia of the cross-section with respect to the **neutral axis,** the bending moment or flexural torque required to bend the rod to a **curvature** C is given by

$$T = EIC. \tag{4}$$

(L.D.W.)

MOMENT-RESISTING JOINT. **Rigid Frame.**

MOMENTUM. The momentum of a body is the product of its mass and linear velocity, while the moment of momentum (or angular momentum) of a body is the product of its moment of inertia and angular velocity. Thus linear momentum is MV, and angular momentum is $I\omega$. Both linear and angular momentum are vector quantities.

M = mass.
I = moment of inertia.
ω = angular velocity.

Because of the relation of momentum to force as set forth in the second of Newton's laws, this is a fundamental concept of dynamics.

A body tends to continue unchanged in momentum unless acted upon by external forces such as applied working forces, resistance, friction or air drag. The force F acting on a body for t seconds alters its momentum by Ft. The product Ft is known as the impulse, with a free body equal to change of momentum. In rotation, the corresponding quantity is the moment of impulse, that is, the product of the time by the applied torque or force moment.

One of the consequences of Newtonian dynamics is the principle of conservation of momentum. This states, in effect, that no operation of forces between the bodies in a system can change the momentum of the system as a whole, which is the vector sum of the momenta of its particles. As a simple example, take the collision of two balls. They may have very different velocities before and after the encounter, but their resultant momentum is the same; and this is true whether they collide "head on," or one overtakes the other, or one is at rest and is struck by the other; also whether they are moving in the same or in different lines. In the event of a collision or other suddenly applied force, the change of momentum resulting is the measure of the impulse, defined above. This is well illustrated by the impulse given to a croquet ball when another ball in contact with it is held by the foot and struck with the mallet. (F.T.M., L.D.W.)

MONADNOCK. Peneplain.

MONAL. Aves, Galliformes. Brightly colored **pheasants** of several species found in the higher forests of the mountains of Asia. (A.W.L.)

MONAZITE. The mineral monazite is essentially a **phosphate** of the rare-earth metal **cerium,** $CePO_4$, but other rare-earth metals are usually present. So constant is the presence of **thorium** that monazite is the chief source of thorium dioxide. It is **monoclinic,** but found ordinarily as translucent yellow to brown grains with a resinous luster, often as sand. Its hardness is 5.–5.5; specific gravity, 4.9–5.3. Monazite is found in **granites, pegmatites** and similar rocks, but rarely in any concentration. The commercial deposits are residual sands. The Ilmen Mts. in Russia, Norway, India, Madagascar, South Africa and Brazil are well known for their monazite deposits. In the United States monazite is known from Connecticut, New York, Virginia, North Carolina and Idaho. Monazite derives its name from the Greek word meaning solitary, in reference to the relative rarity of this mineral. (E.S.C.S.)

MONCHIQUITE. The term proposed by Rosenbuch and Hunter, in 1890, for a **basic microcrystalline** or **porphyritic dike** rock composed chiefly of femic minerals with little or no **feldspar,** in a matrix of **analcite.** Accessory minerals may be **olivine, nepheline** and **leucite.** (R.M.F.)

MONEL METAL. Nickel Alloys.

MONGOLIAN IDIOT. Mental Deficiency.

MONGOOSE, MUNGOOSE. Mammalia, Carnivora. Slender animals with short legs and a long tail, related to the civets but without scent glands. They live in Africa and the Oriental region and have been introduced successfully into the West Indies and other regions. Mongooses kill many small animals and are valuable for destroying rats and other vermin but will attack useful animals when the vermin supply is low. They are particularly noted for their ability to kill snakes, including the poisonous species. The India mongoose, ***Herpestes mungo,*** is readily tamed and is often kept to free premises of undesirable pests.

The Egyptian mongoose, *H. ichneumon,* is also called the ichneumon. (A.W.L.)

MONKEY. Mammalia, Primates. A name applied to most members of the order excepting the man-like **apes** and the **lemurs.** It is not as accurately defined as the names of the various kinds of monkeys but, in general, monkeys differ from the other forms in the possession of nails on all fingers and toes and in their long tails. Apes, some **baboons,** and a few monkeys have short tails or none, the **marmosets** have claws except on the great toe, and the lemurs and related forms have claws on at least one digit.

The monkeys of the New World form a well-marked group constituting the family Cebidae, characterized by the widely separated nostrils, the non-opposable thumb, and the usually long and prehensile tail. All of them inhabit the tropical forests of South and Central America.

The family includes monkeys of several types. These are the woolly monkeys, woolly spider monkeys, spider monkeys, and squirrel monkeys, and under distinctive names the sapajous or capuchin monkeys, the douroucolis, titis, sakis, uakaris, and howlers.

The Old World monkeys, including the baboons, make up the family Cercopithecidae, characterized by the thin septum of the nose, the usually opposable thumb, and the lack of a prehensile tail. They occur in Africa and the Oriental region and one species, the Barbary ape, is established at Gibraltar.

This family includes, in addition to the baboons, the **langurs, guenons, mangabeys, macaques,** the peculiar proboscis monkey, the black ape and gelada baboon, and the African thumbless monkeys. (A.W.L.)

MONOCHROMATIC ILLUMINATOR. An instrument used to supply a beam of light having some desired, narrow range of wavelengths; sometimes called "monochromator." The common form resembles a prism spectroscope. White light, entering the fixed **collimator** as usual through a narrow slit, is dispersed by a special, 4-sided prism after one internal total reflection (see figure). The image of the resulting **spec-**

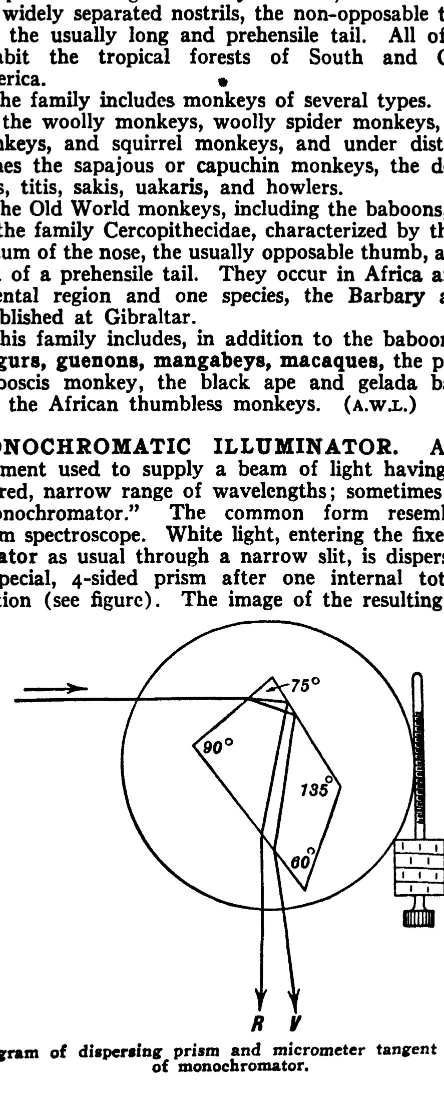


Diagram of dispersing prism and micrometer tangent screw of monochromator.

trum falls on a metal plate, and a second fixed, narrow slit in this plate allows light of approximately only a single wavelength to emerge. The purity of this beam depends upon the narrowness of the two slits, also upon **diffraction** at the slits and **scattering** by the prism. The prism is mounted so that it can be rotated by a tangent screw, thus bringing different parts of the spectrum to the second slit as desired. The tangent screw may be provided with a graduated head reading directly in wavelengths; but too much reliance must not be placed on the indications, since the adjustment is affected by fluctuations of temperature. For **ultra-violet** or **infrared** radiations the prism and lenses must be of materials other than glass, or mirrors may be used instead of lenses. (L.D.W.)

MONOCLINE. If horizontal or slightly inclined beds or stratified formations change their **dip** by increasing their steepness of inclination and then flatten out or resume their normal gentle dip, such a structure is called a monocline. Monoclinical folds may pass into faults. (R.M.F.)

MONOCLINIC SYSTEM. **Crystallography.**

MONOCOQUE. **Fuselage.**

MONOCOTYLEDONS. One of the two subclasses of the **angiosperms,** containing about 25,000 species, many of which are of the greatest value to man. All the **cereal grains** and other grasses belong in this subclass. **Bananas, pineapples** and **palms** are tropical monocotyledons. Many monocotyledons are widely cultivated for their beautiful flowers. Among these are lilies, cannas, irises, and **orchids.**

Certain features are characteristic of plants of this subclass, distinguishing them from the **dicotyledons.** The stems show secondary growth only in a very few monocotyledons. The vascular bundles are usually scattered irregularly in the ground tissue of the stem. The leaves are typically parallel-veined, that is, the several main veins run parallel to one another from the base of the leaf to its tip. The parts of the flowers are generally in multiples of three; that is, there are three **sepals,** three **petals,** three (or six) **stamens,** and a compound **pistil** composed of three **carpels.** The **embryo** of the **seed** is quite unlike that of dicotyledons, having a single seed leaf or cotyledon. In many species this cotyledon is greatly modified, becoming an absorbing organ which never emerges from the seed during germination.

Almost all the monocotyledons are herbaceous plants of small size. A few, such as certain species of *Yucca,* **bamboo,** and the **palms,** become tree-like. Some of the palms have stems 50–100′ tall.

The majority of the monocotyledons are perennial plants which seem well fitted to survive in competition with other plants. (See also **Paleobotany.**) (R.M.W.)

MONODELPHIA. **Mammalia.**

MONOECIOUS PLANTS. The flowers of many plants are unisexual; that is, they contain only **stamens** or **pistils,** but not both. When these two kinds of flowers are borne on the same plant, the plant is said to be monoecious. Familiar monoecious plants are oaks, corn, squash, begonia, and castor beans. The corresponding zoological term is hermaphrodite. (R.M.W.)

MONOGONONTA. **Rotatoria.**

MONOMOLECULAR LAYERS. It has been found possible to deposit, on solid or liquid surfaces, films of material whose thickness corresponds to the effective diameter of a single molecule of the deposited substance. Darrow, for example, in 1925 succeeded in laying down on glass successive layers of certain fatty acids, each of which resulted in the same increase in thickness, as shown by the diffraction effect on **x-rays.** This increase was found to depend upon the number of carbon atoms in the molecule and to increase by the same amount with each additional pair of carbon atoms. Any such layer, one molecule thick, is called a monomolecular layer, or monolayer.

Monolayers deposited on liquid surfaces have been found to affect the rate of evaporation. A vapor may be adsorbed on a glass surface in successive monolayers, the number of which in the completed film (at equilibrium with the vapor) being greater, the greater the density and pressure of the vapor. Frazer observed this with water and with methyl alcohol.

The deposition of molecules by adsorption on metal surfaces differs from that on glass or on liquids, in that the arrangement of the adsorbed molecules depends upon the atomic spacing of the metal in its crystal lattice. This fact, discovered by Langmuir, might be illustrated by the marbles on a Chinese checkerboard, which fit into definite pockets of predetermined spacing. To complete the analogy, Emslie found that if the metal surface is only partially covered, so that there are vacant "pockets," the molecules jump spontaneously from one place to another, remaining at the same site for perhaps several minutes. (L.D.W.)

MONOPISTHOCOTYLINEA. **Trematoda.**

MONOPISTHODISCINEA. **Trematoda.**

MONOPLANE. An airplane with but one main supporting surface, sometimes divided into two parts by the fuselage:

High-Wing Monoplane. A monoplane in which the wing is located at, or near, the top of the fuselage.

Low-Wing Monoplane. A monoplane in which the wing is located at, or near, the bottom of the fuselage.

Midwing Monoplane. A monoplane in which the wing is located approximately midway between the top and bottom of the fuselage.

Parasol Monoplane. A monoplane in which the wing is above the fuselage. (F.T.M.)

MONOSACCHARIDES. **Carbohydrates.**

MONOTOCARDIA. **Gasteropoda.**

MONOTREMATA. The egg-laying mammals. A primitive order containing only the duck-billed **platypus** and the **spiny anteaters** of the Australian region. (A.W.L.)

MONSTER. An abnormal individual. A sport. Departure from the normal range of variation of the species which does not breed true.

Monsters occur in a small percentage of animals as a result of accidents during embryonic development. In man and other mammals they include 2-headed individuals, 1-eyed individuals, and various degrees of duplication in the body up to Siamese twinning. Some of them are presumably due to hereditary factors although the conditions surrounding the embryo may be responsible. The latter cause is especially evident among the invertebrates, where experimental modification of the environment during development may cause monstrosities to appear. (A.W.L.)

MONTH. Originally the term month was used to indicate the period of time required for the **moon** to pass from some particular phase (i.e., full moon) back to the same phase again. Astronomically the term is used to indicate the period of revolution of the moon from any reference point back to that reference point again. The sidereal month is the time it takes the moon to

make one revolution from a given star back to the same star again as seen from the center of the earth. It averages $27^{d}.32166$ (mean solar days) but it varies approximately 7 hours on account of **perturbations.** From the purely mechanical point of view this is the true revolution period of the moon. The synodic month is the period described above (i.e., the period between successive full moons) and averages $29^{d}.53059$ varying by more than 13 hours principally because of eccentricities in the moon's **orbit.** Other types of month which are in use with their average lengths in days are: Tropical (from one celestial **longitude** back to the same again) $27^{d}.32156$, Nodical (from one **node** back to the same) $27^{d}.21222$, Anomolistic (from some point in orbit back to same) $27^{d}.55460$, and Solar ($\frac{1}{12}$ of a tropical **year**) $30^{d}.43685$. (W.K.G.)

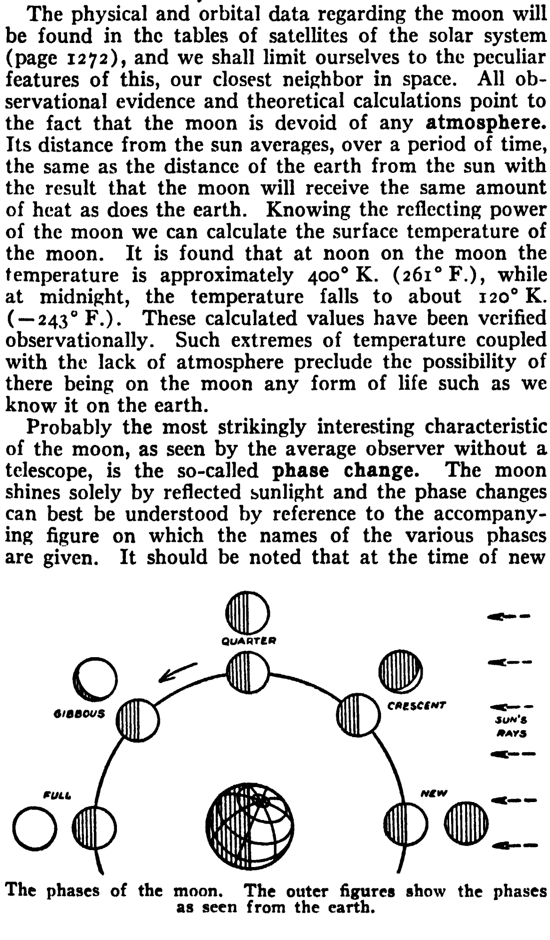
MONUMENT (Geologic Term). **Cirque; Corner.**

MONZONITE. A deep-seated granular **igneous** rock composed of equal amounts of **orthoclase** and **plagioclase feldspars** together with **hornblende, augite** or **biotite** as accessories. The name is derived from Monzoni in Tyrol. It may be considered as a variety of **diorite.** (E.S.C.S.)

MOON. (See tables of satellite data, page 1272.) The moon, the **satellite** of the earth, is, next to the sun, the most conspicuous of all of the astronomical objects. In spite of its apparent brightness and the fact that it has been the subject of countless legends and superstitions throughout the existence of mankind, the moon is in reality a small and unimportant member of the vast universe of celestial objects.

The physical and orbital data regarding the moon will be found in the tables of satellites of the solar system (page 1272), and we shall limit ourselves to the peculiar features of this, our closest neighbor in space. All observational evidence and theoretical calculations point to the fact that the moon is devoid of any **atmosphere.** Its distance from the sun averages, over a period of time, the same as the distance of the earth from the sun with the result that the moon will receive the same amount of heat as does the earth. Knowing the reflecting power of the moon we can calculate the surface temperature of the moon. It is found that at noon on the moon the temperature is approximately 400° K. (261° F.), while at midnight, the temperature falls to about 120° K. (−243° F.). These calculated values have been verified observationally. Such extremes of temperature coupled with the lack of atmosphere preclude the possibility of there being on the moon any form of life such as we know it on the earth.

Probably the most strikingly interesting characteristic of the moon, as seen by the average observer without a telescope, is the so-called **phase change.** The moon shines solely by reflected sunlight and the phase changes can best be understood by reference to the accompanying figure on which the names of the various phases are given. It should be noted that at the time of new



The phases of the moon. The outer figures show the phases as seen from the earth.

moon the dark side of the moon is toward the earth and the moon is invisible, in fact it is a safe statement to make that no one has ever seen a strictly "new" moon, except possibly at the time of a solar **eclipse.** It should further be noted that the illuminated side of the moon is always toward the sun so that, against a dark sky, the horns of the crescent always point away from the horizon. The various weather proverbs connected with "the moon pouring water," etc., are entirely without foundation. The angle which the line connecting the horns of the crescent makes with the horizon depends entirely upon the relative positions of the earth, sun and moon and has no connection whatever with the weather.

At the time when the moon is slightly beyond new phase, and appears as a thin crescent in the western sky, the earth, as seen from the moon, is practically in full phase. That part of the moon which is not illuminated by direct sunlight is lighted by "earthlight" and is visible as "the old moon in the new moon's arms." The apparent difference in size between the sunlit crescent and the earthlit moon is an optical illusion due to the fact that a brighter object always appears larger than a fainter one.

The moon rotates on its axis in the same direction that the earth rotates, and in the same direction that the moon revolves about the earth. This means that the moon keeps approximately the same face toward the earth at all times. Hence, at periods of full moon we always see the face of the "man in the moon" and never the back of his head. However, due to effects known as **librations,** the moon apparently rocks slightly in all directions. As a result of these librations, about 41% of the moon's surface is always visible from the earth, about 41% has never been observed from the earth, and the remaining 18% is invisible or visible, depending upon the particular time of observation and position of the observer on the surface of the earth.

The study of the surface geography of the moon, or selenography, has been carried on ever since the invention of the telescope and that portion of the surface which is visible to the earth has been very carefully mapped. From the reflecting power of the surface and the characteristics of the reflected light we find that the surface is composed of a brownish-yellow rock. Much of the lunar nomenclature was developed 2 or 3 centuries ago and the descriptive terms are unfortunate. For example, the so-called seas, which are the most conspicuous features in a small telescope, and go to make up the imaginative figures of the "man," the "lady," the "crab's claw," etc., to the naked eye, are in reality broad flat plains. In addition to these plains we find mountain ranges with peaks comparable in height to the highest peaks on the earth; rills, or cracks in the surface as much as ½ mile wide and of undetermined depth; rays, or bright streaks radiating out from certain points on the surface; and the so-called lunar craters.

Certainly the most remarkable of all of the surface features are the so-called craters. In accordance with a system of lunar nomenclature first introduced in the middle of the 17th century by Riccioli these craters bear the names of distinguished scientists and philosophers. The craters have a generally circular form, with high mountain ranges rising abruptly from the surface of the moon and frequently with an isolated peak near the center. There are over 30,000 of these craters ranging in size from great walled plains with diameters of nearly 150 miles down to small craterlets 1000′ or less in diameter. In some cases the floors of the craters are depressed below the surrounding surface of the moon, while in others the floors are elevated. The surface of the plain inside the walls is very rough in some cases and very smooth in others.

There is no complete theory to account for all of the lunar surface features. It is possible that the plains and large mountain ranges may be accounted for on the

same theories as those which explain the major geologic features of the earth; but the craters have not thus far been explained. There are two main theories for the origin of the lunar craters: the volcanic and the meteoric. Of these the volcanic is the older and is the theory which gave rise to the name "crater" for these features. The chief objective to this theory is the great difference in size between the explosive volcanoes on the earth, such as Vesuvius, which do not exceed a few miles in diameter, and the great walled plains on the surface of the moon. The meteoric theory was advanced during the latter half of the 19th century and was revived about 25 years ago. Airplane photographs of craters produced on the surface of the earth by bombs bear striking resemblance to the appearance of the lunar formations. Also, there are several meteoric craters on the surface of the earth, notably the great crater near Winslow, Arizona. However, the tremendous size of the lunar craters as compared with similar features on the earth appears as an almost insurmountable objection.

Throughout the ages much has been written and said regarding the influences of the moon on mankind and upon the weather. Practically all of these influences are purely imaginative and the various proverbs relative to the proper time for planting corn, etc., may be relegated to the field of pure superstition. The theory that the first frost of the fall always occurs during the "bright of the moon" may be readily explained by the fact that the first frost will occur on a night when the sky is clear, with a correspondingly high rate of radiation from the surface of the earth, and on clear nights the moon frequently is bright. The amount of energy which the earth receives from the full moon is only about 1/500,000 part as much as is received from the sun, and hence it is obvious that any lunar effects on climate must be negligible. The moon is, however, the dominant factor in the production of **tides** and through this medium exerts a powerful influence on commerce, and may, indirectly, produce some effects on weather conditions near the coast. There is also some slight, but distinct relationship between the changes in distance of the moon from the earth and terrestrial **magnetism.** (W.K.G.)

MOONEYE. Pisces, Teleostei. Moderately large fishes (**Pisces**) of several species found in rivers and lakes of eastern and central North America. One species is also called the silver bass, ***Hiodon tergisus.*** They are not valuable as food. (A.W.L.)

MOONSTONE. Feldspar.

MOORHEN. Aves, Gruiformes. An English name loosely applied to **gallinules** and related species. (A.W.L.)

MOOSE. Mammalia, Artiodactyla. A large **deer** with a broad muzzle, prehensile upper lip, and high shoulders. The male has broad palmate antlers. Two species occur in North America, one, *Alces americana,* ranging over the northern United States and Canada and the other in Alaska. The European species, closely related to the common species of North America, is called the elk. (A.W.L.)

MORAINE. The general term for debris of all sorts originally transported by glaciers or ice sheet long since melted away. The following are commonly recognized types of moraines: **Lateral moraines, medial moraines, terminal moraines, recessional moraines, interlobate moraines** and **ground moraines.** (R.M.F.)

MORBIDITY. 1. The state of being sick or diseased. 2. The sickness rate or ratio of the number of individuals in a community attacked by a given disease to the number remaining well. Morbidity cases are usually expressed as cases per hundred thousand of population. (D.M.H.)

MORDANT. A substance which unites with a dyestuff to form an insoluble compound, called a lake, which colors materials permanently. (See **Dyes.**) (R.M.W.)

MOREPORK. Aves. A name applied in New Zealand to a species of **owl** and in Tasmania to a **nightjar.** (A.W.L.)

MORGANITE. Beryl.

MORIBUND. The state bordering on death. (R.S.M.)

MORMON CRICKET. Insecta, Orthoptera. A large wingless long-horned **grasshopper** of the western United States. It varies in color from pale green or yellow to black. It eats vegetation of all kinds and is a cannibal and scavenger, even eating dead animals. When abundant it is a serious crop pest and one which is difficult to combat. (A.W.L.)

MORMYR. Pisces, Teleostei. Peculiar African freshwater fishes (**Aves**). They vary greatly in form but many have the jaws prolonged into a snout. Family Mormyridae. (A.W.L.)

MORNING GLORY. Sweet Potato.

MORNING SICKNESS. Nausea and vomiting which commonly occur in the first few months of **pregnancy.** It is called morning sickness because it occurs upon rising. (R.S.M.)

MORPHINE. This is probably the most valuable drug in medicine. It is the chief and most powerful of the alkaloids of **opium.** It is usually given as morphine sulfate, hypodermically or occasionally orally. Morphine is most frequently used for the relief of pain of all types. It also induces sleep, depresses respirations, and is a general nervous system depressant. The morphine derivatives have similar actions in varying degrees. Dilaudid has a greater analgesic effect but a minimal hypnotic one. Dilaudid and Pantapon, a mixture of purified opium alkaloids, are sometimes used successfully in individuals who develop toxic reactions to morphine. In addition to relief of pain due to trauma, morphine is used in treating heart pain, particularly that of **coronary occlusion.** It is effective in biliary and renal colic, and intractable pain associated with **cancer** and other malignant diseases. It is also an important drug in treating congestive **heart failure** and severe **hemorrhage.**

Habituation to morphine and its derivatives is easily established. For this reason the drugs are used with great caution, and never in chronic diseases unless the pain is associated with a hopeless situation such as inoperable cancer. Heroin has greater powers of addiction than the other opium derivatives because it produces greater **euphoria.** It is a favorite of addicts in the United States. It, like morphine, is taken by addicts hypodermically or intravenously.

Contrary to popular belief, there are no signs or symptoms of morphine intoxication in addicts. As long as such individuals have an adequate supply of the drug, they are in excellent health. The appearance of the addict as a shifty eyed, emaciated, poorly clothed fellow is due entirely to the psychological maladjustments, and social and financial difficulties that are a part of obsessive devotion to a drug whose traffic is illegal. If the supply is cut off, withdrawal symptoms appear—lacrimation, yawning, sneezing, tremor, and sweating

being the first. The desire for the drug becomes an overpowering obsession; the individual is restless, demanding, and displays mounting excitement. Weakness and psychic depression are marked. Vomiting, colic, and diarrhea are common. Twitching, headache, double vision, and occasionally mania occur. Heart failure and death may result in extreme cases if morphine is not administered.

The treatment of addiction is psychiatric and medical. With the help and cooperation of a competent psychiatrist, a plan of withdrawal of the drug is carried out. The permanence of a cure often depends on the nature of the addiction. In the rare instance where it occurs in a normally adjusted person through injudicious medication, the prognosis is good. If, however, the patient has deep psychoneurotic conflicts, the problem is more difficult, and permanent success is proportional to the effectiveness of psychotherapy in adjusting the disturbed personality. (D.M.H.)

MORPHOLOGY. The division of biological science which deals with structure. Due to the ease and accuracy with which structural differences can be recognized they have always served as the prime means of recognizing both animals and plants and have consequently served as the most useful basis for **taxonomy.** In other fields of biology, such as embryology, histology, cytology and anatomy the first studies were morphological descriptions, followed later by investigations of function. See also **Geomorphology.** (A.W.L.)

MORSE TAPER. Taper.

MORSE THUMP. Inductive Interference.

MORTALITY. The total deaths in a population. Usually expressed as a mortality rate of so many deaths per thousand of population. It is a fundamental factor in studies of population development. Maintenance of a normal population depends upon the birth rate being sufficient to balance the mortality or death rate, and all factors tending to influence the reproduction of animals or their destruction influence this balance. (A.W.L.)

MORTAR. Mortar is the material which is used to bind together the stone or brick of **masonry** construction. Mortar is mixed wet to a plastic state, spread upon the brick to a thickness of from ¼–½″, and the next course of brick pressed into it. The material of mortar hardens in a short time, firmly locking the bricks or stone together in a solid masonry structure. Ordinary mortar consists of a cementing agent and a filler. Lime, sand, and cement are the materials from which mortar is usually made. The mortar plays no small part in masonry construction, since 1 cu. yd. of brick masonry, requiring approximately 500 bricks, will take from ¼–⅓ cu. yd. of mortar. (See **Calcium; Cement.**)

A test comparison of lime and cement mortars shows the latter to be much stronger. However, cement and sand mortar does not work easily under a trowel, and lime paste, made by slaking lime with water, is added to render the mortar more easily worked. This does not materially impair the strength. In earlier days, a great deal of masonry was laid in mortar consisting entirely of lime and sand. The proportions of Portland cement, lime, and sand used in brick construction nowadays is approximately in the volumetric ratio of 1:1:3.

The use of mortar is not confined to masonry, for the mixture used to plaster interior walls or to stucco exterior walls is called mortar when in the state ready for application by workmen. Plaster mortar consists of lime and sand, with fiber or hair as a binder. Such mortars are usually applied in two or more layers, the "scratch" coat being a sand and lime mixture applied directly to lath or other base, for the purpose of keying in the plaster and providing a base for the second coat of the same material. After the second coat the plaster may be finished with a thin coat of lime paste to which plaster of Paris may be added for hardness. This gives a surface known as "hard finish." Alternatively, the wall may receive a lime-sand finish, leaving it somewhat rough with sand grains showing, in which case the work is known as "sand finish." Pigments may be added to the sand finish coating in order to give desired coloration. The thickness of the finish coat is very thin compared to the scratch coat. Stucco is applied to brick, stone, wood or metal lath, and is made of cement, lime, and sand. It is applied in 2 or 3 coats, the exterior coat being colored with mineral colors not affected by the cement, lime, or weather. Colored sands usually give better results than the addition of pigments. It is customary for the surface coat of stucco to be left rough, as the appearance is much superior to a troweled finish. (F.T.M.)

MORTISE. Dado.

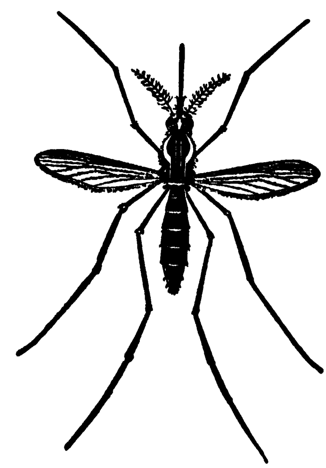
MOSAIC. Iconoscope; Photogrammetry.

MOSAIC VISION. A theoretical interpretation of the action of compound **eyes** of **arthropods.** Each visual unit (ommatidium) of such an eye forms an image of part of the object toward which it is directed and the total image seen by the animal is supposed to be composed of many such partial images formed by the many units in the eye. This type of vision is supposed to be inferior to that of other kinds of eyes in the sharpness of the image perceived but to be extremely sensitive to motion. (A.W.L.)

MOSASAUR. Fossil Reptiles.

MOSELEY'S LAW. X-Ray Spectra.

MOSQUITO. Insecta, Diptera. A small 2-winged fly with slender body, long legs, and narrow wings bearing scales along the veins. The **larvae** are aquatic. Male mosquitoes feed on plant juices and only the females suck blood, but in some species neither sex sucks blood.



Yellow-fever mosquito, *Stegomyic fasciata.* (*F. B. Howard, U. S. Dept of Agriculture.*)

Mosquitoes are well known as a nuisance and in warmer climates they are also dangerous because some species transmit disease. **Malarial** parasites are carried by mosquitoes of the genus *Anopheles* and **yellow fever** by species of *Aedes.* In regions were these diseases occur the destruction of mosquitoes by draining swampy

areas where they may breed, and by applying oil to water that cannot be drained, is important. The protection of patients from the attack of mosquitoes so that the disease cannot be carried to others is accomplished by adequate screening, a measure which is valuable both for comfort and safety in all dwellings. (A.W.L.)

MOSS AGATE. **Agate.**

MOSSES. **Bryophytes.**

MOTH. Insecta, Lepidoptera. **Insects** with the four wings at least partly scaly, the mouth parts formed for sucking, and the antennae rarely clubbed near the tips. No one character serves to distinguish all moths from the butterflies and skippers. Most moths are nocturnal but many are diurnal or **crepuscular.** Most of them have the antennae slender and tapering or broadened by **setae** or by processes from the segments, forming a comblike (pectinate) structure, but a few have an expansion just before the tip like that found in most skippers. Most of the caterpillars of moths pupate in a cocoon or a subterranean cell or in the tissues of plants but a few form a brightly colored naked **pupa** like those of the butterflies. The term does not apply to a principal division of the order but includes many families making up one entire suborder and most of the second. (A.W.L.)

MOTHER. The female parent. Also applied to any unit which gives rise to others, as mother cell, mother colony, etc. (A.W.L.)

MOTHER LIQUOR. The liquid left behind after a solid has been crystallized from a solution. It usually contains the impurities which were present in the solution. (D.E.M.)

MOTHER-OF-PEARL. The smooth lining of the shells of **mollusks,** consisting of calcareous and organic matter, usually iridescent and sometimes brightly colored. Also called nacre.

A large amount of mother-of-pearl is used commercially for pearl buttons, knife handles, etc. For such uses it forms only the exposed surface, with a variable thickness of the middle layer of the shell beneath. Blister pearls are protuberances cut from shells and true pearls are of the same material, deposited about some foreign particle which irritated the animal. (A.W.L.)

MOTION PICTURES. If pictures of a moving object are made in rapid succession, each picture will record the position of the various parts of the subject at the moment of exposure and the series of pictures will represent successive phases in the movement of the different parts of the subject. Then if these same pictures are viewed, or projected, in the order in which they were made and with sufficient rapidity—not less than 16 per sec.—so that no one picture of the series is seen separately, the various pictures merge into one another and the movements of the subject will be reproduced. This is the principle of the motion picture or cinematograph. (See also **Camera, Motion Picture.**) (C.B.N.)

MOTMOT. Aves, Coraciiformes. *Momotus.* Birds **(Aves)** with a long tail and serrated beak, found in Mexico, Central and South America. Several species are reported to nest in burrows in the banks of streams. (A.W.L.)

MOTOR BOATING. This is the effect produced by positive **feedback** producing low-frequency oscillations in an audio **amplifier** so the output sounds like the putput of a motor boat. (L.R.Q.)

MOTOR, ELECTRIC. An electric motor is a machine which, receiving electrical energy, converts it into mechanical energy. Since there are so many different types of electric motors, it seems logical to begin a discussion of them with some attempt at classification of the principal types. Such a classification is given below, and let the reader note that the motors here mentioned are diagrammed in the same order in the illustrations.

A. Direct-current types.
  1. Shunt.
  2. Series.
  3. Compound.
  } Straight or Interpole
B. Alternating-current types.
  1. Synchronous.
  2. Induction.
    a. Polyphase.
      (1) Squirrel-cage rotor.
      (2) Wound rotor.
        (a) Slip ring.
        (b) Brush shifting.
    b. Single-phase.
      (1) Split-phase.
      (2) Repulsion-induction.
      (3) Universal.
      (4) Condenser.
      (5) Series.

Electric motors are built in a range varying from outputs of 1/100 of a **horsepower** up to well over 1000 hp. A 50-hp. motor is considered a large one, and the majority of electric motors now in use ranges between 1/4 and 10 hp. Standard motor sizes above the small fractional sizes are 1/4, 1/3, 1/2, 3/4, 1, 1 1/2, 2, 3, 5, 7 1/2, 10, 15, 20, 25, 30, 40, and 50-hp. Sixty-cycle synchronous speeds are 3600, 1800, 1200, 900, 720, 600, 514, and 450 rpm. Full-load induction motor speeds are 2–5% less than these. The efficiency of the electric motor ranges from 75–95%. It is higher in large motors than in small. Induction motors are more efficient the higher the rated speed, but d-c motor efficiency is little affected by speed. Efficiency is often secondary to reliability; nevertheless, it is a factor to be considered, particularly if the drive is heavy and the motor is well loaded over a considerable part of the time. **Direct-current** motors are much less frequently employed than **alternating-current,** because of the preponderance of a-c over d-c systems. However, speed control and starting torque are so excellent with d c. that it is frequently used in a-c territory where these characteristics are important. D-c power for motors is commonly obtained from the a-c supply through motor-generators, **mercury-arc tubes,** or grid-controlled **rectifiers,** with voltages ranging from 110 to 600. The extra expense of the converter installation lays some handicap upon the employment of d-c motors, and a number of methods have been devised to vary the speed of a-c types, but, in the main, the latter are constant speed.

The losses sustained by a motor in converting electrical to mechanical power arise chiefly through the electrical and magnetic characteristics, but also, in some degree, through bearing friction and windage. The losses are, then, the **resistance** losses occasioned by current flowing through the conductors of the **armature,** the **field,** and the **controller,** the core losses of **hysteresis** and eddy currents, friction and windage. The **cores** of all motors must be built up of laminations insulated from one another by lacquer or enamel, otherwise the core loss becomes excessive.

The motor is so compact that in large sizes, although the efficiencies are high, the heat liberation per unit volume becomes sufficient to need the positive ventilation secured by fans and impellers. In the small open-frame motor the windage of the motor itself is generally sufficient for cooling. Larger sizes are cooled by air forced through the windings by impellers mounted on the motor

shaft, or by external fans. In sheltered locations a simple open frame is employed, but motors may be had completely enclosed so that they may be installed where they will be exposed to the weather. Intermediate between these are such frames as the drip-proof types which are protected from overhead drips, the enclosed and ventilated, and the totally enclosed, the latter being cooled by ventilating air brought to it in ducts. The totally enclosed type would be necessary, for example, in an atmosphere wherein a spark or incipient fire could create an explosion.

The relation between input, output, and efficiency are expressed by the following equations, wherein

P = horsepower output
η = efficiency
I = line current
V = line voltage
$p.f.$ = power factor

For all d-c motors

$$P = \frac{\eta I V}{746}.$$

For single-phase a-c motors

$$P = \frac{\eta I V p.f.}{746}.$$

For three-phase a-c motors

$$P = \frac{\sqrt{3}\eta I V p.f.}{746}.$$

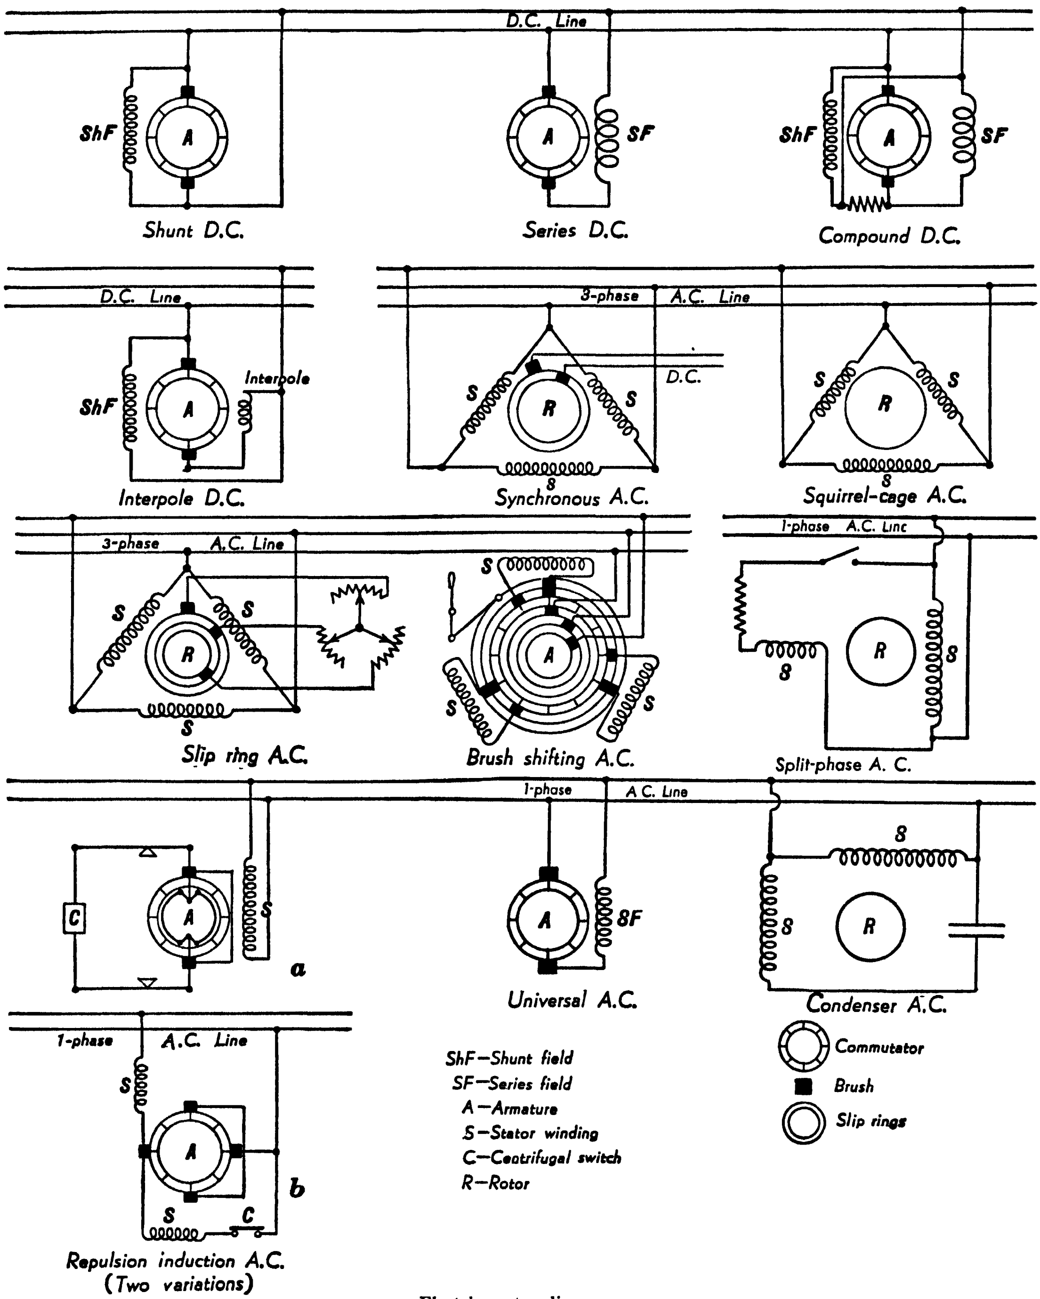
The frames of motors are frequently of cast iron, although welded construction has been employed successfully. The **magnetic circuit**, of course, is of ferrous material, and the conductors are copper. Insulating material is rubber, cambric, varnish, lacquer, enamel, asbestos, mica, wood, fiber-glass and fiber. **Brushes** are usually carbon. The usual position for which a motor is desired is with horizontal shaft, in which case the bearings are held by suitable recesses in the main frame casting, and lubrication achieved by one of the methods outlined under **bearings.** Vertical shaft motors are built having thrust bearings to carry the weight of the motor and any externally attached weight. The end thrust for horizontal shaft motors connected to belts or gears can readily be carried by plain collar thrust bearings. But if the drive itself sets up an additional end thrust, special thrust bearings may be necessary.

Important individual characteristics of electric motors include the following: starting torque, normal speed, **speed regulation,** reversibility, efficiency, and cost. Motors are selected upon the basis of the voltage available, the peak load, the necessary reliability, the desired speed range, and the **load factor.** It is common practice to use polyphase motors for all motors larger than 3 hp., although single-phase motors larger than this will occasionally be found. In order to secure the most economical size, 2300 volts is employed where possible for motors of output exceeding 100 hp.; 440 volts is suitable for medium-sized motors, and 220 volts for small motors, except that fractional hp. motors are almost always 110 volts. The size of wire leading from the supply to the motor is made adequate to deliver the rated current at not more than 2 or 3% voltage drop. A feeder supplying one motor should, according to the electrical code, have conductors of a current capacity not less than 110% of the rated motor current. However, much larger conductors may be required to take care of the starting current. The capacity of wires carrying the starting current of an a-c motor started by a **compensator** should be 200% of the rated current if the rated current is above 30 amperes or 250% if the rated current is below 30 amperes. In the case of across-the-line starting, 300% of the rated current should be used. D-c motors started by a starting box should have leads with current-carrying capacity about 125% that of rated current. All motors should receive some sort of protection, either **fuses,** thermal **cutouts,** or **circuit breakers** actuated by **relays.**

The circuits of the principal types of electrical motors will now be explained briefly. The reader should consult the illustrations for amplification of the text. The shunt motor has a wound **armature,** the ends of the windings of which are brought to a **commutator,** upon which rest **brushes.** The incoming leads are connected to these brushes so that line voltage is impressed across the windings of the armature. The stationary **field coils** are connected across the brushes in shunt arrangement so that they receive a constant voltage. In the illustration, only one coil is shown, but any practical machine would be multipolar. When the motor is running, the coils of the armature cut the lines of force of the magnetic **field,** and so generate an internal voltage known as the counter-electromotive force. The sum of this counter-electromotive force and the resistance drop through the armature must equal the impressed voltage. Consequently the current taken is much larger when the motor is revolving slowly than when it is up to speed. This also explains why weakening the shunt-field current (and thereby the lines of force) causes the armature to increase its speed, since the weakened field causes less counter-voltage, hence allows more current to flow in the armature. Then more torque is produced, which increases the speed until the back voltage allows just the right current to flow to carry the existing load. The torque of the motor is produced by the magnetic reaction existing between the magnetism of the stationary field and the electromagnetic field surrounding the armature conductor.

Unlike the shunt motor, whose field current is practically constant at all speeds, the series motor produces a field which is maximum during starting and decreases as the motor comes up to speed. For this reason, the series motor has a powerful starting torque, and is used for hoists, traction motors, and the like. The shunt motor is essentially a constant-speed type; the series, a variable speed type. A motor having better speed regulation and starting torque can be obtained by a compound winding having both shunt and series fields. However, the simplicity of the shunt-field motor, coupled with the possibility of effecting a reasonable variation in speed by a variable resistance in the field circuit, has caused it to be widely used. It has been found, though, that any considerable weakening of the field is accompanied by sparking at the commutator, due to the demagnetizing **armature reaction.** Small poles, located between the shunt-field poles, and wound with series coils, will compensate for the distortion of the field flux, and such motors are known as interpole motors. (See **Interpole.**)

In the a-c field, the above classification shows a primary division into synchronous and induction types. Of these, the **induction motor** is by far the more important; but the strictly constant speed feature of the synchronous motor has caused its selection in certain cases. The **synchronous motor** is practically an **alternator** operated inverted. It has a polyphase stator winding which carries the main line current. The field is wound on the rotor and is excited by d.c. brought to it by brushes resting on slip rings. The synchronous motor is stable only when operating at a synchronous speed corresponding to the frequency of the system, and if it is loaded to where it lags ever so slightly behind this synchronous speed, it quickly "falls out of step" and comes to rest. The disadvantages of the synchronous motor are principally two: 1. Its constant speed. 2. It requires d-c excitation. Modern construction of polyphase synchronous motors results in good starting torque. The single-phase synchronous motor has no starting torque, but with three-phase the motor may be made self-starting if copper bars similar to the



Electric motor diagrams.

rotor of a squirrel-cage motor are embedded in the rotating field and connected to end rings. To start the motor, the d-c field is open-circuited and the stator windings connected to the line. The motor will then come up to speed, operating as a squirrel-cage induction motor, after which the field current may be applied, upon which the rotor will lock itself into step with the frequency of the system. A synchronous motor is generally used only in large sizes where it has the advantage of providing some power factor correction, since one of the characteristics of this motor is that a leading current will be drawn if the d-c field is over-excited, and this can be adjusted to neutralize the lagging current drawn by induction type motors.

The three-phase squirrel-cage motor is the simplest and most reliable electric motor made. It has a powerful starting torque, and good efficiency, and would probably replace all other types were it not for the following reasons: It is essentially a constant speed motor, it draws a lagging current, and it is not built single-phase. The stationary windings are connected either in Delta or Y, as may suit the individual design, and are so arranged as to produce a rotating field in the space occupied by the rotor. The rotor is a shaft upon which is built up a laminated steel core carrying embedded in its surface copper or aluminum bars which are parallel to the shaft. The inductive action of the field on this "cage" (if the core were removed, the bars would re-

semble the familiar squirrel exercising cage) sets up in the latter induced currents whose magnetic field reacts against the rotating field set up by the stator winding, producing a torque. If the rotor were turning in synchronism with the rotating field there would be no induction and no rotor currents. Therefore it is seen that the rotor cannot possibly operate it at full synchronous speed, even though idling. The difference in speeds is expressed by slip, i.e., difference in speeds divided by synchronous speed, and a certain amount of slip is necessary to secure inductive action. As mentioned before, this varies from 2–5% of synchronous speed. A squirrel-cage motor with rotor blocked acts like a transformer with short-circuited secondary, thus explaining the high starting torque.

There are installations where a polyphase motor is wanted, having some degree of speed control, and which may be brought up to speed more slowly than is customary with the squirrel-cage motor. For this service the more expensive wound-rotor and brush-shifting types may be used on three-phase circuits. The wound-rotor principle is employed chiefly on large motors. As its name implies, the wound rotor has polar windings in the rotor, the ends of which are joined either in Y or Delta, and brought to three slip rings. The currents induced in the rotor are brought out through these slip rings to an external three-phase resistance, which may be varied at will from zero to maximum. The operation is much like that of a squirrel-cage motor, except that, for starting, the rotor current is decreased by inserting the maximum of resistance in the external circuit. This is gradually decreased as the motor comes up to speed, until all of the resistance is short-circuited and the motor is operating inductively with a normal slip. Given constant torque, this motor may be varied in speed by varying the external resistance, but it is somewhat less efficient than the brush-shifting type, because of the energy consumed in the resistance. The brush-shifting motor is used where considerable speed variation is desired at good efficiency, as, for instance, when driving fans or pumps of large size. The brush-shifting motor has the primary winding on the rotating armature, similar to d-c practice. This winding is connected to the three-phase line through slip rings. Another winding, called an adjusting winding, is also placed on the rotor; in fact, in the same slots, but is connected with a commutator, which is made fairly wide. The three-phase stator secondary windings are brought out individually to six brushes which bear on the commutator, and are connected as shown in the diagram. Each set of three brushes is joined by a yoke, so that they may be moved simultaneously, and each pair is placed on opposite ends of the commutator. When these yokes are moved with respect to one another, they cause to be included a certain number of commutator segments in each secondary coil. When each pair of brushes is on a common commutator bar, the motor runs as a straight induction motor at slip frequency. By moving the brushes apart by rotating a yoke, the voltage induced in the commutator coil is added to that in the secondary, and the motor speeds up. These voltages may be subtracted by moving the brush in the opposite direction, resulting in slowing down the motor. Since the forces needed to move the yoke are very small, it may be readily operated by the light pressures produced in an automatic control system.

Turning next to the single-phase motor, it is entirely possible for a single-phase motor to operate inductively like the squirrel-cage motor, provided it can be brought up to speed, but a single-phase squirrel-cage motor has no starting torque, so there have been developed numerous ways of doing this for single-phase motors, most of which are of small size. In the split-phase motor, an inductance and resistance are used to displace the voltage at the mid-point so as to get an arrangement resembling a two-phase impressed voltage. Of course the starting torque obtainable is inferior to that of a polyphase motor, but is sufficient to start a motor attached to a drive requiring low starting torque. A fan illustrates this service. For heavy starting duty the starting torque of a single-phase motor is created by repulsion, which shifts over to induction as the motor comes up to speed. Several systems have been invented, two of which are illustrated. At *a*, the armature windings are brought out to a commutator, upon which rest two brushes connected externally by a low resistance conductor. A stator winding is connected across the line. The short-circuited armature has induced in it the large current necessary to secure starting torque. As the motor comes up beyond a certain speed, a centrifugally operated switch lifts the brushes from the commutator and applies to it a ring which short-circuits all the segments. When this is done the motor operates as a straight induction motor. This principle, known as repulsion-induction—i.e., repulsion starting and induction running—is employed in most small motors which are to produce large starting torques on single-phase supply. At *b* is another repulsion-induction principle, less complicated mechanically. Here the switch operates during starting, and is closed for induction operation.

A universal motor is a series motor which may be operated on either d.c. or a.c. It is usually employed in small sizes only, there being a compensating coil to prevent armature sparking and to improve the power factor.

The condenser motor is a split-phase motor, having the phase displaced by capacitance rather than inductance. It is superior to the former in starting torque, efficiency, and power factor, but more expensive and slightly more bulky. The starting torque of the modern condenser motor compares favorably with the repulsion-start motors, and, since the cost is less, the condenser motor is replacing the repulsion type in many applications. In some of these motors the condenser is disconnected by a centrifugal switch after starting; in others it is left in the circuit to improve the operating characteristics and the power factor of the motor. (F.T.M., L.R.Q.)

MOTOR VEHICLE. By motor vehicle is designated that class of road vehicles, employed generally on the public highways, which serve some useful purpose, such as the carrying of passengers or freight, and which are propelled by a **motor** which is an in-built part of the vehicle. A survey of the motor vehicles in operation at present reveals that there are principally three types, the passenger car, or automobile; the motor coach, or **bus**; and the motor truck. Almost without exception, these are propelled by **internal combustion engines**, of which the bulk are of the **Otto cycle** type, the remainder operating on the **Diesel** cycle. The application of the engine to propulsion of road vehicles was experimented with during the latter part of the 19th century, and the industry might be said to have been born commercially in the 10 years centered around the turn of the century. In the United States, Duryea and Haynes introduced the gasoline-engined automobile to the American public. By 1905, several manufacturers were regularly producing automobiles, and 5 years later they were being turned out by factories which embodied the essentials of the present quantity production methods. The American system of automotive building tended to crowd out the many small independent builders, and the decade from 1915 to 1925 saw consolidations and eliminations which greatly reduced the number of bona fide automobile manufacturers. This period also saw the change from an automobile which was principally an assembly of independent manufacturers' parts into a machine which was largely manufactured, fabricated, and assembled under one management.

The principal parts of an automobile are:

1. Frame.
   Steel frame of channel, I-beam, or tubular members, mainly located in horizontal plane and providing rigidity by beam action principally. The other elements are assembled on this frame.
2. Running gear.
   Wheels.
   Axles.
   Springs.
   Brakes.
   Steering device.
3. Propulsion.
   Engine and clutch.
   Change speed gears.
   Drive shaft.
4. Body.
   Including upholstery, glazing, doors, and interior fitting.
5. Accessories and auxiliaries.
   Radiator.
   Fuel tank.
   Defroster, etc.

Until very recently, there had been no questioning of the suitability of the method of construction involving the building of a rigid underframe to which the other elements of the motor vehicle were attached by bolting or riveting. Nevertheless, with design of the motor vehicle, principally the automobile, emerging from an earlier formative stage into one where more emphasis can be placed on scientific design and research, the desirability of an underframe construction for the high-speed automobile is open to debate. It has been established that a truss construction, wherein the truss members are located in the side walls of the body, is productive of a greater degree of the right sort of rigidity than is an underframe, and at the same time, is lighter. In motor coach construction, especially where there is more emphasis upon reduction of dead weight, and where the service conditions are particularly severe, the so-called chassisless construction, in which the trussing is incorporated in the body, has found favor with designers.

The running gear, which is assembled to the frame, is commonly of a 4-wheel type, the wheels having typically a tread of about 54", and a wheelbase of 110–130". The over-all length of an automobile, bumper to bumper, may often exceed the wheelbase by as much as 30% of the latter. Almost from the inception of the automobile, the pneumatic tire, having an outer casing and an inner air-tight tube, both being founded on rubber as the material, has been standard. These have, however, been built in a wide variety of sizes, many of which were unnecessary and tended to increase the tire cost to the user. There is, however, some standardization among the larger producers of modern and low-priced cars, upon the 16-in. tire, that is, the tire which will be mounted on a rim 16" in diameter. **Brakes** are applied by internal expanding shoes faced with suitable material, which bear upon drums rigidly fixed to the wheel. These brakes are actuated either mechanically by cables and jointed rods, or hydraulically by oil pressure acting against the piston, whose movement is carried mechanically to the brake-shoe cams. Early automobiles were often steered by a tiller, but with increasing road speeds, it was soon found that the most suitable steering mechanism was a wheel, arranged in a position comfortable to the driver. In the United States, this position is founded on the driver's occupying the forward and left-hand seat in the automobile. The principal requirements of the steering device are, first of all, reliability; secondly, freedom from road shocks; and thirdly, ease of manipulation. The automobile builders soon found that the bolster and kingpin steering, which was suitable with horse-drawn vehicles, had to be abandoned in favor of steering knuckles, by means of which the wheels are fastened to yokes at the ends of a fixed axle. The pneumatic tire, backed up by spring shock absorbers in the steering mechanism and an irreversible gear connection between the hand wheel and steering mechanism, combine to take the road shock from the steering wheels. At the same time this incorporates a reduction ratio so that the full swing of the road wheels is accomplished only through several turns of the steering wheel.

The automobile engine is fairly well standardized today on 6- and 8-cylinder gasoline engines, arranged either in line or as a V. These engines are characterized by **poppet valves**, pressure oil **lubrication**, water cooling, **carburetion**, and high-tension spark plug **ignition**. The engine and clutch are usually built as a unit, to which the change-speed gear box is attached so intimately that in effect it becomes a unit with the engine. From the gear box a drive shaft extends to the rear axle and transmits the power as a **torque**. Although each new year sees improvements in automobile engines, these are chiefly an aggregate of small refinements. New designs endeavor to increase efficiency or output, to reduce size or weight, to promote quieter, smoother operation, and to increase life or decrease maintenance. The automobile industry is viewing, and has for some time been cognizant of, the possibility that the **Diesel** engine may prove as suitable or even more desirable than the gasoline engine for the propulsion of motor vehicles. It seems entirely possible that these two engines may both prove suitable for the automotive field, and that certain combinations of circumstances will point to the selection of one of them where other circumstances might indicate the alternative engine. The over-all operating thermal efficiency of the automobile is very low. It is lower than the efficiencies one customarily associates with the **Otto cycle**, because public demand for performance has led to the creation of automobiles whose engines customarily operate at part load, under which conditions the Otto engine efficiency is penalized. Also, in addition to mechanical friction of the drive and running gear, the automobile engine must furnish an ever-increasing amount of electrical power for the operation of the electrical accessories, i.e., lights, horn, defrosters, cigarette lighters, radio, etc. The power required to propel has increased with the demands for higher speed operation. While these might have been offset by proper streamlining, the public mind changes very slowly, and since true streamlining involves radical changes in the conventionally styled car, designers have had to produce the higher speed by engines of greater power. These conditions have led to this situation: Although refinements of engine design have increased their efficiency, the demands for higher peak powers and the auxiliary services have so offset these engine refinements that the mileage achieved per gal. of fuel has remained substantially constant for many years.

Engineers could in a very short time produce a design which would, to a mind unprejudiced by many years of conventional car shapes, appear eminently suitable as a road vehicle. Furthermore, this vehicle would not be any slower, although it would consume only about half as much fuel per mile traveled as the current models. It would be more comfortable and just as safe. But, unfortunately, it would require altogether different styling, and such radical changes as engine in rear, chassisless construction, and others. While these developments are expected to be consummated with time, the fact that the motor vehicle is the personal possession of a large part of the American public, coupled with the slowness of a large population to change its preconceived ideas, prevents any immediate attainment of the technically proven and technically desirable. Engine, Differential, Highways, Ignition System, Internal Combustion Engine, Otto Engine.) (F.T.M.)

MOUFLON. Mammalia, Artiodactyla. A European wild **sheep,** ***Ovis musimon,*** found on the islands of Sardinia and Corsica. The rams have very large horns. (A.W.L.)

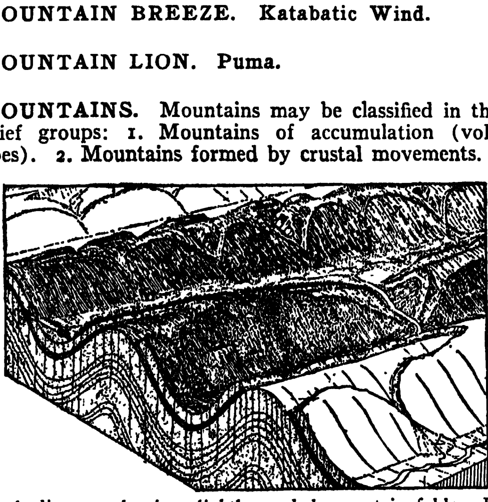
MOULT. 1. **Ecdysis.** 2. The shedding of old feathers by birds preparatory to the development of new. Most birds moult at least once a year, beginning just after the breeding season. Most flying birds shed the large flight feathers in pairs but a few shed them all together and temporarily lose the power of flight. The rest of the plumage is also shed and renewed little by little. Moulting is accompanied in many species by the seasonal changes in plumage which make some species so different in summer and winter. 3. The shedding of the outer layer of the skin by reptiles. (A.W.L.)

MOUNTAIN BOOMER. Reptilia, Sauria. The collared **lizard,** ***Crotaphytus collaris,*** a small species ranging from central California to Missouri and southward. In limited areas as far north as Idaho and Oregon. (A.W.L.)

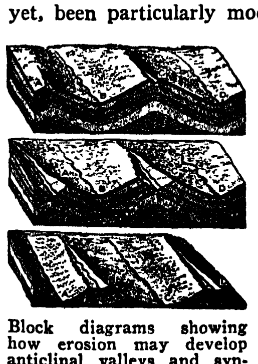
MOUNTAIN BREEZE. Katabatic Wind.

MOUNTAIN LION. Puma.

MOUNTAINS. Mountains may be classified in three chief groups: 1. Mountains of accumulation (volcanoes). 2. **Mountains formed by crustal movements.** 3. Residual mountains (erosional remnants). Structural mountains are those whose form and relief have not, as yet, been particularly modified by erosion. The ridges are still **anticlinal** and the valleys **synclinal.** Later, in the cycle of erosion, the synclines may become mountains and the anticlines, valleys. If the folded mountainous region is ultimately reduced to a **peneplain,** and the peneplain is then lifted without further folding, a new cycle of erosion operating on the same, but base-leveled, structure will develop the type of topography now seen in the Appalachian mountains. (See **Antecedent Stream.**) (R.M.F.)



Block diagram showing slightly eroded mountain folds. Jura Mountains, Switzerland. (*After W. M. Davis.*)



Block diagrams showing how erosion may develop anticlinal valleys and synclinal mountains. (*Tarr, New Physical Geography, Macmillan Co.*)

MOURNING CLOAK. Insecta, Lepidoptera. A large **butterfly,** ***Euvanessa antiopa,*** of Europe and North America. The wings are very deep maroon above, bordered with yellowish-white, and are slightly angular. The species hibernates in the adult stage and is often in flight on the first warm days of spring. (A.W.L.)

MOUSE. Mammalia, Rodentia. A name loosely applied to many species of small burrowing and gnawing **rodents** with slender bodies, long tails, and either the front legs or both pairs short. They are related to the hamsters, jerboas, lemmings, rats, and voles.

Most of the North American species are included in the family Muridae, of which the house mouse is a typical species. The family also contains the grasshopper or scorpion mice, harvest mice, the pine mouse, red-back mice, meadow or field mice, also called voles, and a group variously named wood, deer, vesper, and white-footed mice. The family Heteromyidae contains the pocket mice and kangaroo mice and the family Zapodidae the jumping mice. In addition to these details of classification, a number of species in various groups bear special names. Mice of one or another group are found on every continent, although they predominate in the northern hemisphere. The house mouse is *Mus musculus.* (A.W.L.)

MOUSTERIAN. Paleontology of Man.

MOUTH. The external orifice leading into the **alimentary tract.** Commonly but less correctly applied to designate the terminal cavity of the tract which is the buccal or oral cavity in the vertebrates. (A.W.L.)

MOVABLE BRIDGE. Bridge.

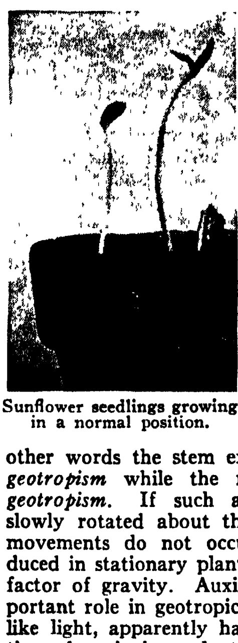
MOVEMENT IN PLANTS. Movement of plants is largely confined to movements of the individual organs as, except in a few of the simplest forms, entire plants cannot move from place to place. Even the movements of stems, roots, flower parts and other organs of plants often escape notice because of the slowness with which most of them take place. The vigor and reality of the autonomous movements of such plant organs can easily be demonstrated by "time lapse" photography in which the plant is photographed at regular intervals over a period of time with a motion picture camera and the resulting film projected at such a speed that a period of several weeks may be represented on the screen in the course of a few minutes.

Most of the movements which occur in the organs of the higher plants may be classified as: growth movements, turgor movements, and hydration movements. Growth movements of plant organs result from enlargement of cells or increase in the number of cells or both. When increase in the size or number of the cells is not uniform throughout an organ curvatures or other growth movements result. Growth movements are usually subdivided into three groups: 1. Tropic movements or tropisms. 2. Nastic movements or nasties. 3. Nutations. Tropic movements are those which occur under the influence of an environmental factor which operates with greater intensity from one direction than from others, the direction of the resulting movement often bearing a direct relation to the direction from which the factor operates. A tropism is said to be ***positive*** when the organ bends towards the direction from which the factor is acting, and ***negative*** when it bends in the opposite direction.

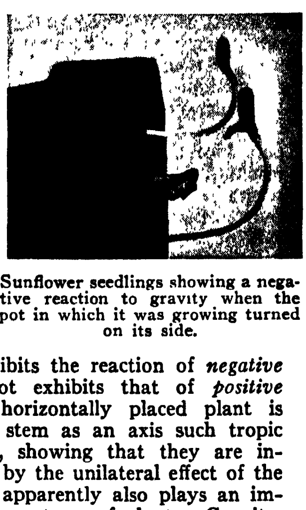
Phototropism is undoubtedly the most familiar of the tropic movements of plants. When a plant, such as a potted plant on a window sill, is so placed as to be more strongly illuminated from one direction than others, the stem bends towards the source of strongest illumination. In young seedlings this reaction may occur within a few minutes. In part this reaction results from a direct retarding influence of light on the enlargement of cells. The cells on the more strongly illuminated side of the stem do not elongate as much as those on the weakly illuminated side and the stem

thus becomes bent towards the stronger source of illumination. In many plants this may be the main or only mechanism of phototropic reaction. In other plants, however, a more complex mechanism operates in addition to the one just described. This mechanism of phototropism has been studied principally in the coleoptiles of grasses. It has been known for many years that if the extreme tip of a coleoptile is shaded with a cap of opaque material or if the tip is cut off, that bending, which takes place in the basal portion, fails to occur. Further investigations have shown that **auxin,** which is apparently made in the coleoptile tip from a precursor translocated up from the grain, is displaced laterally away from the side of the more intense illumination under the influence of such illumination. There may also be some actual destruction or inactivation of the auxin on the side exposed to the higher intensity of light. Downward translocation of auxin in a coleoptile is almost strictly longitudinal, hence the concentration of auxin reaching the elongating cells near the base of the coleoptile on the side away from the stronger light is greater than that reaching the cells on the other side. Since, within limits, cell elongation occurs in proportion to auxin concentration, the cells on the weakly illuminated side of the coleoptile elongate more than those on the opposite side and the coleoptile bends towards the light.

If a young potted plant be placed in a horizontal position it can be observed within a few days that the growing stem has turned in an upward direction and the growing primary root in a downward direction. In



Sunflower seedlings growing in a normal position.



Sunflower seedlings showing a negative reaction to gravity when the pot in which it was growing turned on its side.

other words the stem exhibits the reaction of *negative geotropism* while the root exhibits that of *positive geotropism.* If such a horizontally placed plant is slowly rotated about the stem as an axis such tropic movements do not occur, showing that they are induced in stationary plants by the unilateral effect of the factor of gravity. Auxin apparently also plays an important role in geotropic curvatures of plants. Gravity, like light, apparently has an influence on the distribution of auxin in a plant organ. More than half of the auxin from the tip of a horizontally placed coleoptile, for example, is found in the lower half of the tip. Upward curvatures of horizontally oriented coleoptiles and stems are therefore a result of a greater concentration of auxin reaching the elongating cells on the lower side of the organ than on the upper side. The positive geotropism of roots may also be interpreted in terms of an auxin mechanism. In explaining this effect, however, it is necessary to recall the principle (see **Auxins**) that in a range of concentrations above the optimum that auxins have a retarding effect on the elongation of cells and that the optimum favorable effect on cell elongation varies according to the tissue involved. The optimum concentration for elongation of root cells is known to be considerably less than that for stem or coleoptile cells. Hence the greater concentration of auxin in the lower half of a horizontally placed root as a result of the influence of gravity apparently falls in the range which checks cell elongation rather than favors it. The root cells therefore elongate more on the upper side than on the lower and the root turns down.

Hydrotropism is the term applied to the turning of roots from drier to moister regions of the soil. This reaction of roots is probably not as frequent as is sometimes supposed, but does occur in some species. Hydrotropic curvatures result from differences in the rate of elongation of the cells on the opposite sides of the root but at the present time there is no explanation of the exact mechanism responsible for this differential growth rate.

Many plant organs react to a contact with solid objects, a phenomenon to which the name *thigmotropism* is applied. Thigmotropic reactions are exhibited most clearly by tendrils, although they also may be shown by stems, petioles or other plant organs. A young tendril is a slender, cylindrical organ which makes slow circular movements in space (*nutation*—see later) during its elongation. As soon as the tendril comes in contact with a solid object rapid growth reactions are initiated. The growing tendril tip rapidly winds around the support, often within a period of a few minutes. As a result of further growth reactions the lower straight part of the tendril may become coiled thus drawing the stem to which it is attached closer to the support.

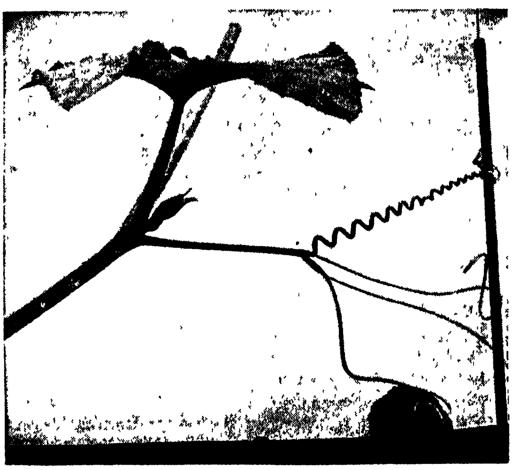
Nastic movements are those which occur in plant organs when the initiating factor affects all parts of the growing organ uniformly or when the factor, although acting largely or entirely from one direction, evokes the same kind of a reaction regardless of the direction from which it acts. Temperature and diffuse light are the most important factors evoking nastic movements. The movements of bud scales, young leaves, and flower petals are examples of nastic movements. In a young flower, for example, the lower sides of the petals grow faster than the upper, and the flower bud remains closed. The subsequent opening of the bud is brought about by a more rapid growth of the upper than the lower side of the petals. The first of the above described nastic movements is called *hyponasty;* the second *epinasty.* The leaves and flowers of many kinds of plants exhibit *photonastic* movements. In some species, for example, the leaves regularly droop from the horizontal position every night; in other species the leaves regularly assume a more nearly vertical position at night than during the daytime. Many such leaf movements, however, are turgor movements rather than nastic movements. Photonastic movements of flowers are more familiar. Some flowers, such as Oxalis, are regularly open in the daytime and closed at night; others such as the Evening Primrose are regularly open at night and closed in the light. *Thermonastic* movements also occur in both leaves and flowers. Many early spring flowers, for example, are open on warm bright days but remain closed on other bright days on which the temperature is lower. Thermonasty of leaves is well shown by the rhododendron in which the leaves droop and roll markedly at temperatures below approximately the freezing point, but normally assume an expanded condition at higher temperatures.

Nutation is the term applied to the irregular spiral pathway which a growing stem tip usually traces as it grows through space. This type of growth movement results from unequal rates of growth in different vertical segments around the stem axis and seems to occur independently of any effect of environmental factors.

The most spectacular examples of nutation are shown in twining plants. The stem tip of such a plant is usually long and slender and devoid of leaves and often

swings through a wide angle as the stem grows ahead through space.

Turgor movements of plant organs are those which are caused by reversible changes in the volume of plant cells. Innumerable examples of such movements in plants can be cited but many of the most pronounced turgor movements occur in species in which pulvini are located at the base of the leaf blade or petiole or both. Such structures occur most commonly in species of the pea family. Externally a *pulvinus* appears as a short, swollen portion of the petiole. Structurally a pulvinus is composed of a compact mass of thin-walled cells which surround a central vascular strand. Movements of leaves or leaflets result from sudden decreases in the turgor of the cells on one side of the pulvinus relative to the cells on the other, the petiole or leaf blade bending towards the side of lower turgor. Loss of turgor of the cells on one side of a pulvinus apparently results from outward movement of water from



Tendril of squash attached to a slender rod. Note that a portion of the tendril twines clockwise and a portion counter clockwise. Slow-motion pictures show that this is accomplished by the central portion turning in a circle as the tendril contracts.

the cells into the surrounding intercellular spaces but the details of the mechanism are not well understood. Turgor movements originating in pulvini may be brought about under the influence of a number of different environmental factors. In the sensitive plant, *Mimosa pudica*, which affords the most striking and probably most familiar example of turgor movements in plants,

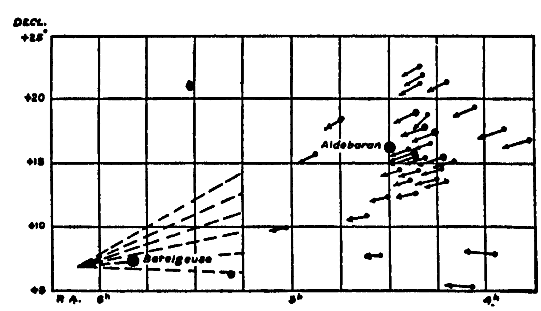
Sensitive plant. One leaf is reacting to the stimulus of touch. (*Pfeffer's Physiology of Plants, Clarendon Press, Oxford.*)

leaf movements may be induced by physical contact, exposure of the plant to various gases, electrical shock, heat, inadequate water supply, change from light to darkness and in other ways. In this species a pulvinus is present at the base of the petiole of each bipinnately compound leaf and also at the base of each leaflet and at the base of each part of the compound leaf. Merely touching one of the terminal leaflets sharply is usually sufficient to cause the entire leaf to close up. It is evident that the "stimulus" applied to the terminal leaflet has been transmitted to other parts of the leaf, resulting in turgor movements originating in many pulvini. Detectable turgor movements may occur in the leaves of a sensitive plant within a fraction of a second after the "stimulus" has been applied, but the mechanism by which such a rapid transmission of the effect occurs is unknown. Recovery of turgor occurs much more slowly, requiring from several to many minutes.

Hydration movements occur in many non-living parts of plants as a result of changes in the degree of hydration of the cell walls. Such movements are usually inconspicuous and mostly of little biological significance. The splitting of dry seed pods and capsules and the movements of the awns of some grasses are examples of hydration movements. (B.S.M.)

MOVING CLUSTERS. Statistical studies of the various stellar motions, such as **proper motion, radial velocity,** and **space velocity,** have proved conclusively that there are a number of groups of stars that are moving through space together. These motions can be considered under two main headings: moving clusters and star streams.

A relatively small number of stars which are known to be moving through space together in parallel paths constitute what is known as a moving cluster. Due to a perspective effect, similar to that discussed in connection with meteoric **radiant points,** the proper motions of the members of the moving cluster will appear to be converging upon, or diverging from, a point on the celestial sphere. The apparent convergence of proper motions of a moving cluster is illustrated by the figure which shows a group of stars in the **constellation** of **Taurus** which form part of the so-called Taurus move-



Convergence of stars in Taurus cluster. (*Adapted from a diagram by Lewis Boss.*)

ing cluster. About 100 stars have been found which belong to this cluster. A number of moving clusters have been found in various parts of the sky and they frequently carry the name of a constellation in which a number of the members of the cluster are found, e.g., the Ursa Major group, the Scorpio-Centaurus group, the Orion group, etc. It must not be understood that all members of a particular moving cluster are to be found in the constellation for which the group is named, for such is rarely the case. For example, members of the Ursa Major cluster are to be found not only in the constellation of **Ursa Major,** but also in **Canis Major,** Corona Borealis, **Auriga,** and others.

A study of the geometry of a moving cluster will indicate that the angular distance of any member of the

cluster from the convergent or divergent point is the angle β as defined in the discussion of **space velocity.** It may be further shown that if the radial velocity of only one member of the cluster can be determined, not only the distance of this star, but also the distance of every member of the cluster, may be determined. With these data at hand, it is possible to find the space distribution of all of the members of the cluster. An analysis of the Taurus cluster indicates that all members of this group are contained within a roughly globular volume of space about 35 **light years** in diameter with its center about 130 light years from the sun. The velocity of the cluster indicates that 800,000 years ago the cluster was only 65 light years from the sun, while 65,000,000 years hence it will have receded to such a distance that it will appear as a sparse globular star **cluster** not more than 20′ in diameter. At present the sun is within the Ursa Major cluster, with the members moving by on both sides. This cluster is somewhat larger than the Taurus group, having a diameter of 500 light years. So far as is known, the sun is not a member of any moving cluster.

The common motions of so many different groups of stars cannot be accounted for on any chance arrangement and at once suggests a common origin for all members of a moving cluster. This hypothesis receives support from the fact that in many cases the various members of a cluster are of similar **spectral class.** Jeans has shown that the attractive forces of stars other than members of the cluster will eventually produce disintegration of the group and on this basis he calculates ages of the order of magnitude of 10^{12} years for the group.

In the early part of the present century Kapteyn was able to show that the space velocities of the stars were not at random, but had two fundamental preferential directions. It is as though there were two great rivers or streams of stars, one moving toward the constellation of **Orion** and the other toward the constellation of Scutum (in the southern hemisphere). The points toward which the streams are moving are known as the vertices of preferential motion, and both are close to the plane of the **milky way.**

While the fact of star streaming is quite definitely established, a complete explanation of it is as yet undetermined. Kapteyn offers an explanation on the basis of two huge clouds of stars moving past each other and intermingling as they flow on toward their vertices. Schwarzschild, on the other hand, proposes an ellipsoidal hypothesis in which the star streams may be explained on the basis of relative motions within a rotating ellipsoidal mass of stars. (W.K.G.)

MUCK. Soil.

MUCKET. Mollusca, Lamellibranchiata. A fresh-water **mussel,** *Actonomais,* of the St. Lawrence and Mississippi River systems. It has a heavy shell which is used in button-making. (A.W.L.)

MUCOUS GLAND. A form of gland whose cells produce a secretion rich in **mucus.** Glands may be of this type or may produce watery secretions, in which case they are said to be serous. Some contain secretory cells of both kinds and are said to be mixed. (A.W.L.)

MUCOUS MEMBRANE. A membrane composed of epithelial cells (see **Epithelium**). Mucous membranes line those canals, cavities, and tracts which communicate with the external air, such as the nose and throat, **respiratory** tract, **generative** and **urinary** passages, and the **digestive system.** (D.M.H.)

MUCUS. A clear slimy secretion secreted by animals where surfaces must be lubricated or moistened. It is produced at the surface of the body by fishes (**Pisces**) and **amphibians.** Terrestrial **vertebrates** secrete it in the linings of the **respiratory** and **digestive systems** in abundance. (A.W.L.)

MUD DAUBER. Insecta, Hymenoptera. Any of several species of **wasps** which make their nests of mud. (A.W.L.)

MUD EEL. Amphibia, Urodela. A long slender aquatic species, *Siren lacertina,* with external gills, small front legs but no hind legs, and three pairs of gill slits. The **eel** is found in swamps throughout the southern half of the United States, east of Texas. (A.W.L.)

MUD SKIPPER. Pisces, Teleostei. Coastal fishes (**Pisces**) of Africa and the Oriental region, including *Periopthalmus.* They have prominent eyes and strong pectoral fins which they use in moving about on the muddy shores and in climbing to a limited extent. They are said to be distinctly mud fishes, incapable of thriving if forced to remain in deep water. (A.W.L.)

MUDFISH. Pisces, Holostei. The fresh-water dog-fish or **bowfin.** (A.W.L.)

MUDPUPPY. Amphibia, Urodela. A large aquatic **salamander,** *Necturus maculatus,* with an elongate body, flattened head, tufted external gills, short legs, and a compressed tail. Found in rivers and lakes of the eastern half of the United States, reaching only the northern part of the Gulf States. Also called the waterdog. (A.W.L.)

MUDSTONE. This is a loosely used term for rocks consisting essentially of consolidated muds, often sandy, which, however, although harder than clay, lack the laminated structure and fissility of **shale.** (R.M.F.)

MUFFLER. A muffler, as its name implies, is some device for silencing or muffling an objectionable noise. Release of the gases from the cylinders of **internal combustion engines** on the exhaust stroke at pressures considerably above atmospheric, has created a condition which has had to be met by the use of mufflers. All things considered, it has been found best to operate the internal combustion engine with incomplete expansion, i.e., release above atmospheric pressure. When the exhaust valve opens, the pressure in the cylinder exceeds that in the atmosphere by 20–50 lbs. per sq. in. The result of the sudden rush of gases out of the cylinder under this driving force is an explosive expansion which creates a sharp, objectionable exhaust noise. To reduce this objectionable feature, mufflers are designed to expand the gases more gradually and keep them confined until the pressure has been lowered nearly to atmospheric. The exhaust puffs from the separate cylinders of a multi-cylindered engine are thoroughly intermingled, and issue from the muffler in a steady stream.

The simplest form of muffler is an expanding tube of conical shape attached to the end of the exhaust manifold. To be effective, this type of muffler must be so large as to be too bulky for automotive purposes. Manufacturers have developed compact designs which contain, within a sheet-steel cylindrical shell, baffles, perforated plates, perforated tubes, and the like, whose function is to break up the separate puffs, intermingle them, and expand them until they will issue smoothly from the muffler stack. The large size of steel mufflers which might be suitable for stationary engines of large capacity would be difficult to maintain, and costly to install, compared to a muffler made of concrete. Where portability, light weight, compactness, are relatively unimportant, the concrete muffle pit, with considerable internal volume, supersedes the automotive-type muffler. However, because of the large-scale pro-

duction of the latter types, they are applied to many engines which might otherwise have been served with muffle pits. The chief drawback of a muffler is that the more effective it is in reducing noise, the more it handicaps the engine performance by creating a back pressure upon the engine manifold. One may find examples where the attractiveness of silent operation has been a factor of sufficient importance to warrant a high degree of muffling, and other instances, where, although quietness of operation would be highly desirable, mufflers have been omitted because they reduced horsepower, added weight, and constituted hazards, due to their high operating temperature. (F.T.M.)

MUGGER. Reptilia, Crocodilia. The Indian **crocodile**, *Crocodylus palustris,* distributed from Beluchistan to Burma and south to Ceylon and other Oriental islands. From the native name, magar. (A.W.L.)

MUGWORT. Artemisia.

MULBERRY FAMILY. Moraceae. Widely scattered in all but the coldest regions of the world are the more than nine hundred species of the Mulberry Family, including trees, shrubs, and herbs. Many are of great economic importance. In Asiatic tropics, for instance, *Ficus elastica* has been used as a source for **rubber**, while *Ficus carica,* a related plant, is the cultivated fig. Another tropical member, *Artocarpus incisa,* is the **breadfruit**. This tree has large glossy incised leaves and bears large fruits which are roasted and eaten. **Hemp**, *Cannabis sativa,* is an important fiber plant. *Humulus Lupulus* yields hops, while various species of *Morus* are important as food for silk worms.

All members of the Mulberry Family contain a milky juice. The flowers are borne in axillary spikes or heads. Many members have **dioecious** flowers, that is, the staminate (see **Stamen**) and pistillate (see **Pistil**) flowers are borne on different plants, while others are monoecious. The staminate flower has a variously 3- to 6-parted **calyx**, no **petals**, and one to four **stamens** with filiform filaments. The pistillate flower has a calyx of three to five, more or less united **sepals** and a single 1- to 2-celled superior **ovary**. The fruit varies greatly in different members of the family.

The true mulberries, trees or shrubs of the genus *Morus* are widely distributed plants of temperate regions. The leaves are alternate. On a single tree one may observe interesting variations of the leaves; on one shoot they may all be entire, while on a nearby shoot they are variously and irregularly lobed or divided. The flowers develop early in the growing season. The plants are either monoecious or dioecious. The staminate flowers are borne in long **catkins** and soon fall from the tree. The calyx is divided into four lobes and there are four stamens inserted at its base. The pistillate inflorescence is a short dense catkin. The flowers have a 4-lobed calyx and a single 1-celled ovary. After pollination the calyx lobes become greatly swollen and fleshy, the individual fruits pressing together tightly to form a multiple fruit. These fruits may be white or pink in the White Mulberry, red in the Red Mulberry, and black in the Black Mulberry. The white mulberry, *Morus alba,* is grown in the Orient largely to supply food for silk worms. The roots of the tree yield a yellow dye, and the wood is used for various purposes. The black mulberry, *Morus nigra,* is grown largely for the fruits, which are greedily eaten by birds, including domestic poultry. The wood is also valuable. Red mulberry, *Morus rubra,* furnishes wood used in making shoe lasts, and for other purposes. All species of mulberry are frequently planted as decorative trees.

Another member of the Mulberry Family which is very valuable is a perennial climbing plant, *Humulus Lupulus,* or the Common Hop. This plant has an extensive underground stem, or rhizome, from which rise the annual climbing stems, which twine in a clockwise direction around any supporting object. The hollow stem is ridged, with downward pointing hairs along each of the ridges. The opposite leaves are large and **palmately** veined. Hops are usually dioecious plants. The staminate inflorescence is a loose panicle; the pistillate, spike-like, with conspicuous bract-like structures subtending each branch. The staminate flowers have a 5-parted calyx and five stamens; there is no corolla. The pistillate flower is a single ovary, partially surrounded by a small **bract** and having two long hairy **stigmas**; around the ovary is a cup-like **perianth**. Hops are wind-pollinated. After fertilization the bracts enlarge greatly. On their outer surface, and also on the surface of the perianth and the subtending bract, yellow grains develop. These grains are called hop-meal and are multicellular cup-shaped bodies developing from single epidermal cells. The cells of these bodies secrete a yellow substance which fills the cup-shaped hollow and which contains the substances which make hops valuable—an essential oil, resins, **tannin**, and a bitter substance, probably **alkaloidal** in nature. The resins are bitter and germicidal.

The principal use of hops is in the brewing of beer. Hops are prepared for the brewing process by drying and bleaching. Prepared hops are boiled with the sweet beer wort, which extracts the bitter principle and imparts to the beer an aroma due to the essential oil of the hops. (R.M.W.)

MULE. Mammalia, Perissodactyla. A hybrid between the domestic horse and ass, produced by mating a mare and a jack. The reciprocal cross of stallion and jennet is called a hinny.

Mules have the large ears, small hoofs, and tufted tail of the ass and the stature of the horse. They are strong and hardy, resistant to disease and adverse conditions. Although they are often of uncertain temper they are such valuable work animals that the mule-breeding industry of the United States has reached a value of $500,000,000 per year at its peak. Mules are bred for various purposes, including riding and driving as well as work of heavier nature. Since they are infertile, they are always bred by crossing the two species. (A.W.L.)

MULITA. Mammalia, Edentata. A South American **armadillo**. (A.W.L.)

MULLERIAN DUCT. A duct of a pair developed in **vertebrates** of both sexes, from which the **oviducts** and, in the mammals, the **uterus** and **vagina** of the female are formed. The Mullerian ducts of the male become vestigal structures in the adult. (A.W.L.)

MULLET. Pisces, Tetelostei. Fish (**Pisces**) of several families. Those of the family Mugilidae are the gray mullets of European terminology and those of the family Mullidae are the red mullets. Several species of the family Catostomidae are called mullets in North America, or mullet suckers because of their close relationship with the fishes of the latter name. One of these species, the common red horse or white sucker, is confusingly called the red mullet.

Most of these fishes are coastal forms which ascend estuaries and even the wholly fresh parts of streams. The red mullets are chiefly tropical. Some of the Mullidae are good food fishes. The Mugilidae are less valued and the Catostomidae are also of moderate worth. (A.W.L.)

MULTIPARA. A woman who has given birth to several children. (D.M.H.)

MULTIPLE CORRELATION. We shall discuss multiple curvilinear correlation. For the theory of ordinary

multiple correlation, see the **coefficient of multiple correlation.** In the case of curvilinear correlation, we have the **regression** curve in four variables as the sum of polynomials in x_i of degree n,

$$x_1' = a_1 + a_{21}x_2 + a_{22}x_2^2 + \cdots + a_{2n}x_2^n$$
$$+ a_{31}x_3 + a_{32}x_3^2 + \cdots + a_{3n}x_3^n$$
$$+ a_{41}x_4 + a_{42}x_4^2 + \cdots + a_{4n}x_4^n.$$

The constants are readily determined by the method of **least squares.** Then we define

$$\rho^2_{1\cdot 234} = 1 - \frac{\Sigma(x_1 - x_1')^2}{\Sigma(x_1 - \bar{x})^2}$$

and $\rho_{1\cdot 234}$ is the multiple curvilinear index of correlation of the **variable** 1 on 2, 3, 4, remembering x_1 is the actual value of the **variate** and x_1' the value found from the regression curve. Similarly we may define $\rho_{2\cdot 134}$, etc. The theory of multiple curvilinear correlation has not been extensively developed. The results have been stated for four variables. Similarly the theory may be extended to m variables. (L.A.A.)

MULTIPLE DIE. **Die Casting.**

MULTIPLE EFFECT. **Evaporator.**

MULTIPLE INTEGRALS. **Double Integrals** and **Triple Integrals.**

MULTIPLE PROPORTIONS, LAW OF. If two chemical **elements** unite to form more than two compounds, the different amounts of one which unite with a fixed amount of the other stand in the ratio of small whole numbers, e.g., **hydrogen** and **oxygen** can form either **water** or **hydrogen peroxide.** Analysis shows that 2 grams of hydrogen combine with 16 grams of oxygen to form water; on the other hand, 2 grams of hydrogen combine with 32 grams of oxygen to form hydrogen peroxide. The ratio of oxygen which combines with a fixed amount of hydrogen (in this case 2 grams) is 16 to 32 or 1 to 2. (See **Chemical Composition.**) (R.K.S.)

MULTIPLE ROOTS OF AN ALGEBRAIC EQUATION. **Polynomial Equations.**

MULTIPLE SCLEROSIS (Insular Sclerosis, Disseminated Sclerosis). A disease of the central nervous system characterized by degeneration of nervous tissue in multiple areas causing many varied symptoms, mostly of the motor system. It is one of the common organic diseases of the nervous system and is more prevalent in Europe than in America.

The cause of the disease is not known. It occurs in young adult life—usually in the 20's and early 30's.

The symptoms are extremely varied. Some of the more common ones are disturbances of speech, tremor, disturbances of gait, nystagmus, spastic paralysis of the extremities, paralyses of the eye muscles, and atrophy of the optic nerves.

The disease tends to have periods of remission but eventually leads to a fatal result. No proven case has recovered, although a patient may live for many years. There is no efficient treatment. (R.S.M., D.M.H.)

MULTIPLE-SLIDE MACHINE. **Press Working.**

MULTIPLETS. **Atomic Spectra; Hyperfine Structure.**

MULTIPLEX CIRCUIT. This is a system of automatic or teletypewriter telegraph service in which several messages may be transmitted simultaneously over the same line. (L.R.Q.)

MULTIPLICATION. Multiplication is one of the fundamental operations with **numbers,** by which two or more numbers are combined to give a number; the result is called the product.

This operation is subject to several fundamental rules or laws: the commutative and associative laws, and in combination with addition, the distributive law.

The commutative law for multiplication of numbers is expressed by the formula

$$a \cdot b = b \cdot a$$

for any two numbers a and b; in words, the product of any two numbers is the same in whatever order they are multiplied.

The associative law for multiplication of numbers is expressed by

$$(ab)c = a(bc)$$

for any three numbers a, b, c; in words, the product of any three numbers is the same in whatever manner they are grouped.

The distributive law for addition and multiplication of numbers is expressed by the formula

$$a(b + c) = ab + ac$$

for any numbers a, b, c; in words, the product of a factor by a sum of two terms is equal to the sum of the products of the factor by each of the terms of the sum. A similar statement applies when the sum contains more than two terms.

The product of two numbers of the same sign is positive, that of two numbers of unlike signs is negative, the **absolute value** being the product of the absolute values of the numbers.

To find the product of two **polynomials,** we multiply each term of one polynomial by each term of the other, and add these results.

The following special product formulae are of frequent use:

$a(b + c + d) = ab + ac + ad,$
$(a + b)(c + d) = ac + ad + bc + bd,$
$(x + a)(x + b) = x^2 + (a + b)x + ab,$
$(a \pm b)^2 = a^2 \pm 2ab + b^2,$
$(a + b)(a - b) = a^2 - b^2,$
$(a \pm b)^3 = a^3 \pm 3a^2b + 3ab^2 \pm b^3,$
$(a \pm b)(a^2 \mp ab + b^2) = a^3 \pm b^3,$
$a^n - b^n = (a - b)(a^{n-1} + a^{n-2}b + \cdots + ab^{n-2} + b^{n-1}),$
$a^n - b^n = (a + b)(a^{n-1} - a^{n-2}b + \cdots - b^{n-1})$ if n is an even integer,
$a^n + b^n = (a + b)(a^{n-1} - a^{n-2}b + \cdots + b^{n-1})$ if n is an odd integer.

From these one may obtain at once certain useful special quotients.

By reversing the above product formulae, we obtain formulae for **factoring.** (L.L.S.)

MULTISTIGMATEA. **Thaliacea.**

MULTITUBERCULATES. **Fossil Mammals.**

MULTIVIBRATOR. **Relaxation Oscillator.**

MUMMICHOG. Pisces, Teleostei. The common **killifish,** *Fundulus heteroclitus,* also called the **mud fish.** A small shore fish, common from Maine to Mexico. (A.W.L.)

MUMPS (Epidemic Parotitis). A generalized contagious disease with marked local involvement of the **parotid glands,** and occasional involvement of other glandular structures, especially the **testicles.**

Mumps occurs most frequently between 5 and 15 years of age. The disease is caused by a filtrable virus and one attack usually gives immunity through life.

Mumps may be transmitted before signs of glandular swelling appear, and contagion usually persists while this swelling lasts. The incubation period varies from 8 to 30 days, usually averaging from 15 to 18 days. The first symptom is usually swelling and pain of one or both of the parotid glands. At times the other salivary **glands** are involved—the sublingual and submaxillary glands. In rare cases these glands alone may be involved instead of the parotid.

The most frequent complication is inflammation of the testicles, or orchitis, occurring in 15–30% of cases in adults. Very rarely does it occur before puberty. Orchitis is accompanied by pain and swelling of the testicle, malaise, and fever. It is a serious complication because it may result in testicular atrophy and sterility. Meningo-encephalitis is the next most frequent complication. It has a good prognosis. Inflammation of the ovaries is less common. Other complications which are uncommon are pancreatitis, pneumonia, and bronchitis. Deafness may occur and be permanent.

Convalescent serum and gamma globulin are of use prophylactically after exposure. There is no specific treatment. (D.M.H.)

MUNGOOSE. **Mongoose.**

MUNIA. Aves, Passeriformes. Any bird of numerous species of weaver **finches** constituting the genus *Munia*. They are native to Africa and the Oriental region. The commonest species is the rice bird, paddy bird, or Java sparrow, which is regarded as a pest in the rice fields and has been kept extensively as a cage bird in Europe. (A.W.L.)

MUNTJAC. Mammalia, Artiodactyla. Small Asiatic deer of several species. They stand only about two feet high and have small two-tined antlers somewhat like those of the American prong horn. The common Indian species, *Cervulus muntjac,* is called the kakar. (A.W.L.)

MUNTZ METAL. **Brass and Bronze.**

MURAENA. **Eel.**

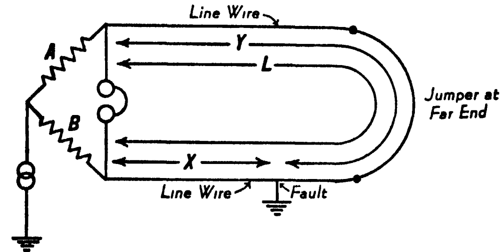
MURIATE. Term applied to **chlorides**. Muriate of potash, **potassium** chloride; muriatic acid, **hydrochloric acid.** (R.K.S.)

MURINE. **Opossum.**

MURMUR. An abnormal sound heard over the heart area, either by the ear placed against the chest wall, or with the aid of a stethoscope. Murmurs are classed as organic or functional; and loud, soft, rough, blowing, high-pitched, low-pitched. Organic murmurs are associated with structural deformities of the valves, shrinking and constriction, or dilatation, such as occur with **rheumatic fever,** bacterial **endocarditis, arteriosclerosis** and **syphilis.** The deformity may be part of the acute lesion in rheumatic fever, or it may represent the healing and residual scarring of the valve in **rheumatic heart disease.** The flow of blood over such deformed valves is responsible for the abnormal sounds. Functional murmurs are frequently heard in normal hearts, in normal healthy individuals; the mechanism of their production is a matter for debate. In profound **anemia** a different type of functional murmur is heard. It is due to dilatation of the heart and its valves, and disappears when the anemia is overcome. (D.M.H.)

MURRAY COD. Pisces, Teleostei. A fish belonging to the large **sea-bass** family. (A.W.L.)

MURRAY LOOP. This is a bridge type measurement made on communication lines to locate accidental **grounds.** As may be seen in the figure, it is a Wheat-



stone bridge in which the line wires form two arms. The balance point gives

$$X = \frac{BL(r_1 + r_2)}{2r_2(A + B)}$$

where r_1 is the resistance per ft. of the upper wire and r_2 of the bottom wire. Other quantities are shown on the diagram. (L.R.Q.)

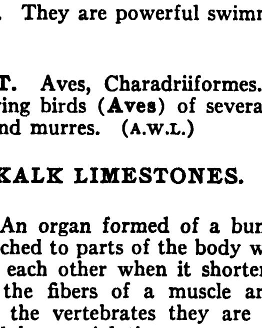
MURRE. Aves, Charadriiformes. Moderately large marine birds (**Aves**) related to the auks. The name is, to some extent, synonymous with **guillemot** but different species have been named as one or the other by ornithologists. They are powerful swimmers and divers. (A.W.L.)

MURRELET. Aves, Charadriiformes. Small species of marine diving birds (**Aves**) of several genera related to the auks and murres. (A.W.L.)

MUSCHELKALK LIMESTONES. **Triassic.**

MUSCLE. An organ formed of a bundle of contractile fibers attached to parts of the body which are moved in relation to each other when it shortens. Among the invertebrates the fibers of a muscle are loosely associated but in the vertebrates they are bound together and enveloped by special tissues.

The typical vertebrate muscle is surrounded by a connective **tissue** sheath, the external perimysium, which continues into it a series of septa (**septum**) called the



Cross-section of muscular tissue, enlarged, showing bundles of muscular tissue.

internal perimysium. Between the septa lie bundles of muscle fibers, each surrounded by a delicate continuation of the connective tissue closely joined to the surface of the fiber. Blood vessels and nerves supplying the muscle course through the perimysium.

Muscles differ in form according to the relations of their fibers to the tendons with which they connect. If the tendon is terminal, the fibers are longitudinal. In penniform muscles the tendon runs along one side and the fibers are oblique to the axis of the muscle, resulting in a feather-like appearance. If the tendon runs down the middle the result is a bipenniform muscle, and even more complex patterns of this type occur. Digastric

muscles have a tendon at each end and another in the middle connecting two contractile portions.

Individual muscles throughout the body have received special names according to their anatomical relations or functions. Thus the name extensor communis digitorum applies to the muscle of the human arm whose contraction straightens all of the fingers, and the sterno-cleido-mastoid is a muscle attached to the sternum, clavicle, and mastoid process. Several hundreds of distinct muscles of the human body bear such names.

(See also **Muscular System** and **Muscular Tissue.**) (A.W.L.)

MUSCLE SPINDLE. A sensory organ found in the muscles of **vertebrates.** It consists of a group of modified muscle fibers surrounded by nerve endings and is supposed to be stimulated by the variations of pressure resulting from the contraction of the muscle. (A.W.L.)

MUSCOVITE. POTASH MICA. The mineral muscovite is an **orthosilicate** of **alminum** and **potassium** which crystallizes in the **monoclinic** system although frequently found in pseudo-**hexagonal** forms. Usually tabular in **habit,** the most prominent characteristic is the highly perfect basal **cleavage** yielding remarkably thin laminae which are often highly elastic. Hardness, 2–2.25; specific gravity, 2.76–3; luster, vitreous to pearly; color, colorless through grays, browns, greens, yellows, and rarely violet or red; transparent to translucent.

Muscovite is the commonest mica, being found in **granites, pegmatites, gneisses,** and **schists,** and as a **contact metamorphic** mineral, or as a secondary mineral resulting from the alteration of **topaz, feldspar, kyanite,** etc. In pegmatites it is often found in immense sheets which are commercially valuable. A complete list of occurrences of muscovite would be impossible. In the United States excellent specimens are found in the pegmatites of New England, where they are associated with rarer minerals like **tourmaline, beryl,** etc. Pennsylvania, Maryland, Virginia, North Carolina, Georgia, South Dakota, and New Mexico also furnish large and fine examples of this mineral.

The name muscovite comes from Muscovy-glass, a name formerly much used for this mineral because of its use in Russia for windows. It is in much demand for the manufacture of insulating and fireproofing materials and to some extent as a lubricant. (E.S.C.S.)

MUSCULAR SYSTEM. The entire assemblage of contractile structures by which movement is produced in complex animals. **Muscular tissue** consists of several types of specialized cells, variously disposed. Some are scattered in the walls of hollow organs or among other tissues and some are bound together to form separate **muscles.** The latter are more conspicuous since they are separate organs, but all contractile structures properly belong to the muscular system.

In the simplest animals with special muscular tissues, the **worms,** muscle cells pass across the loose tissues within the body and form layers in the body wall. Their disposal is often in a circular layer, with fibers running around the body, and a longitudinal layer with fibers parallel to the main axis. The contractions of these layers lengthen and shorten the body and so carry on the creeping movements characteristic of worms. Special groups of muscle fibers also govern such special structures as the setae of earthworms. These muscles have an attachment to the body wall called the origin, and an insertion in the tissue surrounding the part to be moved.

In animals with a rigid skeleton an arrangement of muscle fibers like that of the body wall of worms persists in hollow organs like the alimentary tract, and in organs like the heart and urinary bladder a less regular arrangement provides for the uniform contraction of all parts of the wall. Locomotion and similar movements, however, are due to the action of muscles on skeletal

Muscular system.

supports which serve as systems of levers. Usually the shortening of a single muscle regulates the movement of one part in relation to another; it is said to have its insertion in the part moved and its origin at the other point of attachment. When a muscle is used for slowing a movement, it is stretched; and when it is used for equilibrium, as in standing, the length does not change. These activities are all included under the term contraction for historical reasons.

The nature of movements varies greatly. Extension of jointed appendages, flexion, retraction, rotation, and other movements are carried out by opposed systems of muscles. Any movement is positive, due to the contraction of a specified muscle, and the return of the part to its former position results from the contraction of an opposed muscle, sometimes aided by the action of gravity. The anatomy of the muscular system and the relations of specific muscles have been worked out in great detail in the human body, in other vertebrates, and in some of the **arthropods.** (A.W.L.)

MUSCULAR TISSUE. Muscular tissue is made up of long slender cells specialized for contraction. It is usually mesodermal in origin. There are three kinds of muscular tissue, smooth, cardiac, and striated or skeletal. Among the invertebrates all muscle may be smooth, as in many worms, or striated, as in most arthropods. All three kinds are found in **vertebrates** and cardiac muscle is characteristic of the vertebrate **heart.** Muscle **cells** may contain a few scattered myofibrils, or a large

number, occupying most of the cytoplasm. The myofibrils consist fundamentally of protein chains which are responsible for the contractile properties of muscle.

Among the invertebrates the contractile cells vary greatly. Those of **nematode** worms, for example, consist of a contractile and a noncontractile portion and some muscle fibers of **mollusks** show incipient striation in the form of oblique refractory lines.

The smooth muscle tissue of vertebrates consists of slender tapering cells with a nucleus placed centrally. These cells are involuntary in action and are found in the walls of the alimentary tract, excretory system, blood vessels, and other organs.

Striated muscle is so named because the many fibrils in its cytoplasm are made up of alternating zones of different refractive quality which cause the fiber to show light and dark transverse bands. The fiber is long and cylindrical and contains many nuclei located at the periphery. It is surrounded by a delicate membrane, the sarcolemma. Most striated muscle is the foundation of voluntary movements and from its extensive association with the skeleton it receives the name skeletal muscle.

Cardiac muscle, like skeletal, is striated, although the striations are much finer. It differs in the general branching of its fibers and in its centrally placed nuclei. Cardiac muscle is rhythmically contractile, initiating the heart beat of vertebrates. The nerves which inervate the vertebrate heart serve to modify but not to initiate the contraction of the heart muscle. (A.W.L.)

MUSCULO-EPITHELIAL CELL. A cell forming part of the layers in **coelenterates** such as *Hydra*, provided with basal contractile processes which serve as muscles. (A.W.L.)

MUSHROOM. Agarics and Basidiomycetes.

MUSHROOM POISONING. Eating certain types of mushrooms, notably the *Amanita phalloides, A. muscaria* and *A. verna,* produces severe poisoning. Muscarine and other toxins are responsible. Clinically one or two types of symptoms occur, depending on which variety of toxin is at work. One is chiefly a gastroenteritis, with nausea, vomiting, diarrhea and abdominal pain. With this type the prognosis is fairly good. In the other form, the toxin attacks the nervous system primarily, and headache, muscular cramps, blindness and coma occur. The mortality in such cases is high. (D.M.H.)

MUSICAL SOUNDS. The chief characteristics whereby musical sounds are distinguished from each other and from non-musical sounds are pitch and quality.

Pitch is that which the normal ear recognizes as corresponding to position in the musical scale. It is dependent primarily upon the frequency of the predominant sound waves; for example, middle *c* on the piano has a fundamental frequency of about 264 per sec. The frequency of a musical tone may be measured by means of a sonometer in comparison with a standard **tuning fork.** The sonometer string is tuned to unison with the unknown frequency, and then with the fork of known frequency, by varying its length at constant tension by means of a movable fret; the frequencies are then in the inverse ratio of the lengths. A "siren" may also be used for this purpose; it has a disk with equally spaced holes through which air is blown as the disk is rotated. This gives the frequency by direct count.

Quality is an attribute due to the complexity of a tone. Besides the lowest (and usually the loudest) frequency, called the fundamental, there may be a series of overtones, higher frequencies arising from the vibration of the source in parts or segments. Thus, a string may vibrate as a whole, giving the fundamental, or in halves, thirds, fourths, etc. The exact quality of a tone depends upon the relative intensity of the several components, which may be ascertained by means of a device called a "phonodeik" for amplifying the wave form and by subsequent **harmonic analysis.** Harmony or discord is dependent upon the loudness and frequency of the **beats** between the principal components of the tones concerned. (See **Combination Tones.**)

The musical scale at present used in occidental countries is a geometrical progression of frequencies with ratios or "intervals" each equal to $\sqrt[12]{2}$ or 1.05946. An octave comprises twelve such intervals and has the frequency ratio 2. Various harmonious combinations of the notes on this scale form the chords of ordinary music. In addition to pitch and quality, music utilizes differences in intensity, duration, and spacing (rhythm) of musical sounds, all of which contribute to that subtle attribute known as "expression." (L.D.W.)

MUSK DEER. Mammalia, Artiodactyla. A small **deer,** *Moschus moschiferus,* of the Himalayas. It stands twenty inches high. Antlers are lacking and the upper jaw bears a pair of tusks which may project several inches in the males. In northwestern China a second related species, *M. sifanicus,* occurs. (A.W.L.)

MUSK HOG. Peccary.

MUSK OX. Mammalia, Artiodactyla. An **animal,** *Ovibos moschatus,* of Arctic America related to the sheep but resembling oxen. It is about ⅔ as large as the American bison and is clothed with long hair. The horns are broad at the base but become rapidly narrower as they curve downward from the forehead over the sides of the head. The more slender tips turn abruptly upward.

Musk oxen are hunted by the Eskimos for their hides and flesh. (A.W.L.)

MUSKALLUNGE. Pisces, Teleostei. A large freshwater game fish (**Pisces**), *Esox nobilior,* of North America, found chiefly in colder waters of the northern states and Canada, but occasionally as far south as North Carolina. It is a slender species related to the pikes and pickerel and attains a length of 8′ and a weight of 100 lbs. Specimens over 40 lbs. are, however, rarely taken.

The name is among the most abused of all fishes. It is also spelled muscalonge, muskellunge, maskinongy, masquinonge, and occasionally in other ways. (A.W.L.)

MUSKEG. Swamp.

MUSKMELON. Gourd Family.

MUSKRAT. Mammalia, Rodentia. Moderately large amphibious **rodents** of North America. They are stoutly built, short-legged with partially webbed hind toes, and have a compressed tail. They inhabit swamps and streams, making houses of sticks and also burrowing in the banks. Two species are recognized, one a dark brown animal, *Ondatra rivalicia,* of the coastal part of Louisiana and the other an extremely variable species, *O. zibethica,* found over most of the continent.

Muskrat fur consists of a fine woolly undercoat and long glossy hairs. It is the best of the inexpensive furs and because of the ability of the animal to withstand extensive trapping is now the most important fur commercially. Approximately 15 million pelts are taken annually in North America, many of them from fur farms. The natural colors of the fur are beautiful and many pelts are made up in this state, but many also reach the market as Hudson seal after being plucked, clipped and dyed black.

The muskrat has also been introduced successfully into Europe. (A.W.L.)

MUSQUASH. The Muskrat.

MUSSEL. Mollusca, Lamellibranchiata. A name applied to many **bivalve** mollusks, both marine and fresh-water species. Used to some extent as a synonym of clam, especially in reference to the fresh-water species. Most of the marine forms are normally called either mussels or clams, the species of the family Mytilidae bearing the former name. They include the edible mussel of both American coasts and Europe.

Fresh-water mussels are eaten but they are not an important source of food. They are taken in large numbers from the larger rivers of the country for their shells, which are used in making buttons, and for the pearls which they contain. As many as 50,000 tons of shells have been marketed in a single year, chiefly from the Mississippi River. (A.W.L.)

MUSTANG. Mammalia, Perissodactyla. Western American **horses** descended from stock introduced by the Spanish conquerors. Also known as Indian ponies and bronchos. They are noted for their endurance, agility and spirit. (A.W.L.)

MUSTARD. Brassica.

MUSTARD GAS. Poison Gases.

MUTAROTATION. Carbohydrates.

MUTATION. A characteristic different from any in the ancestry of the individual displaying it, which breeds true. Mutations are like sports in showing abrupt departure from the hereditary characters of the species to which they belong but they differ in being transmissible.

Changes of this type have been important in the study of **heredity,** since they afford contrasts with existing hereditary characters. They have usually been regarded as fortuitous changes issuing from the heritage but it has been found possible to increase their appearance by treating breeding stock with x-rays, radium, heat, and other environmental factors. They are a possible basis of evolutionary change. (A.W.L.)

MUTUAL CONDUCTANCE. This is one of the common vacuum-tube coeffiecients and indicates the effect on the plate current of the grid voltage, other quantities being held constant. It is also known as the transconductance. Mathematically it is

$$G_m = [di_p/de_g]_{E_p \text{ constant}}$$

where di_p is an infinitesimal change of plate current and de_g is an infinitesimal change of grid voltage, while E_p is the plate voltage. (L.R.Q.)

MUTUAL INDUCTANCE. Coupled Circuits and Inductance.

MUTUAL INDUCTION. Electromagnetic Induction.

MYALGIA. Pain in a muscle or muscles usually due to injury or inflammation. (R.S.M.)

MYCELIUM. Ascomycetes, Basidomycetes, Phycomycetes, and Fungi.

MYCETOZOA. Sarcodina. An interesting group of organisms formerly classed with the plants are **slime molds,** related to the fungi, and now included with the 1-celled animals in the phylum **Protozoa.** They consist of a creeping mass of **protoplasm** containing many nuclei. This plasmodium occasionally produces fixed reproductive bodies (sporangia) in which their resemblance to plants is at its height. (A.W.L.)

MYCORHIZAE. Mycorhizae are, strictly speaking, **hyphal** threads of various **fungus plants,** growing in intimate association with some part of the **higher plant,** usually the root. Two different kinds of mycorhizae are known. In one kind, known as ectotrophic mycorhiza, the fungus hyphae form a close welt over the surface of the root with hyphal threads penetrating into the root between the **cortical** cells. This kind is particularly common on the tips of tree-roots, and often causes swelling of the infected roots. The fungus seems to take the place of root hairs, which are not developed in its presence. Apparently the general welfare of the tree is not absolutely dependent on the presence of mycorhizae, though they may materially benefit the tree. The other kind of mycorhiza is the endotrophic form, in which the fungus hyphae are found within the cells of the higher plants. **Orchids** and **Heaths** are well known examples in which endotrophic mycorhizae are found. The fungus enters the plant through the epidermis of the root, passes into the cells of the cortical **parenchyma** and lives there. From these cortical cells the fungus may extend into all the tissues of the higher plant, even reaching the **ovary.** Plants supporting endotrophic mycorhizae seem much more dependent on their presence than those with ectotrophic forms. Indeed, the successful growing of orchids from seed may depend on the presence of the fungus associate which enters the orchid embryo.

Plants growing in bogs, regions in which there is usually a lack of sufficient nitrogen, almost always have mycorhizae. Apparently the mycorhizae obtain the **nitrogen** necessary for the welfare of the higher plant.

This association of mycorhizae with higher plants is often described as a case of symbiosis, a living together of two organisms for mutual benefit. The higher plant receives a greater supply of nitrogen and so benefits; the **fungus** obtains food from the higher plant. (R.M.W.)

MYDRIATIC. Any **drug** that causes dilation of the pupil of the eye. Such drugs are **atropine, belladonna, cocaine,** etc. (R.S.M.)

MYELITIS. This term refers to general or local involvement of the spinal cord by inflammation or softening, resulting from infection, injury, or certain poisons or toxins. Infective myelitis may occur as a complication in many diseases, of which the most common are **measles, chicken pox, mumps, syphilis, diphtheria,** and the various forms of **meningitis.** Toxic myelitis may be due to poisoning by **carbon monoxide, gasoline, chloroform** and other chemicals. Traumatic myelitis may be due to direct or indirect injury about the spine. The disease may be acute or chronic.

Symptoms occurring in myelitis depend on its cause and on the extent of the spinal cord involvement. The common ones are weakness, paralysis, pain and sensory changes. The disease is serious and the mortality is high, varying according to the extent and degree of involvement of the spinal cord. (D.M.H.)

MYLONITE. The term proposed by Charles Lapworth in 1885 for a massive **chert**-like rock occurring at the contact of the shear planes associated with the low-angle **overthrusts** of the North West Highlands of Scotland. Mylonite is therefore developed through the process of **dynamic metamorphism** and derives its name from the Greek, meaning to crush. (R.M.F.)

MYNA. Aves, Passeriformes. Indian birds (**Aves**) closely related to the starlings. (A.W.L.)

MYOCARDITIS. An acute inflammation of the muscular wall of the **heart.** Acute myocarditis is almost always secondary to any of the acute infections such as acute rheumatic fever, diphtheria, malaria, scarlet fever, erysipelas, septicemia, etc. It may result from direct invasion of the heart muscle by the infective organism or, on the other hand, from the toxins liberated by bac-

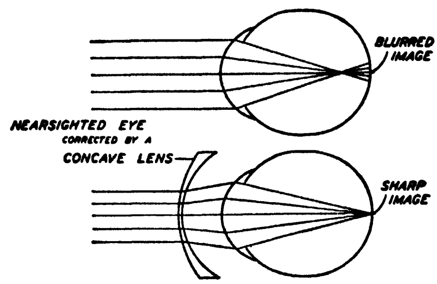
teria and carried to the heart by the blood stream. It is most common in childhood and early life. Often it complicates an acute and infectious disease which masks the symptoms and makes the diagnosis difficult or impossible. Acute myocarditis may be very mild and permit an early and complete recovery, or it may be so severe that death results within a few days.

Chronic myocarditis is a term no longer used. (R.S.M., D.M.H.)

MYOCARDIUM. The muscular layer which makes up the greater part of the wall of the vertebrate **heart.** It is lined with the thin endocardium and covered with a thin epicardium, continuous with the lining of the pericardial cavity. (A.W.L.)

MYONEME. Fine contractile filaments in the cytoplasm of 1-celled animals. (A.W.L.)

MYOPIA. Short sight or **near-sightedness,** due to an increase in the refractive power of the **eye** so that images



(*Carlson and Johnson's The Machinery of the Body, University of Chicago Press.*)

from distant objects are focused before reaching the retina and the image is blurred. The fault may be in too great a convexity of the lens, or an eyeball that is too deep. A concave lens is used to correct this condition. (See **Vision.**) (D.M.H.)

MYRIAPODA. A class of the phylum **Arthropoda,** now obsolete. It has been subdivided to form the four classes, **Chilopoda, Diplopoda, Pauropoda** and **Symphyla.** (A.W.L.)

MYRIENTOMATA. **Protura.**

MYRMECOPHILE. An animal which makes its home in the nests of ants. Among the insects that have become adapted to this mode of life are **crickets, beetles,** and larval flies. In most cases the myrmecophiles seem to feed at the expense of the ants, which may in turn eat secretions produced by their guests. (A.W.L.)

MYRRH. *Commiphora Myrrha.* Burseraceae. Myrrh is obtained from a spiny tree of small size, which grows wild in northeastern Africa and Asia Minor. It has trifoliate leaves, in which the lateral leaflets are very much smaller than the terminal, and small red flowers borne in the axillary buds of the leaves of the previous year. These flowers are **dioecious.** The fruit is a small **drupe.** A **resin** exudes from the stem of the tree, collecting in small lumps. This is myrrh, long known for its fragrance. It is used in perfumes and incense, and in medicine, and was one of the substances used by the Egyptians in embalming their dead. Several other species of the genus yield similar resins, also called myrrh. (R.M.W.)

MYSIDACEA. **Crustacea.**

MYSTACOCETI. The whalebone **whales,** an order of marine mammals including the largest living animals of this class. They are characterized by the presence in the mouth of plates of baleen or whalebone whose fringed ends serve as a sieve through which water is strained to remove the small animals contained in it. The order includes the fin whales or rorquals, the humpback whale, the pigmy whale of the southern hemisphere, the gray whale, the sulfur-bottom whale, and the right whales. (A.W.L.)

MYXEDEMA. **Thyroid Gland.**

MYXINOIDEA. **Cyclostomata.** The hag fishes.

MYXOMYCETES. **Slime Molds.**

MYXOSPONGIDA. **Demospongiae.**

MYXOSPORIDIA. **Sporozoa.**

N

N SERIES. **X-Ray Spectra.**

N.A.C.A. Abbreviation for National Advisory Committee for Aeronautics. A large and influential research agency of the United States Federal Government with headquarters in Washington, D. C., and laboratory facilities at Langley Field, Virginia, Cleveland, Ohio, and Moffet Field, California. Its publications, viz., *Technical Reports, Technical Notes,* and *Technical Memoranda,* have been issued since 1918, and form an important and frequently consulted body of aeronautical information. (F.T.M.)

N.A.C.A. FIVE-DIGIT AIRFOIL FAMILY. **Airfoil Classification.**

N.A.C.A. FOUR-DIGIT AIRFOIL FAMILY. **Airfoil Classification.**

NACELLE. An enclosed shelter for personnel or for a power plant. An airplane nacelle usually is shorter than the fuselage, and does not carry the tail unit. (F.T.M.)

NACRE. **Mother-of-pearl.**

NADIR. **Horizontal Coordinate System.**

NAGYAGITE. A mineral compound of uncertain chemical formula in which the essential elements are lead, gold, tellurium and sulfur. Crystallizes in the monoclinic system. Hardness, 1–1.5; specific gravity, 7.41±; color, dark gray with metallic luster. (R.M.F.)

NAIAD. An aquatic insect larva. **Hemimetabola. Larva.** (A.W.L.)

NAKONG. Mammalia, Artiodactyla. One of the larger harnessed **antelopes** of Africa. This species differs from most harnessed antelopes in its uniform grayish-brown color. The horns are long and spiral. Also called the sititunga. (A.W.L.)

NANNOPLANKTON. The portion of the floating and drifting aquatic animals (**plankton**), including minute species, which pass through ordinary nets and must be secured by centrifuging. (A.W.L.)

NAPE. The back of the neck. (A.W.L.)

NAPHTHA. **Hydrocarbons.**

NAPHTHALENE. Naphthalene ($C_{10}H_8$ or)

is a colorless, odorous (odor of "moth balls"), solid, melting point 80° C., boiling point 218° C., sublimes, insoluble in water, slightly soluble in cold alcohol, soluble in hot alcohol or in ether. Naphthalene reacts (1) with oxidizing agents, e.g., **sodium** dichromate, plus **sulfuric acid,** to form 1,4-naphthaquinone, (2) with oxygen of the air, in the presence of **vanadium** pentoxide as a **catalyzer** at 425° C., orthophthalic acid is formed, with **chlorine in chloroform,** to form naphthalene tetrachloride ($C_{10}H_8Cl_4(1,2,3,4)$), white solid, melting point 182° C., (3) with concentrated **sulfuric acid,** to form various naphthalene sulfonic acids. This reaction is important on account of the ease of transforming the sulfonic acid group ($-SO_2OH$) into the hydroxyl group ($-OH$) by heating with **sodium** hydroxide, and because of the solubility in water of the sulfonic acids (see **Thioalcohols and Related Compounds**). With **mercuric** salt present as a catalyzer sulfuric acid forms ortho-phthalic acid, (4) with concentrated **nitric acid,** to form alpha-nitronaphthalene ($C_{10}H_7NO_2(1)$), yellow solid, melting point 59° C., (5) with **picric acid** ($(1)HO \cdot C_6H_2 \cdot (NO_2)_3(2,4,6)$), to form yellow crystalline naphthalene picrate, melting point 149° C., (6) with hydrogen to form "tetralin" ($C_{10}H_{12}$) and then "decalin" ($C_{10}H_{18}$).

Naphthalene is obtained from coal tar in the fraction **distilling** between 180° C. and 200° C., from which the crystals are separated by **filtration** after cooling. The product is purified by treatment with concentrated **sulfuric acid,** and subsequent **sublimation.** Naphthalene may be detected by appearance of a carmine red color on heating with **mellitic acid** anhydride. Naphthalene is used (1) as an insecticide, (2) in the preparation of **phthalic acid,** (3) in the preparation of azo-**dyes** and indigotin, which is the chief constituent of the dyestuff **indigo,** (4) for the manufacture of the solvents "tetralin" and "decalin." (R.K.S.)

NAPHTHOLS. **Phenols.**

NAPIERIAN LOGARITHMS. **Logarithms.**

NAPOLEONITE. **Corsite.**

NAPPE. A great overfold of the "crust" of the earth including a thick **stratigraphic** series of formations frequently representing one or more geologic periods of the earth's history. Under great continued compressional stress the overfold may be faulted and ride forward so as to produce a profound and relatively horizontal translocation of the earth's "crust." Some thrust masses of this type are supposed to have traveled as much as 200–300 miles from the region in which the rocks were originally formed. The type locality of nappes is the Swiss Alps, where they form the principal structural features of this highly deformed and structurally complex mountain system. (R.M.F.)

NARCOMEDUSAE. **Hydrozoa.**

NARCOTINE. **Alkaloids.**

NARES. Terminal orifice of the nasal passages. The external openings are the external or anterior nares and the openings at the communication of these passages with the **pharynx** in air-breathing **vertebrates** are the posterior or internal nares. (A.W.L.)

NARWHAL. Mammalia, Odontoceti. A moderately large animal, *Monodon monoceros,* of the **dolphin** family, characterized by the single long straight tusk, spirally twisted, which extends forward from the upper jaw. The tusk is a single tooth, usually that of the left side. Its mate in the male and both of these teeth in the female are rudimentary. The narwhal has no other teeth except a few irregular rudiments. The tusk attains a length of 8′ and the animal reaches a length of 12–16′. (A.W.L.)

NASAL BONE. One of a pair of small bones forming the bridge of the human **nose** and the corresponding portion of the skull in other vertebrates. (A.W.L.)

NASO-LABIAL GROOVE. A groove extending from the nostril to the mouth in some of the fishes (**Pisces**) and **amphibians.** (A.W.L.)

NASTIES. Movement in Plants.

NATRIUM. Sodium.

NATROLITE. The mineral natrolite, one of the **zeolites**, is a **sodium aluminum silicate** corresponding to the formula $Na_2Al(AlO)(SiO_3)_3 \cdot 2H_2O$. It is **orthorhombic**, crystallizing in slender prisms of nearly square cross-section which are terminated by flat pyramids. There are also fibrous to compact varieties. Natrolite is a brittle mineral; hardness, 5–5.5; specific gravity, 2.2; luster, vitreous; color, red, yellow, white, or colorless; transparent to opaque. Natrolite is found with other zeolites in fissures and cavities in basaltic and related rocks. Czechoslovakia, France, Italy, Norway, Scotland, Ireland, Iceland, Greenland, and South Africa contain well-known localities for natrolite. In the United States it is found in the Triassic **traps** of New Jersey. Its name natrolite refers to its soda content. (E.S.C.S.)

NATURAL FREQUENCY. This term is commonly applied to **coils** and **antennae** in communication circuits. In the former it designates the frequency at which the inductance of the coil and its **distributed capacity** produce resonance. Referred to the antenna it means the lowest frequency at which there will be a standing wave on the antenna. (L.R.Q.)

NATURAL GAS. Petroleum.

NATURAL LOGARITHMS. Logarithms.

NATURAL NUMBERS. Number.

NAUPLIUS. A form of **larva** occurring in some of the **crustaceans.** It is the first stage to hatch from the egg and is a minute ovoid creature, unsegmented, with three pairs of appendages. (A.W.L.)

NAUTICAL ASTRONOMY. The term nautical astronomy is applied to those problems in the transformation of **spherical coordinates** and in the solution of the **astronomical triangle** which are of particular importance to the navigator. Among such problems may be cited the determination of **latitude, longitude,** and **azimuth** from a single **altitude** of a celestial object as taken with a **sextant.** (See **Celestial Navigation.**) (W.K.G.)

NAUTICAL MILE. This is the fundamental unit of distance used in navigation and, for purposes of convenience, has been defined as 6080′. Rigorously the nautical mile was defined as the length of 1 minute of arc on a great circle drawn on the surface of a sphere with the same area as the earth. In accordance with this rigorous definition the length of the nautical mile is 6080.27′.

The nautical mile is frequently confused with the geographical mile, which is defined as the length of 1 minute of arc on the earth's **equator.** The geographical mile has a length of 6087.15′.

Owing to the fact that the earth is an oblate spheroid and flattened at the poles the length of 1 minute of arc measured along a **meridian** varies in different latitudes. It is shortest at the poles and longest at the equator, having an average length of 6076.82′.

With sufficient accuracy for navigational purposes the minute of arc on the meridian, the minute of arc on the equator, and the nautical mile may all be considered as 6080′. It will be noted that such an assumption will never introduce an error greater than 0.8%. (W.K.G.)

NAUTILUS. Mollusca, Cephalopoda. The name of a genus of marine **mollusks,** also anglicized as a common name. The animal lives in the last and largest chamber of a shell which is coiled in a flat spiral. The three or four existing species are found in shallow to moderately deep water in the tropical oceans. They are eaten by the natives of some of the Pacific islands.

The paper nautilus, *Argonauta,* is not a true nautilus, but is more closely related to the octopus. (See also **Invertebrate Paleontology.**) (A.W.L.)

NAVEL. The scar on the abdomen of mammals where the **umbilical cord** was attached during prenatal life. The **umbilicus.** (A.W.L.)

NAVEL ORANGE. Parthenocarpy; Citrus Fruits.

NAVIGATION. A literal translation of the Latin word *navigare* is "to conduct a ship," and navigation is sometimes defined as the art or science of conducting a ship from place to place on the surface of the **earth.** However, the actual conducting of a ship more properly belongs to seamanship or airmanship than to navigation.

The subject matter of navigation, in the present usage of the term, can be considered under one of three main headings: 1. The **sailings.** To find the **direction,** or directions, in which to **head** a ship in order that it may proceed on the most practical **course** from one place to another. 2. **Dead reckoning.** To find the position of a ship at any particular instant, provided that its position at some previous time is given and that, since leaving this position, the headings, distances run on each heading, and the effects of environment and motions of the medium supporting the ship are known. 3. **Piloting, contact flying, celestial navigation.** To find the position of a ship at any instant by means of observations, not necessarily visual, of one or more objects on the surface of the earth or on the **celestial sphere.**

The number of individual methods and instruments employed in modern navigation is far too great to even list in an article of this character. The more important instruments and methods will be discussed under their individual titles throughout this volume. (W.K.G.)

NAVIGATIONAL COMPUTER. A navigational computer is fundamentally a circular **slide rule,** with the slide and scale carrying material of particular importance to navigators. On most navigation computers the slide is marked off in units of time, either minutes or hours and minutes, and the scale is graduated in miles. By setting 60 minutes on the slide to the speed of the ship (distance traveled in 1 hour) any other number of the scale will be the distance traveled in the corresponding time indicated on the slide. On some computers different colors are used on the scale and slide to indicate other frequently used calculations, e.g., rate of fuel consumption as a function of air speed.

By using "cut-outs" and auxiliary scales on the computers, the conversion from calibrated **air-speed meter** reading to true air speed, the conversion from **altimeter** reading to true altitude, and other such important conversions, may be readily made.

There is no standard type of computer and many navigators have gotten into serious difficulty by using a new type of instrument without carefully studying the description issued with it. (W.K.G.)

NAVIGATORS' STARS. A list of 55 stars has been designated as the "navigators' stars." The list was selected to cover the entire **celestial sphere** in such a manner that a navigator, no matter at what season or in what part of the earth he may be operating, will have two or three navigators' stars available for observation. The names and positions of these stars are listed in the

Air Almanac, published by the U. S. Naval Observatory, and in a number of other publications. (W.E.C.)

NEANDERTHALOIDS. Paleontology of Man.

NEAR-SIGHTEDNESS. Myopia.

NEATSFOOT OIL. Esters.

NEBULA. The term nebula (stellar nebulosa) was originally used by astronomers to describe any luminous spot which remained fixed relative to the stars. Before the application of the telescope to astronomy probably the only objects to which the term applied were those which we now refer to as star clusters, although there is a tenth-century reference to the great spiral in Andromeda. Following the application of the telescope to the study of the heavens, many more nebulous objects were discovered. Originally these objects were grouped into three main classifications: the diffuse nebulae, the planetary nebulae, and the spiral nebulae. Further research indicated that the spiral nebulae were very different from the other two. The application of the large telescopes of the present century has proved that they are in reality groups of stars, the term nebula has been dropped, and they are now referred to simply as spirals.

The diffuse nebulae are divided into two main groups, the dark and the bright. For many years the study of photographs of the Milky Way have shown "black holes" and other configurations that gave distinct evidence that clouds of dark material were obscuring stars that were beyond. Detailed investigation of the spectra of the spectroscopic binaries has shown that, although the great majority of the absorption lines from these objects shows the periodic displacement due to the motions of the components, nevertheless there are a few lines which remain stationary. The only plausible explanation is that these "stationary lines" are due to absorption by gaseous material in what had hitherto been referred to as empty space. When the color characteristics of stars in any one of the spectral classes are carefully studied, it is found that the more distant ones show a distinct reddening. The reddening can be well explained by the assumption of interstellar dust, which produces a reddening effect in much the same way that our atmosphere produces that reddening of sunlight which is more evident when we see that object through a thick layer (e.g., at sunset).

The study of this interstellar material forms one of the most interesting problems of modern astrophysical research, but the conclusions at the present time are not positive. Suffice it to state that interstellar material exists and that it contains gases, in atomic or molecular state, and also some form of dust-like material. The temperature of the interstellar region is of the order of magnitude of absolute zero and we are unable to state just what sort of "dust" might be formed under these conditions.

There is considerable evidence that the interstellar material is present in all parts of space. However, there is a definite tendency for the mixture of gas and dust to collect in clouds and condensations. When one of these dark clouds is between the earth and a region where the stars are apparently most numerous, e.g., in the plane of the milky way, we can observe the darkness of the cloud against the background of stars. Such obscuring clouds of interstellar material are known as dark nebulae.

When one of these clouds is in the vicinity of a bright star, the intense radiation from the star will illuminate the cloud and we observe what is known as a bright diffuse nebulae. Studies of the spectra of these objects show that the light is made up both of reflected starlight and also of radiation from the interstellar material. The character of the reflected light is similar to that from the nearby stars. The radiation from the nebulous material itself, however, is of quite a different character from star light. This nebular spectrum is of the bright-line type and is produced by the absorption of radiation from the star by the gas atoms, and then reradiation of this energy in frequencies characteristic of the gas atoms and their states of ionization. This hypothesis receives almost positive confirmation from the fact that the character of the nebular spectrum depends upon the spectral type of the nearby stars. If the star is hot (B-type) the nebular spectrum is rich with bright lines, but in the vicinity of a relatively cool star (M-type) the nebular spectrum is almost entirely that of reflected star light.

When the spectra of the bright nebulae were first studied, and before the modern hypothesis as to their general structure was even guessed, 2 bright lines were oberved to be present which could not be identified with any known terrestrial or solar element. It was supposed that these lines were due to some material that existed only in the nebulae, and the element was called Nebulium. We now know that the lines are due to the oxygen atom, which is in such abnormal condition that the particular lines could never appear in any laboratory spectrum.

In addition to the diffuse nebulae, there are others that are known as planetaries, because of the fact that they have quite definite shapes and look more or less like a planet when observed with a telescope. The general appearance of these objects, on detailed photographs, is that of a shell of gaseous material. They are generally elliptical in form, and may have the appearance of being made up of several elliptical shells with their axes at various angles to each other. Frequently a very blue, and hence probably very hot, star is observed at the center of the shell. Even when the star itself is not seen, astronomers are of the opinion that it is actually there, but that the shell is thick enough in the line of sight to prevent its being seen from the earth.

The spectra of the planetaries is, in general, the same as that of the diffuse nebulae found in the vicinity of B-type stars. In some cases, where the central star can be studied, variations in its light have been found and the nebula radiation is found to vary with that of the star. It is evident that the planetary nebulae are actually stars with very extended and attenuated atmospheres. There is no hypothesis to completely explain why some stars are in this condition, whereas the vast majority are not. Careful studies of the spectral lines from the planetaries indicate that the shell may be expanding. Expanding shells of gas have been observed around some novae, but the rate of expansion is far in excess of that found in the planetaries.

NEBULIUM. Nebula.

NECK. In zoology, a slender region connecting two other parts of a body. Particularly the region between the head and trunk of many vertebrates. The vertebrate neck contains a series of cervical vertebrae, respiratory and food passages, and part of the central nervous system, but it is not invaded by the body cavity. It varies greatly in relative length, a long neck usually compensating for long legs to enable the animal to reach the ground.

In geology, a volcanic conduit of plug-like character consisting of lava and other volcanic products, which has been exposed by erosion. (A.W.L., R.M.F.)

NECROPSY. An autopsy examination of the body to discover or verify the cause of death, and to study the pathology of disease. (D.M.H.)

NECROSIS. The local death of cells results in changes in the tissue known as necrosis. These consist of disintegration of the cellular structure with destruction of the nucleus and coagulation or liquefaction of the cytoplasm (see cell). The causes of necrosis include inter-

ference with the blood supply of a tissue (see **gangrene**), physical injury, and deleterious actions by bacteria or their toxins. (D.M.H.)

NECTARY. Flower.

NECTOCALYX. A modified **medusa** occurring in coelenterates of the order **Siphonophora. Hydrozoa.** (A.W.L.)

NECTONEMATOIDEA. Nematomorpha.

NEEDLE BEAM. Underpinning.

NEEDLE BEARING. Bearings.

NEEDLING. Underpinning.

NEGATIVE FEEDBACK. Feedback.

NEGRO BUG. Insecta, Hemiptera. Small shining black **bugs** with a smooth convex upper surface. They resemble beetles superficially. Most of the abdomen is covered by a greatly enlarged sclerite of the thorax which also conceals most of the wings. (A.W.L.)

NEKTON. The portion of a population made up of animals which are capable of directive locomotion through a fluid medium. Usually applied only to aquatic animals, including the fishes, although flying creatures constitute a similar part of the terrestrial fauna and may be called an aerial nekton. (See also **Plankton** and **Invertebrate Paleontology.**) (A.W.L.)

NEMATHELMINTHES. The roundworms, a major division of the animal kingdom containing both free-living and parasitic species, many living in the human body. The most widely known species are the intestinal worms of man and the domestic animals, the hookworms, the spiny-headed worms, and the horsehair worms.

The phylum is characterized as follows: 1. The body is not segmented and is usually cylindrical, tapering at the ends. 2. The ectodermal covering is noncellular and secretes an elastic cuticle. 3. The body wall includes an inner layer of muscle cells divided into contractile and noncontractile parts. 4. The alimentary tract is a slender tube. In some species it is tubular for only part of its length and in some it is completely lacking. 5. The excretory system consists of two lateral tubes. 6. The nervous system includes a ring around the esophagus and longitudinal cords extending through the body. A dorsal and a ventral cord are the chief nerve tracts. 7. The space between the body wall and the gut is filled with large cells containing many **vacuoles** which join extensively and form an apparent body cavity.

The phylum is divided into three classes which differ enough to be segregated by some biologists:

Class **Nematoda.** Without a spiny proboscis. Intestine present. The typical roundworms. The **hookworms, eelworm,** and **Guinea worm** are among the species parasitic in man. Some species attack plants and some live in earth or water.

Class **Nematomorpha** (Gordiacea). The **hairworms** or horsehair worms. No spiny proboscis. Body cavity lined with epithelium. Alimentary tract present. Adults free in water, larvae parasitic in insects or crustaceans.

Class **Acanthocephala.** With a spiny proboscis. No gut. Parasitic in the intestine of vertebrates. (A.W.L.)

NEMATOBLAST. A term proposed by Becke, in 1903, for pseudo-**porphyritic** minerals of fibrous habit developed in **metamorphic** rocks. (R.M.F.)

NEMATOCYST. A structure discharged by the stinging cells of coelenterates (**cnidoblast**). It consists of a flask-shaped body bearing barbs and a long slender filament. (A.W.L.)

NEMATODA. The threadworms. A class of the phylum **Nemathelminthes** containing worms of many habits, some parasitic in man and the domestic animals. The body lacks a spiny proboscis and is marked by slender longitudinal lines along the sides. These lateral lines follow the excretory tubes.

Two orders are recognized:

Order Hologonia. Genital tract an unbranched tube. Both large and small species, parasitic in man and domestic animals. Trichinella (**Trichina**), a serious parasite sometimes taken into the human body in insufficiently cooked pork, is a member of the order.

Order Telogonia. Genital tract of female with two or more branches. Most nematodes belong in this order, including free-living, plant-feeding, and parasitic forms. The **Guinea worm, eelworm,** and **hookworm** belong here. (A.W.L.)

NEMATOMORPHA. The **hairworms** or **horsehair worms,** a class of the phylum Nemathelminthes. These worms receive their popular name from the old belief that horsehairs soaked in water turn into them. Their abrupt appearance in watering troughs and small pools is, in fact, due to their living in the bodies of insects and crustaceans as larvae and emerging when they take on the adult form to live in the water.

They differ from the true **nematodes** in the absence of lateral lines and in the presence during adult life of a limited body cavity lined with epithelium. In appearance they are very long and slender, bluntly rounded at the anterior end and blunt or forked at the posterior end.

They have also been called Gordian worms from their occasional massing in tangled clusters reminiscent of the famous Gordian knot.

The class includes two orders:

Order Gordioidea. Fresh-water and terrestrial species.
Order Nectonematoidea. Marine species only. (A.W.L.)

NEMERTEA. Marine worms with a flattened body, often long and ribbonlike in form. They are unsegmented and have no body cavity, hence they are sometimes included with the flatworms as a class of the phylum **Platyhelminthes.** More often they are made a separate phylum because the alimentary tract is a tube opening with an anterior mouth and a posterior anus. Like the free-living flatworms, they have ciliated (**cilia**) integument. They are also provided with an eversible proboscis associated with but not derived from the alimentary tract. No common name is available save nemertean or nemertine worms.

These worms live among seaweed or at the bottom of the ocean and prey on living animals or eat dead ones. They are not economically important. A few fresh-water species and a few parasitic forms are known.

The phylum is divided into four orders:

Order Paleonemertea. Long and slender. Mouth behind brain. Outer muscles of body wall circular. Marine species.

Order Heteronemertea. Long and slender. Mouth behind brain. Outer muscles of body wall longitudinal. Marine.

Order Hoplonemertea. Either long and slender or short and thick. Mouth in front of brain. Marine, fresh-water, terrestrial, and parasitic species, the last living on crabs.

Order Bdellonemertea. Short, flat, and broad, with a sucker at the posterior end. Three species which

live in the gill chamber of marine and fresh-water mollusks. (A.W.L.)

NEODYMIUM. Symbol: Nd. Atomic number: 60. Atomic weight: 144.27. Density: 6.96. Melting point: 840° C. (**Isotopes**: page 290.) Type of compound: Nd_2O_3, blue. Color of salts: rose-red. Discovered by Welsbach in 1885. A member of the **cerium** sub-group of the rare earth metals. (R.K.S.)

NEOLITHIC. **Paleontology of Man.**

NEON. Symbol: Ne. Atomic number: 10. Atomic weight: 20.183. Density: 0.9004 gram per liter, 0° C., 760 mm., or 0.696 when air equals 1.000. Melting point: −248.7° C. Boiing point: −245.9° C. Isotopes: 20 (90.0%), 21 (0.27%), 22 (9.73%), have been separated by **diffusion**; identified and quantitatively estimated by the mass **spectrograph.**

Neon is a colorless, odorless gas, of negative chemical properties with ordinary materials. Discovered by Ramsay and Travers in 1898.

Neon is present in ordinary **air** to the extent of 1 part neon in about 65,000 air. In a vacuum electric discharge tube neon shows a crimson glow, and is widely used in advertising illumination. One of the early elements to be discovered having the property of **isotopism.** (R.K.S.)

NEOPITHECUS. **Paleontology of Man.**

NEOPLASM. Any new or abnormal overgrowth of cellular tissue. A neoplasm is a cellular **tumor** and may be either benign or malignant. (R.S.M.)

NEOPRENE. The generic name for synthetic rubber made by the polymerization of 2-chloro-1,3-butadiene, which is itself made by the action of hydrogen chloride on monovinylacetylene. Vulcanized neoprenes are outstanding in their resistance to oils, greases, many chemicals, as well as to heat, sunlight, and ozone. (R.K.S.)

NEOSALVARSAN. **Arsphenamine.**

NEOTENY. The retention of characteristics of immature stages during adult life. Neoteny and **paedogenesis** are difficult to distinguish in some cases. The latter is the attainment of sexual maturity by structurally immature animals. Both are illustrated by distinct cases among the insects, where immature and adult life are marked by distinct stages. The **larvae** of some **gall gnats** produce young, sometimes for a series of several generations, but the fact that some individuals become winged adults marks the condition as paedogenesis. On the other hand, the females of some **beetles** (Phengodidae), when they have attained the stage corresponding to the winged adult males, still retain the form of the larva and are called glow worms. This is a distinct case of the persistence of larval characters in adult life, or neoteny. Among the vertebrates the phenomenon of neoteny has been most extensively studied in the **axolotl.** (A.W.L.)

NEOTYPE. A specimen selected to represent the type when the type has been lost. (R.M.F.)

NEOZOIC. In historical geology the time from the end of the Mesozoic to the present. (Compare with **Cenozoic.**) (R.M.F.)

NEPENTHES. **Insectivorous Plants.**

NEPHELINITE. A dense, sometimes **porphyritic** rock made up almost wholly of **nephelite** and **augite.** If olivine is present the rock is then classified as a nephelite **basalt.** (E.S.C.S.)

NEPHELITE-SYENITE. A coarse crystalline **igneous rock** composed chiefly of alkali-**feldspars, nepheline**, and **femic** minerals, such as the soda-**pyroxenes** and **amphiboles.** Accessory minerals are other soda-**feldspathoids, zircon, apatite**, and **sphene.** Nepheline syenites occur in Canada in the provinces of Quebec, Ontario, and British Columbia. The principal foreign localities are Norway, Greenland, Sweden, the Ural Mountains, the Pyrenees, Italy, Brazil, China, and the Transvaal region. (R.M.F.)

NEPHOSCOPE. **Meteorological Instruments.**

NEPHRIDIUM. The excretory tubule in **annelid** worms. It consists typically of a convoluted tubule with a ciliated (**cilia**) opening called the nephrostome at the inner end, communicating with the body cavity. At the outer end it empties by a minute pore on the surface of the body. True nephridia are associated with the **coelomoducts** in the excretory systems of annelids. (A.W.L.)

NEPHRITIS, BRIGHT'S DISEASE. Inflammation or injury to the **kidney**, involving in varying degrees the cellular, intercellular, and blood-vessel tissue of the kidney. The term does not include the pus-producing infections which may involve the kidney.

Nephritis was first accurately described by Richard Bright in 1836. The term now covers a variety of disease states of unknown etiology which may be acute or chronic, all of which are characterized by the presence in the urine of **albumin** (albuminuria) and at times blood, cells and casts. **Edema, hypertension** and **uremia** are also characteristic features. The main types of nephritis are (1) glomerulonephritis, acute or chronic, (2) arteriolar nephrosclerosis, (3) nephrosis, (4) miscellaneous nephritides.

Acute glomerulonephritis, like **rheumatic fever**, seems definitely to be related to infection of the upper respiratory tract with hemolytic streptococci. The exact mode of pathogenesis is not understood, but it is a well-recognized fact that virtually all cases of the disease follow **streptococcus tonsillitis, pharyngitis**, or **sinusitis**, etc. At times the respiratory infection may be so mild as to pass unnoticed, but immunological techniques will establish the recent presence of such infection. Predisposing factors are largely dependent upon conditions conducive to spread of respiratory infections.

Acute glomerulonephritis usually begins with hematuria (blood in the urine), headache, puffiness about the face, and decreased urinary output. The urine contains albumin, red blood cells, and casts of the kidney tubules. Transient elevation of the blood pressure is characteristic. In the severe or fulminating variety, fever, generalized edema, marked hypertension, visual disturbances, varying degrees of uremia, nausea, vomiting, delirium, convulsions, coma and death may ensue. Commonly, one or more features, such as edema and backache, dominate the picture, and the course is relatively mild. There is no specific treatment: bed rest and restriction of sodium chloride in the diet to control the edema are the most important measures. The use of sulfonamides has not yet been clearly evaluated. The prognosis in acute cases is good, the immediate mortality being 4%. Most patients recover completely, but a few go on to latent or chronic disease.

Chronic glomerulonephritis does not have such a clear-cut relation to hemolytic streptococci as the acute form, and its etiology is even more obscure. The onset is usually gradual, with weakness, lassitude, edema, headache and hypertension. The urine is of low specific gravity, contains albumin, casts, but few or no red cells. **Anemia** is a common finding. The disease usually runs a long course over a period of years, with variations in signs and symptoms. At times, edema may be massive

Eventually death occurs from hypertension and **heart failure,** or kidney failure and uremia. The treatment of the various stages is symptomatic, and guided by the symptoms present. Bed rest, salt restriction, **transfusions, digitalis,** etc., may be indicated.

The **pathology** of glomerulonephritis is characterized by various degrees of inflammatory and degenerative change in the glomeruli, the blood vessels, and the interstitial tissue of the kidney. In the acute form, edema, infiltration with inflammatory cells, and small areas of hemorrhage appear. In the chronic form the picture is one of scarring and obliteration of the glomeruli, with destruction of the majority of functional units.

Arteriolar nephrosclerosis is the renal lesion occurring as part of the picture of hypertensive cardiovascular disease. About 10% of patients with this disease die of kidney failure and uremia. The clinical picture is the same as with chronic glomerulonephritis with emphasis on the hypertensive feature, but the kidneys at autopsy show characteristic vascular lesions. The arterioles, or small arteries, have markedly thickened walls with necrotic inflammatory changes. The glomeruli and tubules show varying degrees of degeneration and obliteration and there is fibrosis of the interstitial tissue. Sometimes, however, the pathological picture is indistinguishable from that of chronic glomerulonephritis.

Nephrosis is a term used to describe the edematous stage of chronic glomerulonephritis, and to describe a distinct disease, separate from glomerulonephritis. This latter, or true lipoid nephrosis, occurs as a chronic disease of children, characterized by massive edema and albuminuria without hypertension or hematuria. Pathologically it is primarily a disease of the kidney tubules. The clinical course is over a period of weeks up to several years, but the patient eventually recovers and remains well. Death from nephrosis is rare, and when it occurs is commonly due, for no apparent reason, to pneumococcus **peritonitis.** Therapy consists of a high protein diet, salt restriction, and **diuretic** drugs.

Miscellaneous nephritides comprise a diverse group including transfusion nephritis, which follows **transfusion** with incompatible blood; syphilitic nephritis, a rare manifestation of tertiary **syphilis;** focal nephritis occurring in the course of an infection when bacterial emboli lodge in the kidneys; and arteriosclerotic nephritis, a mild disease due to sclerosis of the large kidney vessels. (D.M.H.)

NEPHROMIXIUM. An excretory organ of segmented worms formed of the united **nephridia** and **coelomoducts.** (A.W.L.)

NEPHROSTOME. The ciliated (**cilia**) opening of the excretory tubules of segmented worms and vertebrates which communicates with the **coelom.** It is characteristic of the primitive form of tubule in both groups but is lacking in many species. The connection with the body cavity is then supplanted by an association of the excretory organs with the **circulatory system.** (A.W.L.)

NEPTUNE. (See tables of planetary data, page 1109). Possibly the most interesting feature of the **planet** Neptune is the circumstance which led to its discovery. After Uranus was discovered an orbit was computed, and, by reckoning backwards, it was found that the planet had been observed as a star on several occasions many years previous to its announcement as a planet. The **orbital** elements computed from the observations made shortly after the discovery did not satisfy the old observations accurately, and, what was worse, the planet soon began to deviate from the computed path. Even the introduction of **perturbations** by all of the then-known planets failed to completely remove the deviations, and after a prodigious amount of computing, Leverrier, a young French astronomer, and Adams, an Englishman, both predicted that a new planet would be found in the **constellation of Aquarius.** Search was made in this vicinity by the German astronomer Galle on the basis of Leverrier's prediction, and by Challis at Cambridge, England, using Adams' prediction. Challis observed the new planet first, but failed to recognize it until after Galle had announced the discovery on September 23, 1846. The discovery of Neptune can safely be regarded as one of the greatest successes of the Newtonian gravitational theory and the methods of orbit computation.

Neptune itself is a planet slightly less than 4 times the diameter of the earth, and a mass slightly greater than 17 times that of the earth. Its mean density is only 0.29 times that of the earth, and this low value, coupled with the high value of the **albedo** (0.52), indicates that the planet probably has a thick layer of atmosphere.

Neptune is invisible to the naked eye, having a stellar **magnitude** of about 7.7, but can be readily observed in any telescope with aperture greater than 1". In small instruments it can only be distinguished from the stars by observing the change in position from night to night, but with larger instruments it appears as a small greenish disk. Observations indicate that the disk is apparently circular and that there are no distinguishable surface markings. Hence, telescopic observations tell nothing regarding the rotation period. In 1928 Moore and Menzel, at the Lick Observatory, found from spectroscopic observations, employing the **Doppler** principle, that the planet has a rotation period of slightly less than 16 hours, and that the planet is rotating in the same directional sense as the majority of the other members of the solar system.

Neptune has one **satellite,** discovered by Lassell very shortly after the discovery of the planet. Telescopically the object is very faint and can only be observed with large instruments. From the brightness it is estimated that the satellite is similar to our own **moon** in size. The orbit of the satellite is inclined at about 20° to the plane of the planet's equator and the satellite revolves about the planet in the direction opposite to that of the majority of the members of the solar system. (W.K.G.)

NEPTUNIUM. Chemical Composition, I. Elements.

NERNST EFFECT. If heat is flowing through a strip of metal and the strip is placed in a magnetic field perpendicular to its plane, a difference of electric potential develops between the opposite edges. This phenomenon, discovered by Nernst in 1886, is analogous to the **Hall effect,** but with a longitudinal flow of heat replacing the longitudinal electric current. If, to one looking along the strip in the direction of the heat flow, and with the magnetic field directed downward, the transverse potential drop is toward the right, the Nernst effect is said to be positive. (But Nernst at first used the opposite convention) Bismuth, in which the phenomenon was first observed, shows the positive effect, iron the negative. (See also **Ettingshausen** and **Righi-Leduc effects.**) (L.D.W.)

NERNST HEAT THEOREM. Entropy.

NEROLI OIL. Volatile Oils.

NERVE. A slender cord made up of nerve fibers (**neuron**). In the **vertebrates** the nerve is surrounded by loose connective tissue called the epineurium. Each small bundle of fibers within the epineurium is surrounded by a thin compact perineurium, and from this layer thin septa, the endoneurium, run between the irregular groups of fibers within the bundle.

Nerves form **the** communicating paths between the **central nervous system** and the various parts of the

body, as well as the connections between ganglia. They have been given special names according to their anatomical distribution, and a few functional properties have been indicated by descriptive terms. Thus sensory or afferent nerves carry impulses from sense organs to the central nervous system and motor or efferent nerves lead out to muscles and other effectors. Most nerves of the body contain fibers of each kind and so are mixed nerves. Nerves arising from the brain in the vertebrates are called cranial nerves and those connected with the spinal cord are spinal nerves. Typically all of these main nerves of the vertebrate are supposed to be based on the form of the spinal nerves, which connect with the cord by two roots. The dorsal root bears a spinal ganglion and carries all the sensory fibers and the ventral root lacks a ganglion and is motor. All sensory nerves bear a ganglion or arise from a sensory layer such as the retina of the eye and no purely motor nerves have ganglia.

The motor components of these nerves grow out from cells in the central nervous system and the sensory components grow into the central system from ganglia or from sensory cells and also out from the ganglia toward the periphery of the body. (A.W.L.)

NERVE IMPULSE. A progressive transfer of a condition of excitation along a **nerve** fiber, initiated by a stimulus acting upon a sensory organ, by a cell within the nervous system, or experimentally by direct stimulation of the nerve fiber.

The nerve impulse involves measurable chemical changes and energy consumption accompanied by changes in electrical potential associated with membrane depolarization. The electrical changes have been extensively used in the investigation of nerve physiology and of the brain. The passage of the nerve impulse over the synapse is accompanied by the action of acetylcholine in cases which have been studied, while terminal nerve fibers may form either acetylcholine or sympathin, the latter being closely related to adrenalin.

The impulse activates some organ of the body or enters the nervous system, where it is relayed to other parts. (A.W.L.)

NERVOUS COORDINATION. The attainment of harmonious action of all component parts of the animal and the adjustment of its behavior to environmental conditions by communication and regulation through the **nervous system.** All coordinative processes are of this type or of the type carried on by the secretion and distribution of **hormones.** Nervous coordination has the advantage of rapidity, since the **nerve impulse** travels much more rapidly than materials can be transported. It is responsible for the immediate adjustment of the animal to fluctuating conditions, while chemical coordination is extensively involved in the maintenance of the normal organic processes which are a more uniform part of the animal's activity. Coordination in general is, however, due to close interaction of the two types; neither is wholly independent of the other.

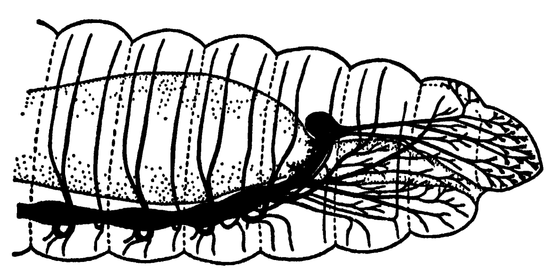
The process of coordination through the nervous system is based on the general sensitiveness of **protoplasm** known as irritability and on the property of conductivity by which some result of stimulation passes rapidly through the adjacent substance. All living **cells** are irritable to some extent. They respond to some stimulus with characteristic activity. Sensory organs possess this property to a high degree and in addition are specialized to receive a certain kind of stimulus. **Nervous tissue** is specialized for ready activation and for the rapid conduction of the impulse generated within it.

The organs which receive stimuli as a special function for the benefit of the animal, whether relatively simple cells or extremely complex organs like the human **eye,** are known as receptors. They have special nerve endings, often associated with other structures, and are connected by afferent or sensory nerves with other parts of the nervous system or, in very simple animals, with some organ capable of acting in response to the condition from which the stimulus arose. Organs of the latter category are muscles, glands, electric organs, light organs, and some pigment cells, and are known collectively as effectors. Usually one or more cells of the nervous system intervene between the sensory cell associated with the receptor and the motor cell which communicates directly with the effector. The more complex this nervous chain, the more intricately may nerve impulses be relayed through different paths in the body, but in all cases the net result is the same. All adjustments are due to the reception of stimuli by sense organs, both internal and external, followed by appropriate reaction of other parts of the body. (A.W.L.)

NERVOUS SYSTEM. An organic system specialized for the ready reception of stimuli and the rapid transmission of a resulting change in its substance called the **nerve impulse** to other parts of the body. The function of the nervous system is the regulation and coordination of the various parts of the body known as **nervous coordination.**

All animals except **protozoans** and **sponges** have a nervous system derived from the ectoderm. In the **coelenterates** it consists of scattered cells associated in a network which extends through the body without marked centralization. In the flatworms the network persists, but in it nerve cells are massed near the anterior end of the body to form a cerebral ganglion or **brain,** and definite longitudinal paths can be traced from this center back through the body. This centralization is associated with the change from radial to bilateral **symmetry** and persists in all bilaterally symmetrical animals. With the attainment of radial symmetry by the echinoderms it is again lost. The departure from the nerve net is marked by the attainment of synaptic organization. In the nerve net impulses pass in either direction over nerve fibers and in the synaptic system they pass over the synapse in only one direction. The ends of the fibers of different cells are closely associated in the **synapse** through which the impulse in one fiber acts as a stimulus to the others.

In all of the more complex nervous systems a major center, the **brain,** is present as a part of the central

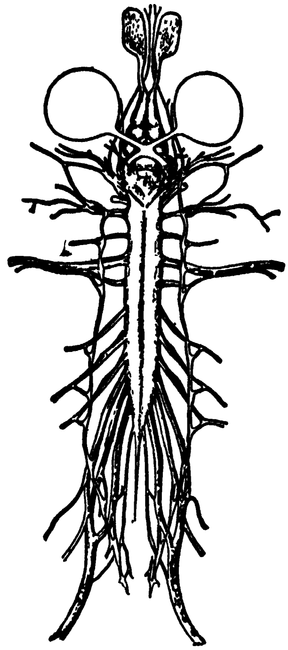


Nervous system of the earthworm. Drawing showing a lateral view of the arrangement of the larger nerve trunks in the left half of the anterior segments of the earthworm.

nervous system, and supplementary centers called ganglia, each containing a small number of nerve cells, are scattered through the outlying parts of the system. All of these parts are connected by nerve cords or **nerves** and are joined in the same way with other structures of the body.

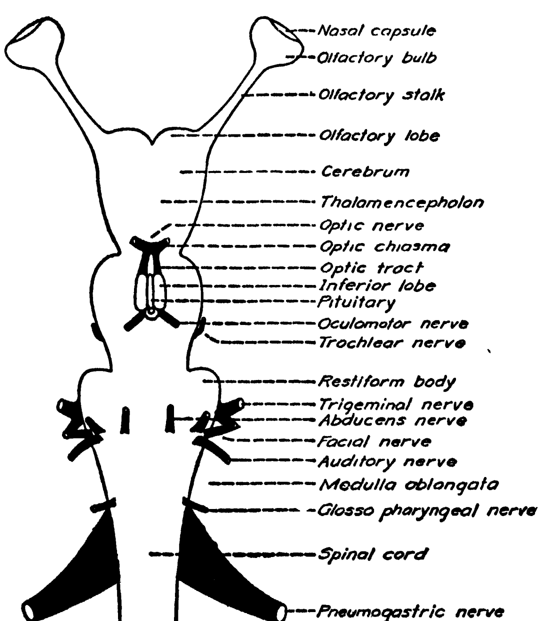
The most common type of nervous system among invertebrates consists of a small brain lying above the alimentary tract near the anterior end of the body. It is connected by cords passing down around the sides of the gut with a ventral nerve cord. In the **annelid** worms this cord is a chain of ganglia, one lying in each segment. Conclusive evidence from **embryology** and minute anatomy shows that the primitive cord was a

paired structure and that each segment contained a pair of ganglia connected by transverse nerves as well. In most existent species the adult shows no visible evidence of the paired condition.



Ventral view of the nervous system of frog. (*After Woodruff. Foundations of Biology, from Ecker, The Macmillan Co.*)

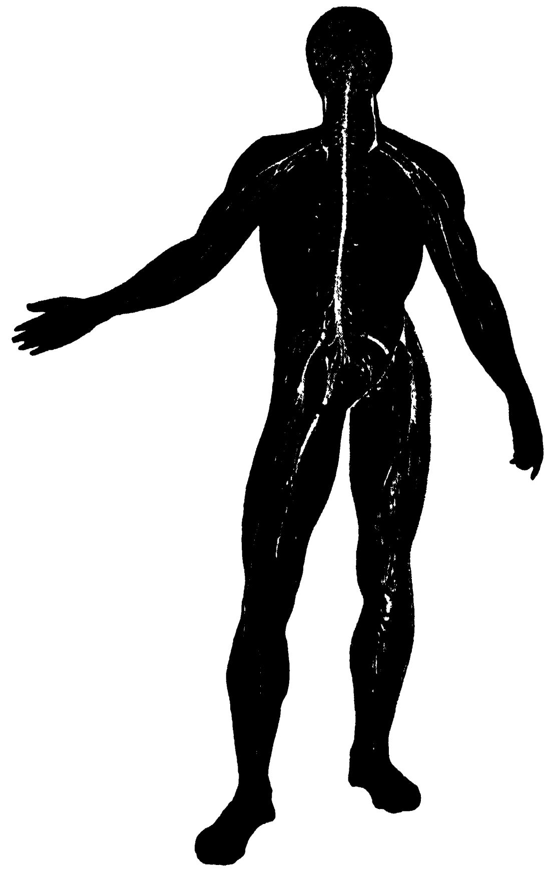
In the **arthropods** a concentration of ganglia in some species has resulted in one large ganglionic mass near the **anterior** end of the ventral cord.



Ventral view of dogfish brain, showing cerebral nerves. (*Drawn by W. J. Moore.*)

Many **mollusks** have a number of pairs of ganglia of about equal size as nerve centers, although the cephalopods have a concentrated brain equal to any other invertebrates.

In the **vertebrates** the entire central nervous system lies above the alimentary tract. The brain is large and complex in most classes. From it a **spinal cord** runs back along the axis of the body. Both brain and spinal cord bear nerves which extend throughout the animal.



Nervous system of man.

Below the spinal cord two chains of ganglia connected by slender nerves with each other and with the spinal nerves constitute the sympathetic chains of the autonomic nervous system. Nerves of this system supply the viscera and are widely distributed elsewhere in the body. In cooperation with the parasympathetic fibers of the cranial and sacral nerves, they control the functions which cannot be deliberately regulated by individual desire, such as the movements of the alimentary tract. (A.W.L.)

NERVOUS TISSUE. Nervous tissue proper is composed of cells specialized to a high degree in the properties of irritability and conductivity. These cells are called **neurons.** With the exception of a portion of the nervous system of echinoderms which is said to be mesodermal, all nervous tissue originates from the ectoderm. More complex nervous systems such as those of the vertebrates also contain a supporting tissue called **neuroglia,** chiefly from the same source.

The bodies of nerve cells in most animals are concentrated in the central nervous system and in ganglia, while **nerves** are composed wholly of fibers and accessory sheaths. Even in the central system the tissue is not uniform, for some parts are fiber tracts and others are **nuclei** containing cell bodies or more extensive cellular layers like the cerebral cortex. Various regions, moreover, contain cells of special forms. Cells of the cortex, for example, include several forms with rounded

to pyramidal bodies and a moderate number of processes, while in the cerebellum (**brain**) one form of cell is small, giving the tissue a granular appearance, and another, known as a Purkinje cell, bears a single process at one pole and numerous branching processes of mossy appearance at the other. In ganglia, too, the cells have characteristic forms. All nervous tissue, however, is composed of no more than the two components, neurons and neuroglia. (A.W.L.)

NEST. A place chosen or a structure built by an animal for shelter or concealment, usually for the reception of the eggs or young and as a home for the young during their early development.

The nest may be no more than a favorable spot on the ground or on the bottom of a body of water. Such spots are sometimes modified slightly, as in the shifting of stones by fishes preparatory to depositing their eggs, or they may be used as found. In other cases animals seek a more elaborate home such as a cave or a hollow in a tree, and often the retreat sought has already been prepared and used by another animal. Birds illustrate all of these habits. Not only do they deposit their eggs on the bare ground or in burrows, hollows, and nests prepared by other species, but also construct some of the most elaborate nests known. Most species build a characteristic nest of sticks, fibers, or some other material. Some are expert weavers and others merely pile their materials together. The use of a salivary secretion by some of the swifts in the construction of their nests is widely known from the use of the nests in the Orient as an article of food.

Many insects also build nests for the rearing of their young, and here, too, the nest may be only a burrow or a crevice, or it may be an elaborate structure such as the paper or mud nest of a wasp and the waxen combs of the honey-bee. (A.W.L.)

NET SECTION. **Tension Member.**

NETTLE. **Mint Family.**

NETTLE CELL. **Nematocyst.**

NETTLE HAIR. A form of hair-like scale found on some **caterpillars** which causes an irritation of human skin resembling that of nettles. Caterpillars of the Io and the brown-tail moths have larger poisonous spines of similar properties. The irritation caused by some species is very mild but others are much more severe. (A.W.L.)

NETWORKS. **Kirchhoff's Laws.**

NEUMANN BANDS. Mechanically formed **twin bands** of microscopic dimensions in iron or steel, believed to be formed by spontaneous reorientation of a portion of a crystal when subjected to sudden deformation or impact. (R.H.H.)

NEURAL CREST. A strip of tissue formed from the ectoderm between the outer layer of the **neural fold** and the **neural tube**. The two strips later fuse and then separate and divide into longitudinal series of masses, metamerically arranged, from which are formed the ganglia of the dorsal roots of the spinal **nerves**, the sympathetic ganglia, nerve sheath cells, pigment cells of the skin, and a part of the mesenchyme. (A.W.L.)

NEURAL FOLD. A longitudinal fold of tissue in the vertebrate embryo which contributes to the formation of the **neural tube**. A pair of these folds arises along the dorsal surface, flanking the median line, very early in development. (A.W.L.)

NEURAL TUBE. The embryonic structure from which the entire central **nervous system** of the **vertebrates** and much of the peripheral system are developed.

Early in embryonic life the ectoderm thickens along the upper surface of the body in the middle line. On each side of this thickened strip the tissue rises in folds which finally approach each other and fuse, leaving the median strip in the form of a tube, now lying inside the body. The further differentiation of the tube produces the central nervous system of the adult and the growth of other structures from it is the source of the motor nerve roots. (A.W.L.)

NEURALGIA. Pain in a **nerve** or along the course of a nerve. It is difficult to differentiate sharply between neuralgia and neuritis. But, if there is a distinction, the term neuritis should be confined to acute and chronic inflammation of the peripheral nerves, while neuralgia is due to acute and chronic inflammation of the pathway stations (ganglia) lying along the course of nervous pathways. The pain in neuralgia is usually of a sharp, shooting, intermittent type and accompanied by increased sensitivity of the skin supplied by the nerve. Many varieties of neuralgia are differentiated according to the part affected. Some of the common forms are: 1. Trigeminal neuralgia, a very severe form marked by agonizing pain over branches of the trigeminal nerve in the face. Palliative relief is obtained by injections of alcohol into the ganglion of the nerve and permanent and instantaneous relief by cutting the sensory root of the nerve. 2. Intercostal neuralgia—may be mistaken for **pleurisy** as the intercostal nerves, after leaving the spinal cord, run around each side of the chest between the ribs. It is accompanied by a skin eruption in **herpes zoster** or shingles. 3. Morton's neuralgia—pain in the joint of the third and fourth toe caused by pinching of a nerve in this region. 4. Sciatic neuralgia. (See **Sciatica.**) (R.S.M.)

NEURASTHENIA. **Psychoneurosis.**

NEURITIS. An inflammation of a **nerve**, either chronic or acute. Mononeuritis or localized neuritis is the term used when one nerve is involved. When several or many nerves are involved the term multiple neuritis or polyneuritis is used. Localized neuritis develops from injury, infection, chronic intoxication, or metal poisoning. Neuritis, either localized or multiple, complicates many of the infectious diseases, such as **typhoid, diphtheria, tuberculosis, smallpox,** etc. Other causes include pressure on a nerve by a **tumor** or calcium deposits in **osteo-arthritis**, etc.

Multiple or polyneuritis is inflammation and degeneration affecting the peripheral nerves, usually in their distal portions. The commonest cause is dietary deficiency, primarily of **vitamin** B_1 (thiamine) which is usually associated with chronic alcoholism; other causes are various toxins, either chemical agents such as arsenical drugs, lead, nitrobenzol, coal-tar products, or toxins produced by bacteria.

The clinical picture is similar no matter what the cause: there is a gradual onset of numbness and tingling of the hands and feet, weakness of the limbs, altered sensation to touch, and pain, loss of deep reflexes, and eventually paralysis and atrophy of the extremities. Treatment is directed first toward removal of the cause If the disease is due to vitamin B deficiency, large doses of thiamine as well as other members of the B complex are effective. (D.M.H.)

NEUROGLIA. Supporting **cells** of the central **nervous system** derived, with the possible exception of microglia, like the nervous tissue from the ectoderm. The cells are of various forms. A common form in the vertebrate nervous system is the astrocyte, which has many fine processes radiating in all directions from the

cell body. In some astrocytes the processes are fibrous. They form a network among the nerve cells and fibers. (A.W.L.)

NEURON. A **nerve** cell with all of its processes. The processes include the dendrites which carry impulses to the **cell** body and the axon which carries an impulse from the cell body to some other nerve cell or to an organ such as a muscle. At the end the processes branch. This part of the axon is called the terminal arborization. The axon may also bear branches nearer to the cell body, called collaterals.

Many nerve fibers in the central system and in peripheral nerves are surrounded by a sheath consisting of a fatty material called myelin, and in the nerves a cellular neurolemma or sheath of Schwann invests the whole. The latter sheath ends before the terminal arborization, and the myelin some distance before that. (A.W.L.)

NEUROPODIUM. The ventral part of the **pseudopodium** of segmented worms. (A.W.L.)

NEUROPTERA. **Insects** of varied form and habits, including the **dobson fly,** the golden eyes or **lacewings,** the **alder flies,** and the **ant lions.** The order is characterized by the four membranous wings, usually with a large number of branching veins which are united in some species to form a network. The mouth is formed for biting but in some larvae the **mandibles** and **maxillae** fit together to form a piercing and sucking organ. The insects are predacious.

Neuroptera are of little economic importance save as food for fishes. The larvae of lacewings prey on **aphids,** hence they are of some assistance in holding these pests in check.

The order contains about 1200 species. (A.W.L.)

NEUROPTERIS. **Paleobotany.**

NEUROSIS. **Psychoneurosis.**

NEUROSYPHILIS. **Syphilis** involving principally the central nervous system. The common forms are locomotor **ataxia,** syphilis of the spinal cord, paresis, syphilis of the brain and meningo-vascular syphilis. Neurosyphilis is one of the late stages of untreated syphilis occurring many years after the primary infection. (R.S.M.)

NEUTRAL AXIS. The line of intersection of the **neutral plane** and any normal cross-section of a structural member is called the neutral axis. When a straight bar of homogeneous material (rectangular for sake of illustration) is bent the fibers which are nearer the axis of flexure will shorten and those on the opposite side will lengthen. There is one plane within the bar, parallel to its edges, in which there is no **deformation** of the fibers; this plane is known as the neutral surface. The **flexure** theory shows that the neutral axis passes through the center of gravity of the cross-sectional area of any member subject to transverse bending only. (C.W.C.)

NEUTRAL SURFACE. **Neutral Axis.**

NEUTRAL WIRE. **Three-Wire System.**

NEUTRALIZATION. In certain vacuum-tube **amplifier** circuits energy may be fed back from the plate to the grid circuit through the **interelectrode capacity** and thus cause undesirable oscillations. The introduction of the screen grid in the **tube** is one means of preventing this feedback. Another widely used remedy is to balance out the **feedback** with externally produced opposite feedback. This is called neutralization. When the energy for neutralization is fed from the plate to the grid circuit it is known as plate neutralization, while if the feedback energy is obtained from the grid and fed to the plate circuit it is plate neutralization. Both are widely used for radio-frequency amplifiers. Neutralization is not ordinarily needed in audio circuits because of the lesser effect of feedback at the lower frequencies. (See also **Acid; Bases;** and **Salts.**) (L.R.Q.)

NEUTRINO. Certain radioactive changes result in a distribution of energy among the particles involved, apparently in conflict with the laws of conservation of energy as well as of momentum; unless it be assumed that some particle, as yet not directly observed, partakes in the process in such a way as to carry off the missing energy and fill out the apparently unbalanced momentum. Since the hypothetical particle is not retained within the walls of any ordinary container, it must have great penetrating power and is therefore presumably neutral. Once called the "neutret," it is now commonly designated as the neutrino. Pending further experimental evidence, all assumptions regarding the properties of the neutrino, if it exists, must be regarded as tentative. (See also **Nuclear Particles.**) (L.D.W.)

NEUTRON. In the course of experiments on the "atom-smashing" effects of alpha rays from thorium upon substances containing the lighter atoms, such as hydrogen, beryllium, and carbon, early experimenters detected a secondary emission of extraordinary penetrating power which, however, produced no visible tracks in a **cloud chamber,** though it could be detected by a Geiger **counting tube.** Naturally, this was interpreted as evidence of a very hard **gamma** ray arising from artificial disintegration of the light atom. But when these secondary rays were sent through a cloud chamber, there would sometimes appear a single cloud track originating mysteriously in mid-air and proceeding with every evidence of great speed and energy. Now, gamma rays and other photons not only do not produce cloud tracks themselves, but, since their mass is vanishingly small, their collisions with atomic particles cannot give the latter any considerable "recoil" momentum. (See **Compton Effect.**) Thus physicists were confronted with the dilemma of conceding an exception to the conservation laws of energy and momentum in the case of photon collision, or of recognizing the existence of a new **nuclear particle** having curious properties.

It was Chadwick who, in 1932, first showed that the second of these alternatives would meet all the known facts, provided it be assumed that the new particle is in the nature of a **proton** bereft of its positive charge and therefore electrically neutral. This particle, whose reality is now universally admitted, is the neutron. Having protonic mass, it readily imparts momentum to other particles upon collision; while the fact that it is neutral enables it to pass through the open structure of atoms without interference except on the rare occasion of an actual mechanical collision with an electron or a nucleus. The one property accounts for the effect observed in the cloud chamber, the other for the ability of neutron rays to penetrate even several cm. of lead without marked absorption. Subsequent research has shown that the neutron is not a neutral proton, but has a mass about 1% greater, and a magnetic moment differing both in magnitude and in sign, from that of the proton. It is now believed that the nucleus of **deuterium** or "heavy hydrogen," called the deuteron, is composed of one proton and one neutron. (L.D.W.)

NÉVÉ. **Glacier.**

NEWARK SERIES. This is a geological term, discussed under **Triassic.**

NEWT. Amphibia, Urodela. Air-breathing **salamanders** which are at least partially aquatic in habits. The many species are found chiefly in the northern hemisphere. (A.W.L.)

NEWTON. The m.k.s. absolute unit of force; viz., that force which, if applied to a free body having a mass of 1 kilogram, would give it an acceleration of 1 meter per sec. per sec. It is equal to 100,000 **dynes**, and approximately equal to 0.102 of the weight of 1 kilogram mass under standard gravity or to about 3.6 ounces of force. The joule, m.k.s. unit of work or energy, is equal to 1 meter-newton. The newton is named for Sir Isaac Newton, whose second dynamic law is the basis of the absolute measure of force. (See **M.K.S. System; Newton's Laws of Dynamics.**) (L.D.W.)

NEWTONIAN POTENTIAL FUNCTION. **Potential.**

NEWTON'S LAW OF COOLING. From experiments upon the cooling of bodies, Newton concluded that, over moderate temperature ranges, the rate of cooling is proportional to the difference between the temperature of the cooling body and that of the surrounding medium. This may be expressed as a differential equation, the solution of which for the temperature T as a function of the time t is

$$T = T_m + (T_o - T_m)e^{-At}$$

in which T_m is the air temperature and T_o is the value of T at the beginning of the time interval t. A is a constant depending upon the size, shape, material, and surface of the body. While the law is only roughly approximate, it is nevertheless very useful for calorimeter corrections, etc. (See **Thermal Radiation** and **Stefan-Boltzmann Law.**) (L.D.W.)

NEWTON'S LAWS OF DYNAMICS. The classical or Newtonian **dynamics** rests upon certain propositions first enunciated in systematic form by Sir Isaac Newton, which he set forth as three "Laws" of force and motion.

The first Law states, in effect, that bodies of matter do not alter their motions in any way except as the result of **forces** applied to them. A body at rest remains at rest, or if in motion it continues to move in the same direction with the same speed, unless a force is impressed upon it. It is quite conceivable that Newton's interpretation of "force" was the primitive concept which we all have, based on muscular effort, and that he regarded this statement as the expression of a natural law connecting force with motion. On the other hand he may have recognized in this first Law, as we now do, an objective definition of force, namely, that which is capable of altering bodily motions in the face of an opposition called **inertia** whose nature is even now not fully understood.

The second Law is made up of two distinct parts: 1. When different forces are allowed to act upon free bodies, the rates at which the **momentum** changes are proportional to the forces applied. 2. The direction of the change in momentum caused by a force is that of the line of action of the force. Part 1 may now be regarded, from the more rigorous viewpoint of **dimensional analysis**, as a definition of the standard measure of force. Two forces are judged equal if they produce change of momentum at equal rates; one force is twice as great as another if it changes the momentum at twice the rate; etc. The absolute or Gaussian force units, such as the **dyne**, so much used in dynamic theory, are based upon this system of measure. Part 2 emphasizes the **vector** character of force, and points out that no single force, acting alone, can cause a change of motion in any direction save that of its own line of action. If the effect is apparently in some other direction, as when a string operates over a pulley, the force is always combined with one or more auxiliary forces, the **resultant** of all of them being in the direction of the observed change of motion.

The third Law asserts the equality of "action and reaction." In the case of forces acting on bodies at rest, the principle is easily illustrated. When a steel truss rests on a pier and presses downward upon it with a force of 100,000 lbs., the pier exerts an upward thrust or "reaction" against the truss, also of 100,000 lbs., and this thrust, tending to bend the truss upward, is a most important factor in computing the stresses in the truss members. The Law also applies to forces acting upon bodies free to yield and to receive acceleration; a fact not explicitly stated by Newton, and discussed more fully elsewhere as **d'Alembert's principle.**

These propositions constituted the unquestioned foundation of dynamics until about the beginning of the 20th century. So far as practical operations with bodies of ordinary size are concerned, they still answer every purpose. It is only when we consider motions with velocities comparable to that of light, or attempt to analyze the mechanics of bodies of the atomic and electronic order of magnitude, that the Newtonian dynamics breaks down and must be replaced by a system founded upon the postulates of **relativity** and the concepts of the **quantum theory.** (L.D.W.)

NEWTON'S METHOD FOR SOLUTION OF EQUATIONS. Let $x = a$ be a first approximation to a real **root** of an **equation** $f(x) = 0$, found by trial or by graph or otherwise. Then a second approximation to the root is given by the formula

$$a' = a - \frac{f(a)}{f'(a)}.$$

A new approximation may be obtained by substituting a' for a in this formula again, and so on until the desired degree of accuracy is attained. The formula is based upon finding the point where the tangent at $x = a$ to the curve cuts the X-axis. (L.L.S.)

NEWTON'S RINGS. An interference phenomenon, easily observed by laying a slightly convex lens upon a flat glass plate. When the lens and plate are arranged so that monochromatic light is reflected at a suitable angle to the observer's eye, the point of contact is seen to be surrounded by a series of concentric, alternately bright and dark rings, which become closer together with increasing radius. The rings are due to the interference of light at the film of air between the glass surfaces, which film increases in thickness with increasing distance from the contact point. If the radius of curvature of the convex surface is R, and if, counting the central contact-spot as the zero ring, we number the rings in order, both bright and dark, from the center out, the radius of the Nth ring in monochromatic light of wavelength λ is approximately

$$a = \sqrt{\frac{NR\lambda}{2}}.$$

With white light, the bright rings become colored spectra, the overlapping of which at larger values of N causes the system to become indistinct and disappear. (L.D.W.)

NEW ZEALAND FLAX. **Flax.**

NEYMAN-PEARSON THEORY OF TESTING HYPOTHESES. In testing a statistical hypothesis we may make two types of **errors,** Type *I* and Type *II*. If we reject a true hypothesis we commit an error of Type

I. If we accept a false hypothesis, we commit an error of Type *II*. Naturally no error is committed in calling a true hypothesis true and a false hypothesis false. Now in the Neyman-Pearson theory, the probability of making a Type *I* error is controlled in advance as .05 or .01 and then that test of the statistical hypothesis is preferable which minimizes the **probability** of Type *II* errors while Type *I* errors are controlled. If a test exists which controls Type *I* errors and minimizes the probability of a Type *II* error for any hypothesis which is false, then we say such a test is uniformly most powerful. When uniformly most powerful tests exist, they are preferred above all others. When a uniformly most powerful test does not exist, other tests have been developed. In the Neyman-Pearson theory it is important to consider what the alternative hypotheses are in relation to the hypothesis being tested. The theory is a recent development originated by J. Neyman and E. Pearson and has been greatly extended by them and by A. Wald. (L.A.A.)

NICCOLITE. A nickel **arsenide** mineral, NiAs, crystallizes in the **hexagonal** system but is usually found massive. Color, light copper-red; hardness, 5.0–5.5; specific gravity, 7.33–7.67; luster, metallic; opaque. Found in several European localities and in the Province of Ontario, Canada; in the United States at Franklin, New Jersey, and Silver Cliff, Colorado. It is used as an ore of nickel. (E.S.C.S.)

NICHOL'S RADIOMETER. **Radiometer.**

NICKEL. Symbol: Ni. Atomic number: 28. Atomic weight: 58.69. Density: 8.9. Melting point: 1452° C. Boiling point: 2900° C. (**Isotopes**: page 290.)

Nickel is a silver-white metal, harder than **iron**, capable of taking a brilliant polish, malleable and ductile, magnetic below 345° C. Compact nickel is not oxidized on exposure to air at ordinary temperatures; soluble in **nitric acid**; does not react with **alkalis**; becomes passive in concentrated nitric acid. Finely divided nickel dissolves 17 times its own volume of **hydrogen**, and is extensively used as a **catalyzer** in the **hydrogenation** of oils. Discovered by Cronstedt in 1751.

Nickel is used (1) in **electroplating**, as a protective and ornamental coating for less resistant metals, especially iron and steel, (2) in coins of small denominations (25% Ni, 75% **copper**), (3) in nickel steel "invar" (36% Ni, 64% iron) of low coefficient of thermal expansion for standards of length, "permalloy" (80% Ni, 20% iron) for sheathing electric **cables**, 45 to 80% nickel and 55 to 20% iron for electromagnetic applications requiring high permeability and low hysteresis loss, (4) in monel metal (about 62% Ni and 31% copper), nichrome or chromel wire (50%–80% Ni, 11%–25% **chromium**, remainder iron) of high electrical **resistance** for heating units; german or nickel silver (10%–30% Ni, 50%–65% copper, remainder **zinc**), (5) in the alkaline (Edison) storage battery (see **Accumulator**), (6) extensively in corrosion resistant apparatus, (7) as an alloying element in steel, generally 1 to 5% nickel but larger percentages in some stainless steels.

Nickel occurs as sulfide (**pentlandite**) ($NiS \cdot 2FeS$) in Sudbury, Ontario, the ore averaging 3% nickel and 1.5% copper along with iron and some precious metals, and as silicate carrying 4%–8% Ni and no copper in New Caledonia. The Sudbury ore is roasted, and then treated in a **blast furnace** to obtain nickel and copper sulfides (25% metals), then in a **converter**, the product being composed of about 56% nickel, 24% copper and 20% **sulfur**. This is roasted to form nickel and copper oxides, and the copper oxide removed by dilute **sulfuric acid**. The residue is reduced to metallic nickel by heating with water gas (**hydrogen** and **carbon monoxide**), and the metal treated at 50° C. with **carbon monoxide** (Mond process), to form volatile nickel carbonyl, a very poisonous gas, which is then decomposed at 200° C. on nickel shot, nickel depositing on the shot and carbon monoxide being regenerated and used again.

Acetate: Nickel acetate, nickelous acetate ($Ni(C_2H_3O_2)_2$), green solid, soluble.

Carbonyl: Nickel carbonyl ($Ni(CO)_4$), liquid, melting point −25° C., boiling point about 43° C., by the reaction of carbon monoxide and nickel metal at about 50° C., and decomposed at 200° C. to nickel and carbon monoxide.

Chloride: Nickel chloride, nickelous chloride ($NiCl_2 \cdot 6H_2O$), green crystals, soluble.

Cyanide: Nickel cyanide ($Ni(CN)_2$), greenish-yellow precipitate by nickel salt solution and **potassium** cyanide solution; nickel potassium cyanide ($K_2Ni(CN)_4$), soluble, by excess of potassium cyanide with nickel salt solutions. Unchanged in boiling solution, and recovered by crystallization as reddish-yellow solid.

Hydroxides: Nickel hydroxide, nickelous hydroxide ($Ni(OH)_2$), light green precipitate by reaction of nickel salt solution and **sodium** hydroxide solution; nickelic hydroxide ($Ni(OH)_3$).

Nitrate: Nickel nitrate, nickelous nitrate ($Ni(NO_3)_2 \cdot 6H_2O$), green crystals, soluble.

Oxides: Nickel monoxide, nickelous oxide (NiO), green to grayish green (yellow when hot) solid, by heating nickelous hydroxide or carbonate; nickel sesquioxide (Ni_2O_3), black solid, by heating nickelous nitrate, but the identity of this oxide is questioned; trinickel tetroxide (Ni_3O_4), gray solid, by heating the sesquioxide in **hydrogen** at 190° C.; nickel dioxide or its hydrate ($NiO_2 \cdot nH_2O$), black solid, by reaction of nickel salt solution and **sodium** hypochlorite solution, but the identity of this hydrate is questioned.

Sulfate: Nickel sulfate, nickelous sulfate ($NiSO_4 \cdot 6H_2O$), green crystals, soluble.

Sulfide: Nickel sulfide, nickelous sulfide (NiS), black precipitate by reaction of nickel salt solution with **ammonium** sulfide solution, relatively insoluble (after precipitation) in **hydrochloric acid**.

Dimethylglyoxime or diacetylglyoxime yields a characteristic red precipitate with nickel salts, of delicacy sufficient to detect one part of nickel in 400,000 parts of solution.

Nickel salts are green in solid or solution. (R.K.S.)

NICKEL ALLOYS. Although not produced in large tonnages, there are many nickel alloys that are well-known because of their special properties. The normal compositions of several of these alloys are listed. In most cases the balance consists of relatively small amounts of silicon, manganese, carbon, and sulfur. In nearly all cases there are many modifications of the trade-named alloys.

Commercially pure wrought nickel in the form of sheets, wire, tubing, etc., has many applications because of its corrosion-resistance. These include utensils and food-processing equipment, marine construction, coinage, and chemical equipment. Nickel also has many radio and other electrical applications such as spark-plug wires. Electroplated nickel has been widely used as a protective coating on steel.

The 80% Ni-20% Cr alloy and other compositions with 45–65% Ni (e.g., Nichrome) are used as resistance wires for heating elements. Constantan has a high electrical resistivity and a very low temperature-coefficient of resistivity. It is widely used with copper as a thermocouple element for temperature measurement. Inconel is both a heat- and corrosion-resistant alloy generally used in sheet and other wrought forms for applications such as exhaust manifolds, dairy equipment, and chemical apparatus.

Permalloy, Hipernik, and Perminvar are representative of a large group of high nickel magnetic alloys.

Monel metal is a high-strength, corrosion-resisting alloy available in many wrought and cast forms for use in processing equipment, marine applications, household appliances, etc. One variety, "K" Monel, can be heat treated by **precipitation hardening** to about twice the strength of annealed Monel.

The Hastelloy-type alloys have excellent resistance to hydrochloric, sulfuric, and other acids.

K42-B is one of the newer high-temperature alloys. It has exceptionally high **creep** strength and oxidation-resistance at temperatures as high as 1500° F.

Invar has a very low temperature-coefficient of thermal expansion. It is used for measuring tapes, instruments, and bimetallic thermostats. Elinvar has a low temperature-coefficient of elasticity which makes it useful for springs in watches and precision instruments.

The 35% Ni and 25% Ni heat-resistant alloys are used principally as castings for furnace parts. Lower nickel—higher chromium compositions are generally classified as **stainless steels.**

The 30% Ni-copper alloy and the nickel-silver alloys are listed under **brass and bronze.**

(R.H.H.)

NICKEL IRON. **Iron.**

NICKEL SILVER. **Brass and Bronze.**

NICOL PRISM. One of the best known devices for producing plane-**polarized light.** It consists of two

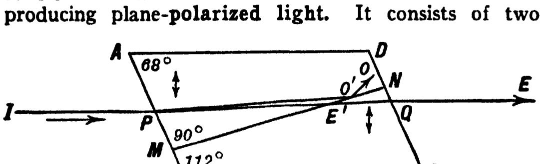

Diagram of Nicol prism. Double-headed arrows indicate direction of optic axis.

pieces of Iceland spar (pure calcium carbonate) cut as shown in the figure. The optic axis of each is approximately indicated by the double arrow, and they are cemented together with colorless Canada balsam along the plane *MN*. If the incident beam *IP* is unpolarized, it suffers **double refraction** at *P*, dividing into an ordinary component *PO'* and an extraordinary component *PE'*. The refractive index of Iceland spar for the ordinary ray (sodium light) is 1.658 and for the extraordinary it is 1.486, while that of Canada balsam for both is 1.53. The ordinary ray therefore encounters at *O'* a less refractive medium, and, the incidence being at an angle larger than the critical angle, it is totally reflected (*O'O*); while the extraordinary ray incident at *E'* encounters a more refractive medium, therefore cannot suffer total reflection and most of it passes on along *E'Q*, emerging along *QE* completely plane-polarized with its vibration plane in the plane of the paper. Modifications of this prism, having different shapes and using other cements, have been designed for special purposes. The use of such polarizers is somewhat limited by the scarcity and costliness of large Iceland spar crystals of suitable quality. (See also **Petrographic Microscope.**) (L.D.W.)

NICOTINE. **Alkaloids.**

NICTITATING MEMBRANE. The third **eyelid** of vertebrates. (A.W.L.)

NIDAMENTAL GLAND. Glands of the female reproductive system of **cephalopod** mollusks which secrete an elastic envelope about the egg. (A.W.L.)

NIGHTHAWK. Aves, Caprimulgiformes. **Nightjars** or **goatsuckers** of the New World. They have a very short beak and wide mouth, adapted for taking insects in flight, and are on the wing late in the day. Their

Nighthawk. *Chordeiles virginianus.* Mottled-blackish brown and reddish; lighter below, with wavy brown bars. A large white patch on each wing; the male has white on throat and tail also.

flight is easy and powerful and their long dives, terminating in a peculiar hollow boom, are a memorable exhibition.

The common nighthawk, *Chordeiles virginianus,* is widely distributed in North America and winters far into South America. A second species, the Texan nighthawk, *C. acutipennis,* enters the southwestern United States. (A.W.L.)

NIGHTINGALE. Aves, Passeriformes. A **warbler,** *Luscinia megarhyncha,* of western Europe, noted for its song. Farther east two other species, the eastern, *L. pheilomella,* and Persian, *L. hafizi,* nightingales, are found. (A.W.L.)

NIGHTJAR. Aves, Caprimulgiformes. Birds (**Aves**) with mottled plumage, a wide mouth and a short beak. They are insect-eaters, flying chiefly at twilight. Every continent has some of the numerous species except Australia.

In North America the **nighthawk** and **whip-poor-will** are the most widely known representatives of the group, with the **poor-will,** chuck-will's widow, *Antrostomus carolinensis,* and Merrill parauque, *Nyctidromus albicollus,* as less widely distributed species.

Also called goatsuckers. (A.W.L.)

NIGHTSHADE. **Potato Family.**

NILGAI. Mammalia, Artiodactyla. An Indian **antelope,** *Boselephas tragocamelus,* of moderate size. The male has small horns, only slightly curved. (A.W.L.)

NIMBOSTRATUS. **Clouds.**

NIMBUS. **Clouds.**

NIOBIUM. **Columbium.**

NITRATES. See each element for inorganic and organic nitrates; **Nitric Acid.**

NITRATION. Nitration is the process of the addition of the NO_2 group to a carbon atom, usually replacing

hydrogen attached to carbon. The addition may be accomplished by means of (1) strong nitric acid, (2) mixed acid, nitric and sulfuric, (3) a nitrate plus sulfuric acid, (4) nitrogen pentoxide, (5) a nitrate plus acetic acid. More than one hydrogen atom can be replaced in a compound, but each succeeding one is replaced with more difficulty than the preceding.

Paraffin hydrocarbons may be nitrated by nitric acid in the vapor phase, giving rise to the nitroparaffins, which are starting compounds for other aliphatic compounds.

Certain aliphatic alchols such as glycerine form esters with nitric acid such as nitroglycerine. Those are misnomers, since they are not nitro compounds. Nitroglycerine, for instance, is glyceryl trinitrate.

Aromatic compounds are usually nitrated in the liquid phase. Various rules of addition govern the position of the entering nitro group, depending upon the conditions. For example, in the benzene series, the second nitro group can enter in the ortho, meta or para position, but the presence of some other group usually fixes the position of the entering nitro group. For example, it enters meta to a nitro, sulfonic, or carbonyl group, and ortho and para to a chloro, bromo, or hydroxy group. Various other rules govern other conditions in other aromatic series.

One of the great uses of nitration is to break into a pure hydrocarbon, which is usually more difficult to do by other means. The nitro group may then be changed and another group take its place. Typical examples are nitration of ethane to form nitroethane, and of benzene to form nitrobenzene, which is easily changed to aniline.

An important economic consideration in any nitration process is the recovery of the spent acid. Since the nitration reaction forms water, the reagents gradually become diluted to a point where they will not react any more. The water may be taken up during the reaction by removing it with oleum or acetic anhydride, a practice which still leaves large amounts of the reagents at the end of the process.

The nitric acid is usually concentrated by distilling it from sulfuric acid solution which retains the water. After the nitric acid has been driven off, the temperature is raised and the water driven off the sulfuric acid, thereby concentrating the latter.

As an example of nitration, let us consider the preparation of nitrobenzene. Mixed acid consisting of strong sulfuric plus nitric acid is slowly added to benzene in a closed iron vessel provided with stirrer and reflux condenser. The acid must be added to the benzene. If it were done the other way the benzene which was added first would be quickly nitrated all the way to a trinitrobenzene. The temperature is maintained from 45–55° C. After the nitration is finished, the nitro compound is separated from the acid by decantation, since the nitrobenzene is lighter and does not mix with the acid. The nitrobenzene is washed with water and with dilute caustic or sodium carbonate solution and then again with water to give a neutral product. To obtain dinitrobenzene the reaction would be run with stronger acid and at a temperature of about 100° C.

Since the reaction used concentrated sulfuric acid, ordinary iron vessels can be used, but the neutralization process must be carried out in lead-lined tanks. Good agitation and adequate cooling facilities are necessary to avoid any local overheating and the formation of higher nitrated compounds. (D.E.M.)

NITRE. Nitre or saltpeter is a naturally occurring mineral form of **potassium** nitrate, KNO_3. It is found only in small amounts as **orthorhombic** crystals or crystalline masses or crusts in limestone caverns or in soils. It is not an important mineral. (R.M.F.)

NITRIC ACID AND NITRATES. Nitric acid (HNO_3) is a colorless solution, commercially of strength 36° Baumé (specific gravity at 60° F., water at 60° F., 1.330, 52.30% HNO_3); specific gravity 1.42 (approximately 69% HNO_3). Sometimes colored yellow to brown by nitrogen tetroxide. Higher strengths of nitric acid than 69% HNO_3 are used as "fuming nitric acid" (85% to 95% HNO_3). "Mixed acid" is a mixture of nitric and **sulfuric acids.** There is a maximum constant boiling point 120.5° C. (760 mm.) at 68% HNO_3 (distillate) for mixtures of nitric acid and water. A commonly used strength for dilute nitric acid is 31.5 grams HNO_3 per 100 milliliters of solution (5 normal).

Dilute nitric acid reacts (1) with many hydroxides, e.g., **sodium** hydroxide, to yield the corresponding nitrate, e.g., sodium nitrate, solution (2) with many ordinary oxides, e.g., **magnesium** oxide, to yield the corresponding nitrate, e.g., magnesium nitrate, solution (3) with many carbonates, e.g., **calcium** carbonate, to yield the corresponding nitrate, e.g., calcium nitrate, solution plus **carbon dioxide** gas (4) with some sulfides, e.g., **copper** sulfide, to yield the corresponding nitrate, e.g., copper nitrate plus **hydrogen sulfide gas,** (5) with many metals, e.g., **copper,** to yield the corresponding nitrate, e.g., copper nitrate, solution plus **nitric oxide** gas, (6) with cold freshly prepared solution of **ferrous** salt, when carefully stratified by concentrated sulfuric acid beneath, to yield a brown boundary layer of solution (nitrates react similarly).

Higher strengths of nitric acid react similarly in kind in the cases of (1), (2), (3), (6) above, but not, in general, in the remaining cases, (4) **sulfides** react to yield the corresponding nitrates, but accompanied by **sulfate** or **sulfur,** (5) reactions with metals depends upon the metal and the strength of nitric acid. **Copper** and concentrated nitric acid yield copper nitrate and **nitrogen tetroxide.** **Iron** is made passive by concentrated nitric acid, so that when dipped into copper sulfate solution copper metal is not deposited (on nonpassive iron a deposit of copper metal forms). **Tin** and **antimony** yield stannic and antimonic oxides respectively.

Concentrated nitric acid is thus (7) a powerful oxidizing agent and further examples of its action are the oxidation of **sulfur** to **sulfuric acid,** of **hydrogen sulfide** to sulfur, of **hydriodic acid** to **iodine,** and of cane sugar (sucrose) to **oxalic acid,** (8) a powerful nitrating agent, thus **phenol** is nitrated to nitrophenols

REPRESENTATIVE ESTERS OF NITRIC ACID

Methyl nitrate	(CH_3ONO_2) explodes at 65° C.
Ethyl nitrate	($C_2H_5ONO_2$), boiling point 88° C.
Glycol dinitrate	($C_2H_4(ONO_2)_2$), explodes at 114° C.
Glycerol alpha-mononitrate	($CH_2OHCHOHCH_2ONO_2$), melting point 58° C.
Glycerol beta-mononitrate	($CH_2OH \cdot CHONO_2 \cdot CH_2OH$), melting point 54° C.
Glycerol 1,2-dinitrate	($CH_2OH \cdot CHONO_2 \cdot CH_2ONO_2$), explosive.
Glycerol 1,3-dinitrate	($CH_2ONO_2 \cdot CHOH \cdot CH_2ONO_2$), boiling point 148° C. at 15 mm. pressure.
Glyceryl trinitrate (nitroglycerine)	($CH_2ONO_2 \cdot CHONO_2 \cdot CH_2ONO_2$), melting point 13° C., explosive at 260° C.
Cellulose trinitrate	($C_{12}H_{10}(OH)_7(ONO_2)_3$)
Cellulose tetranitrate	($C_{12}H_{10}(OH)_6(ONO_2)_4$)
Cellulose pentanitrate	($C_{12}H_{10}(OH)_5(ONO_2)_5$)
Cellulose hexanitrate (guncotton)	($C_{12}H_{10}(OH)_4(ONO_2)_6$)

(mono- ortho- or para-, di- 2,4-nitro, tri-2,4,6-nitro), (9) an esterification agent, e.g., **glycerol** esterified to glyceryl nitrates (mono, di, tri-nitrate).

In order to obtain nitric acid, (1) sodium nitrate is heated with the proper amount of sulfuric acid, whereupon nitric acid is **distilled** and condensed, with some accompanying loss due to formation of nitrogen oxides, (2) free nitrogen of the air is "fixed" by combination with hydrogen to form ammonia (see graph, page 79) which may then be mixed with air or oxygen at a suitable temperature and passed over a **catalyzer**, which is usually smooth compact **platinum** in the form of very fine wire gauze in order to expose a maximum surface for the weight used. The resulting nitrogen oxides—nitric oxide and nitrogen tetroxide—are absorbed in water, and the dilute acid obtained is subsequently concentrated by distillation. Nitrogen oxides are also obtained by passing air (oxygen and nitrogen) through an electric arc. This is the "arc" process for fixing nitrogen.

The uses of nitric acid have been suggested by the chemical reactions previously cited, and the largest quantities are used in nitration and esterification of organic substances for explosives, plastics and dyes, and as an acid to prepare nitrates.

All nitrates are soluble in water. A few are decomposed by water with the formation of insoluble basic nitrates, e.g., **bismuth** nitrate ($Bi(NO_3)_3$) to bismuth oxynitrate ($BiONO_3$), which are dissolved by excess nitric acid. Most nitrates (distinction from basic nitrates) are less soluble in nitric acid than in water, e.g., **lead** nitrate. Metallic nitrates, when heated, behave in an individually characteristic manner, e.g., **potassium** nitrate, melting point 333° C., evolves oxygen gas at high temperatures, leaves a residue of nitrite; **ammonium** nitrate, melting point 170° C., evolves nitrous oxide gas at somewhat higher temperatures; **copper** nitrate melts upon heating and at higher temperature evolves nitrogen dioxide and oxygen gases, leaving a residue of cupric oxide; **silver** nitrate, melting point 212° C., at 320° C. decomposition begins into oxygen and silver nitrite, at high temperatures the residue is silver.

A common test for nitrates is as follows: An aqueous solution of the nitrate is carefully mixed with an equal volume of concentrated **sulfuric acid**, cooled and a layer of **ferrous** sulfate is carefully poured down the side of the test tube to form two layers in the tube. A brown ring at the interface indicates presence of nitrate. (R.K.S.)

NITRIC OXIDE. Nitrogen.

NITRIDING. Surface hardening of alloy steels by heating at 900–1200° F. in an atmosphere of partially dissociated ammonia. As in **cyaniding**, hardening results from the formation of nitrides of iron and of certain alloying elements that may be present in the steel. Much longer heating time is required than in **carburizing** practice, and while the depth of penetration is generally less, the maximum hardness at the surface is higher, 900–1100 D.P.H. (*Vickers* Brinell) compared to 800–900 D.P.H. for an average carburized case. Nitriding also differs from carburizing in that the parts are fully heat-treated to develop the required core properties before the nitriding treatment. Because of the comparatively low temperature of the process, distortion and dimensional changes are at a minimum. Nitrided steels have good corrosion-resistance when used for valves, pump parts, shafting, and bearing surfaces operating in steam, crude oil, gasolines, and gaseous products of combustion. The fatigue strength is also improved by nitriding.

Other typical applications are piston pins, crankshafts, cylinder liners, timing gears, gauges, and ball and roller bearing parts. (R.H.H.)

NITRILES. Hydrocyanic Acid and Cyanides.

NITRITES. See each element; see also **Nitrous Acid**, for inorganic and organic nitrites.

NITRO- AND NITROSO-COMPOUNDS. Nitro-compounds contain the nitro-group ($—NO_2$) attached directly to **carbon** atom; nitroso-compounds contain the nitroso-group (—NO) similarly attached. A very important member of this group is nitrobenzene, which upon reduction yields a variety of products, important in the synthesis of drugs and dyes.

ALKYLNITRO-COMPOUNDS:

Primary	Secondary	Tertiary
$CH_3CH_2 \cdot NO_2$	$(CH_3)_2CH \cdot NO_2$	$(CH_3)_3C \cdot NO_2$
Nitroethane	Nitrodimethylmethane (2-nitropropane)	Nitrotrimethylmethane

ISOMERIC NITRITES:

$CH_3CH_2 \cdot ONO$	$(CH_3)_2CH \cdot ONO$	$(CH_3)_3C \cdot ONO$
Ethyl nitrite	Isopropyl nitrite	1,1-dimethylethyl nitrite

ALKYLNITROSO-COMPOUNDS:

$(CH_3)_3C \cdot NO$
Nitrosotrimethylmethane

NITRATES:

$CH_3CH_2 \cdot ONO_2$	$(CH_3)_2CH \cdot ONO_2$	$(CH_3)_3C \cdot ONO_2$
Ethyl nitrate	Isopropylnitrate	1,1-dimethylethylnitrate

NITROSAMINE:

$(C_2H_5)_2N:NO$
Diethylnitrosamine

Upon reduction, nitro- and nitroso-compounds form the corresponding **amine**; nitrosamines form the corresponding **hydrazine**.

Upon oxidation, nitroso-compounds form the corresponding nitro-compounds.

Upon treatment with **sodium** hydroxide solution, nitrites and nitrates form the corresponding alcohol plus **sodium** nitrite and nitrate, respectively. Primary and secondary nitro-compounds, with **sodium** methylate ($NaOCH_3$) in alcohol form salts of isonitro-compounds, $CH_3CH_2NO_2$ yielding $CH_3CH:NO(ONa)$, and $(CH_3)_2CHNO_2$ yielding $(CH_3)_2C:NO(ONa)$. These salts are derived from an acid form $\left(—CH:N\begin{smallmatrix} \nearrow O \\ \searrow OH \end{smallmatrix}\right)$ of the pseudo-acid $\left(\text{true nitro-compounds}\left(—CH_2 \cdot N\begin{smallmatrix} \nearrow O \\ \searrow O \end{smallmatrix}\right)\right)$.

Upon treatment with **nitrous acid**, primary nitro-compounds form nitrolic acids, e.g., nitroethane ($CH_3CH_2 \cdot NO_2$) yields ethylnitrolic acid $\left(CH_3C\begin{smallmatrix} \nearrow NOH \\ \searrow NO_2 \end{smallmatrix}\right)$, which dissolves in **sodium** hydroxide to form $\left(CH_3C\begin{smallmatrix} \nearrow NONa \\ \searrow NO_2 \end{smallmatrix}\right)$ red color; secondary nitro-compounds form pseudo-nitrols, e.g., 2-nitropropane ($(CH_3)_2CHNO_2$) yields 2,2-nitrosonitropropane $\left((CH_3)_2C\begin{smallmatrix} \nearrow NO \\ \searrow NO_2 \end{smallmatrix}\right)$, colorless, solid but on fusion or in solution changes to blue color; tertiary nitro-compounds are unaffected.

Upon treatment with **sodium** hypobromite (or hypochlorite) primary and secondary nitro-compounds form bromo- (or chloro-) nitro-compounds, thus, nitroethane $CH_3CH_2 \cdot NO_2$) yields 1-bromo-1-nitroethane ($CH_3CHBr \cdot NO_2$), and 1,1-dibromo-2-nitroethane ($CHBr_2 \cdot CH_2NO_2$); 2-nitropropane ($(CH_3)_2CH \cdot NO_2$) yields 2-bromo-2-nitropropane ($(CH_3)_2CBr \cdot NO_2$); tertiary nitro compounds are unaffected.

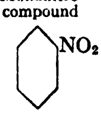
(R.K.S.)

Alkylnitro-compounds are made (1) by reaction of the alkyl iodide (see **Iodine**) and **silver** nitrite. Higher alkyl members yield increasing proportions of nitrite along with the nitro-compound, but these frequently may be separated by fractional **distillation.** Tertiary alkyl iodides do not behave in this manner; (2) by reaction of alpha-substituted halogen acids and **sodium** nitrite, followed by loss of **carbon dioxide,** e.g., chloroacetic acid ($CH_2Cl\cdot COOH$) yields nitroacetic acid ($CH_2NO_2\cdot COOH$) and then nitromethane plus **carbon dioxide,** (3) by reaction of the **hydrocarbons** with **nitric acid.**

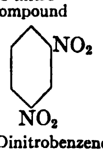
Benzenoid Nitro- and Nitroso-compounds:

Mononitro-compound



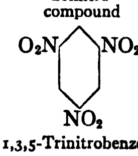
Nitrobenzene

Dinitro-compound



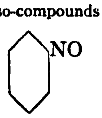
1,3-Dinitrobenzene

Trinitro-compound

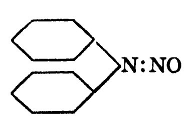


1,3,5-Trinitrobenzene

Nitroso-compounds



Nitroso benzene



Diphenyl nitrosamine

Under the proper conditions of concentration of **nitric acid** and of temperature, **benzene** forms mainly nitrobenzene, nitrobenzene forms mainly 1,3-dinitrobenzene, and 1,3-dinitrobenzene, mainly 1,3,5-trinitrobenzene.

When nitrobenzene is treated (1) with **zinc** and **calcium** chloride or ammonium chloride solution, betaphenylhydroxylamine (C_6H_5NHOH) is formed, and from this by treatment with **chromic acid** or ferric chloride nitrosobenzene is formed, (2) with **tin** or **iron** and **hydrochloric** acid, **aniline** ($C_6H_5NH_2$), is formed and from this by treatment with **nitrous acid** followed by treatment with **stannous** chloride plus **hydrochloric acid** **phenylhydrazine** ($C_6H_5NH\cdot NH_2$) is formed. (For other reactions of nitrobenzene see **Azo-, Diazo- and Related Compounds.**)

Mono- or poly- substituted nitro-compounds are changed in whole or in part to the corresponding aminocompounds by proper choice of reducing agent and temperature, e.g., in acid medium 1,3-dinitrobenzene yields 1,3-phenylendiamine ($C_6H_4(NH_2)_2(1,3)$), and with ammonium sulfide yields 3-nitraniline ($(1)H_2NC_6H_4NO_2(3)$). When diphenylnitrosamine is reduced, 1,1-diphenylhydrazine ($(C_6H_5)_2N\cdot NH_2$) is formed.

NITROBENZENE. Nitro and Nitroso Compounds.

NITROCELLULOSE. Explosives.

NITROGEN. Symbol: N. Atomic number: 7. Atomic weight: 14.008. Density: 1.2505 grams per liter, 0° C., 760 mm. or 0.967 when air equals 1.000. Formula of nitrogen gas: N_2. Melting point: −209.86° C. Boiling point: −195.8° C. Critical temperature: −147.1° C. Critical pressure: 33.5 atmospheres. **Isotopes:** 14 (99.62%), 15 (0.38%).

Nitrogen is a colorless, odorless, tasteless, non-toxic gas, found free in the **atmosphere** (78.03% by weight nitrogen) mixed with **oxygen, argon, carbon dioxide,** and water vapor. Nitrogen was recognized as a simple gas by Lavoisier about 1776, although previously isolated by Rutherford in 1772. The free gas **nitrogen** is among the least reactive substances chemically, but many of its compounds display marked reactivity, e.g., **nitric acid,** glyceryl nitrate, **cellulose** nitrates, nitrotoluene, **picric acid,** the last four being important explosives. Nitrogen occurs combined locally in Chile as **sodium** nitrate, and as a constituent of many plant and animal proteins (see **Aminoacids**). In the atmosphere nitrogen serves as a diluent for the oxygen in the processes of burning and respiration. Nitrogen is an important element in plant nutrition, e.g., in the form of nitrates, in animal nutrition, e.g., in the form of **proteins,** and many of its compounds are important **explosives, dyes,** and **drugs.** The fixation of atmospheric nitrogen is accomplished in nature by certain **bacteria** of the soil. Several processes have been exploited for the commercial fixation of nitrogen of the atmosphere. Of these, one of the first was the combination of nitrogen and oxygen into nitric oxide by means of the electric spark, developed in Norway, another was the formation of **aluminum** nitride and thence **ammonia,** but the process which has survived practically to the displacement of all others is the combination of nitrogen and **hydrogen** gases in the **catalytic** reaction to form **ammonia.** (See **Chemical Changes,** also **Nitric Acid.**)

Nitrogen, mixed with about 1% **argon,** may be

obtained from the air by passing the latter over heated **copper** or **iron** to remove the **oxygen**, or pure by fractional **distillation** of liquid air whereby the nitrogen distills off before the oxygen. Pure nitrogen may also be obtained by heating such compounds as **ammonium** nitrite, **ammonium** dichromate, and collecting the gas. Mixed with **carbon monoxide** in producer gas, nitrogen may be utilized without separation by first making methyl alcohol from carbon monoxide and hydrogen and then using hydrogen and nitrogen for ammonia. When nitrogen at low pressure is subjected to the silent electric discharge, activated nitrogen is produced. Activated nitrogen displays a golden yellow afterglow upon cessation of the current, increased by cooling and decreased by heating. This form of nitrogen is very active with **phosphorus**, with alkali metals (forming **azides**), with the vapor of **zinc**, **mercury**, **cadmium**, **arsenic** (forming nitrides), with many metallic chlorides (forming a green fluorescence), and with **hydrocarbons** (forming **hydrocyanic acid** and cyanides). The transformation of nitrogen to activated nitrogen is partial, and its return to ordinary nitrogen takes place rapidly, in about one minute.

Acids: Nitrogen is a constituent of several acids. In increasing order of oxidation the following are those without carbon: **hydrazoic** acid (HN_3); **hydroxylamine** (H_2NOH); **hyponitrous acid** ($H_2N_2O_2$); **nitrous acid** (HNO_2); **nitric acid** (HNO_3); those which contain carbon: **hydrocyanic acid** (HCN); **cyanic acid** (HCNO); **fulminic acid** (HONC); **uric acid** ($C_5H_4N_4O_3$).

Bases: Nitrogen is a constituent of several bases. In increasing order of oxidation the following are those which do not contain carbon: **ammonia** (NH_3); **hydrazine** (N_2H_4); **hydroxylamine** (H_2NOH); those which contain carbon: **amines**, such as methyl amines, phenyl amines; **hydrazines**, such as phenyl hydrazine; **pyridine**; **ureas**; **semicarbazides**; **guanidines.**

Chlorides: Nitrogen chloride (NCl_3), yellow volatile oil, odor of chlorine, very explosive in light, on heating, or with various substances, such as turpentine. With water yields **ammonia** and **hypochlorous acid**; formed by reaction of **ammonium** chloride concentrated solution with excess **chlorine**; nitrosyl chloride (NOCl), orange yellow gas, boiling point $-5°$ C., formed by distilling **sodium** nitrite plus **phosphorus** pentachloride.

Hydrides: **Ammonia** (NH_3); **hydrazine** (N_2H_4); **hydrazoic acid** (HN_3).

Iodide: Nitrogen iodide (NI_3), reddish solid, very explosive by slight mechanical shock, in light, or on warming.

Nitrides: **Magnesium** nitride (Mg_3N_2), yellow solid; boron nitride (BN), white solid; trisilicon tetranitride (Si_3N_4). Formed by reaction of certain elements (or

their oxide plus carbon) and nitrogen (or ammonia) upon heating.

Oxides: Nitrous oxide (N_2O), colorless gas, boiling point $-90°$ C., of pleasant odor, of sweetish taste. Used as an anaesthetic in minor operations—when used as such extreme caution must be exercised to avoid the presence of poisonous oxides of nitrogen. Made by heating ammonium nitrate, and collecting and purifying the gas; nitric oxide (NO), colorless gas, boiling point $-152°$ C., reactive with air or oxygen forming brown nitrogen tetroxide, and in early times used thus to test "the goodness of air." Made (1) by the reaction of dilute **nitric acid** and **copper**, (2) by the catalytic oxidation of **ammonia** and air, (3) in the electric arc process of nitrogen-oxygen (air) fixation; nitrogen trioxide (N_2O_3), brown gas, behaving at ordinary temperatures as if a mixture of nitric oxide and nitrogen tetroxide, boiling point $-27°$ C., the anhydride of nitrous acid, and with water forms nitrous acid; nitrogen tetroxide, nitrogen dioxide, nitrogen peroxide (N_2O_4), brown gas, color deepens with increase of temperature to 140° C. when there is present nitrogen dioxide (NO_2) only. Made by reaction of concentrated nitric acid and copper; nitrogen pentoxide (N_2O_5), white to yellowish solid, melting point 29.5° C., the anhydride of nitric acid, and with water forms nitric acid. Formed by dehydrating nitric acid with **phosphorus** pentoxide, and recovered from the mixture by volatilizing in a current of dry air.

Other compounds of nitrogen are discussed as follows:

Acridines. (See **Pyridine and Related Compounds.**)
Alkaloids.
Amines.
Aminoacids.
Aminoazo-compounds. (See **Azo- and Related Compounds.**)
Aminoguanidines. (See **Amines and Amides.**)
Ammines.
Ammonia.

Note: Sulfur-nitrogen organic compounds are listed under **Sulfur.**

NITROGEN CYCLE. Bacteria.

NITROGLYCERIN. Explosives.

NITROLIC ACIDS. Nitro- and Nitroso-Compounds.

NITROSYL CHLORIDE. Nitrogen.

NITROUS ACID AND NITRITES. Nitrous acid (HNO_2) is a blue solution, unstable, the blue color soon disappears, especially on warming, with the formation of brown nitrogen tetroxide (see **Nitrogen**) and **nitric acid** in solution. Nitrous acid reacts in some cases as an **oxidizing agent**, in other cases as a **reducing agent**, and is unusually interesting on that account. As an oxidizing agent, nitric oxide is usually formed, e.g., with **ferrous** salt solution changed to ferric, with **hydrosulfuric acid** to **sulfur**, **sulfurous acid** to **sulfuric acid**, **hydriodic acid** to **iodine**; **nitrogen** is formed with **urea**, with **ammonia** and with **formaldehyde**; ammonia with aluminum in **sodium** hydroxide medium. As a reducing agent, nitric acid is formed, e.g., with **potassium** permanganate changed to manganous, with dichromate to **chromic**, with chlorate to **chlorine**, with bromate to bromine, with iodate to **iodine**, with **hypochlorite** in **sodium** hydrogen carbonate medium to **chloride**.

Prepared by reaction (1) of **nitrogen** trioxide (or nitric oxide plus **nitrogen** dioxide) and water, (2) **barium** nitrite solution and **sulfuric acid**, and filtering off barium sulfate, (3) sodium nitrite solution and an acid.

Sodium nitrite is formed (1) by heating sodium nitrate solid and **lead**, with stirring, preferably in an iron dish, and upon cooling, dissolving the nitrite and filtering off lead oxide, (2) by reaction of nitric oxide plus nitrogen dioxide with **sodium** hydroxide or carbonate solution.

Silver nitrite is insoluble, and formed as a precipitate by reaction of sodium nitrite solution and silver nitrate solution.

With numerous organic substances characteristic colors are developed. Nitrous acid is (1) used in organic chemistry as an important reagent, e.g., with **amines**, and (2) **the color developed in dilute solutions is used as a**

method of quantitatively estimating nitrous acid, e.g., **sulfanilic acid** plus alpha-naphthylamine develops a red color. A complex nitrite, potassium cobaltinitrite, yellow insoluble, is important in the detection of **potassium** in salt solution, soluble sodium cobaltinitrite is used as the reagent.

Esters: methyl nitrite (CH_3ONO), boiling point $-12°$ C.; ethyl nitrite (nitrous ether) (C_2H_5ONO), boiling point 17° C.

Indication of the presence of a nitrite is given by the appearance of brown fumes on treatment with dilute **sulfuric acid** in the cold. (R.K.S.)

NITROUS OXIDE. **Anaesthesia; Nitrogen.**

NOBEL PRIZE AWARDS. In chemistry, physics, and physiology or medicine. (See **History and Evolution of Chemistry.**)

NOCTILUCA. Protozoa, Mastigophora. A genus of **protozoans** with one phosphorescent species. This minute form is sometimes so abundant in the ocean that the water appears luminous at night. (A.W.L.)

NOCTULE. Mammalia, Chiroptera. A **bat** found in Europe, Asia, the Oriental region, and northern Africa. It has a wing spread of more than a foot. (A.W.L.)

NOCTURIA. Increased frequency of urination at night. It occurs with infections of the urinary tract, obstruction (e.g., benign prostatic hypertrophy), and in advanced kidney disease (e.g., nephritis) in which there is loss of the normal power of the kidney to concentrate urine. (D.M.H.)

NODDY. Aves, Charadriiformes. A group of birds (**Aves**) related to the terns. They are chiefly tropical. (A.W.L.)

NOISE AND VIBRATION. The two chief characteristics of vibration are **frequency** and **amplitude.** A mechanical vibration which is felt as a shake or tremor differs from one which manifests itself to the senses as noise or sound only in the value of its frequency. When the frequency is low, say less than 15 oscillations per sec., vibration is felt as a shake or tremor, and then is only perceptible to the senses if its amplitude amounts to .016″ or more. When the frequency lies between 15 and 30 oscillations per sec., the shake or tremor is accompanied by noises such as clicks and rumbles. For example, all major earthquakes are accompanied by a rumble, so deep that observers usually differ as to whether the sensation it produces is felt or heard. When the frequency lies about 30 oscillations per sec., vibration passes into the range of sound. The limits of frequency for musical sounds are usually given as 40 to 15,000 oscillations per sec. The upper limit of audibility extends to about 15,000 oscillations per sec., depending upon the age of the person. For a vibration of given frequency, the intensity is proportional to the square of the amplitude, or linear magnitude, of the disturbance. Thus in the case of sound, the amplitude of vibration determines the loudness while the frequency determines the pitch. For vibrations of low frequency which are felt as tremor or shake, various experiments have been made to determine the limiting amplitude and frequency at which they become apparent to the senses.

The use of **insulation** for localizing vibration in structures is only one phase of the complicated problem of vibration control. The general problem, whether considered in relation to structures or machinery, is a dynamic rather than a static one. Probably it is for this reason that greater progress toward a solution has been made in mechanical than in structural lines. The general problem of vibration control may be classified under several heads. In the design of permanent machinery installations such as lighting and power units in office buildings and apartments; batteries of looms, printing presses, or machine tools in shops and factories; marine installations; automotive and aircraft power plants, etc., the first step consists in eliminating the unbalanced effects in rotating parts by means of dynamic balancing. In general, however, this by itself is never completely effective. In reciprocating machinery, where the power fluctuates, it is of utmost consequence to design parts affected by vibration so as to avoid critical speeds. In buildings and other structures, critical speeds are those speeds of operation at which synchronous vibration is set up in one or more members of the structure. See **Resonance.** If the design of the structure cannot be altered, synchronism may be destroyed by changing the speed of the machine causing vibration. When vibration is due to outside sources such as street traffic, some other remedy, such as insulation, must be adopted.

Mechanical insulators fall into two general classes: Those that are elastic and resilient, such as rubber, felt, and cork; and those which are almost entirely lacking in these qualities, such as sand, gravel, lead, and asbestos. Properly speaking, there is no such thing as a vibration absorbent, since this implies dissipation of energy through internal work in the form of molecular friction, heat losses, etc. Resilient materials store up energy like a spring and give this up again when released without appreciable loss, and their insulating properties depend on this feature; whereas non-resilient materials like sand and gravel serve mainly to destroy the rigidity, or interrupt the continuity, of otherwise rigid structures.

The most general principle of vibration control is that vibration should be damped out as near as possible to its source. When the source of vibration is under control, as in the case of a stationary machine in a building, this principle implies that the machine shall be of correct design, properly balanced, and with adequate foundation, thereby preventing so far as possible the occurrence of vibration, or reducing it to a minimum, before any attempt is made to introduce resilient supports or vibration dampers for short-circuiting residual vibration.

When the source of vibration lies entirely outside control, as in the case of vibration in a building due to street traffic, the use of resilient dampers or isolators often becomes the chief remedy. Also when the problem is to prevent vibration from affecting some particular object, such as a piece of delicate scientific apparatus, local insulation by the use of resilient supports is in general the most effective means of securing results.

The sensation of **sound** is produced, in general, by compressional waves transmitted through the air from some vibrating source. Sound may also be communicated to the ear through the medium of a solid body which transmits vibration directly to the bones of the skull, or by means of a metal plate held firmly between the teeth. When the sound wave is periodic, a musical sound is produced, the pitch of which depends on the frequency of vibration. When the sound wave is nonperiodic, the resulting sensation is what we call noise.

The transmission of sound implies a transmision of wave energy. The numerical amount of such wave energy measures what is called the **intensity** of the sound. Sound intensity is thus a definite physical quantity, and is defined as the amount of energy transmitted per unit of time through a unit area of a plane, normal to the direction of travel of the sound wave.

When a sound is transmitted through the air, it proceeds outward from the source in spherical waves, alternating between compression and rarefaction with the same frequency as its source. When such a sound wave in air impinges on a surface, such as the wall of a room, part of its energy is reflected, part absorbed, and part transmitted through the wall, in proportionate amounts depending on the construction of the wall and the nature of its surface.

Experiments on soundproofing structures, such as those carried out at the U. S. Bureau of Standards for a period of years on standard building construction and more recently on aircraft cabins, as well as somewhat similar but independent developments in connection with the insulation of sound stages of talking picture studios, have disclosed certain basic facts with regard to practical methods for preventing sound transmission.

For ordinary building construction it has been found that in the case of solid walls such as those of brick or masonry, whatever tends to make the wall stiffer or heavier, tends to improve its sound-insulating properties.

However mechanical may be the age in which we live, the foundations of this or any nation's wealth is based on human resources. The nervous and muscular system which directs and controls human effort, whether mental or manual, is, in fact, a very highly organized machine, and from a purely mechanical standpoint its efficiency depends very largely on the prevention of fatigue and the restoration of used tissues through sleep and relaxed muscular and nervous tension. With all forms of mechanical waste carefully guarded against by scientific management, authorities on industrial economics assure us that the greatest waste in industry today is that caused by nervous fatigue induced by excessive and incessant noise.

During the past few years tremendous advances have been made in the solution of problems in vibrating systems by the use of dynamical analogies. By establishing analogies between electrical, mechanical and acoustical systems, the solution of vibrating problems in mechanical and acoustical systems is reduced to the solution of an electrical network. In this way the widespread knowledge of electrical networks is used to solve problems in complex dynamical systems—that are so difficult by classical methods—in the most simple and logical way. These methods are applied to problems in electricity, dynamics, acoustics and mechanics. They include the development and design of sound systems, electromechanical transducers, machines and mechanisms, and the control of noise, vibrations and oscillations. These methods may also be applied to transient phenomena, such as impulsive forces in engines and machines. Specifically, dynamical analogies is an indispensable scientific tool in the analysis, study and design of mufflers, dampers, vibration isolators, of microphones, loud speakers, pickups, galvanometers, and other electromechanical transducers as well as filters and corrective networks. (See *Dynamical Analogies*, by H. F. Olson, D. Van Nostrand Co., Inc.)

NOISE SUPPRESSOR (Radio). This is a vacuum-tube circuit designed to suppress undesirable noise in a receiver. Suppressors are of two types, interchannel noise suppressors and large signal suppressors. The first acts as a sort of **automatic volume control** to cut off the audio **amplifier** when no carrier is being received. The second is a peak limiting circuit to suppress all signals above a certain amplitude. (L.R.Q.)

NOMENCLATURE. For **chemical nomenclature**, see article under that heading. In the biological sciences, nomenclature is the names of species and the groups in which they are classified, and the procedure governing the selection of such names. A part of **taxonomy.**

All zoological nomenclature is dated from Linnaeus' *Systema Naturae*, Tenth Edition, 1758. The same scientist is credited with the establishment of the system of binomial nomenclature which applies to every species a name consisting of the name of the genus to which it belongs, followed by the name of the species. The name of the author of the species or an abbreviation is also appended, and it is permissible, if the species is later removed to another genus, to place this author's name in parentheses and follow it with that of the author of the new combination.

In modern zoology a series of International Rules of Zoological Nomenclature prepared by the International Commission on Zoological Nomenclature is regarded as the authoritative code for naming taxonomic divisions and for the regulation of certain other procedure of taxonomy. Disputed points are submitted to the Commission and opinions on such points are published from time to time.

A general provision is that all scientific names must be published in such form as to satisfy the Commission's definition of publication. In addition a priority rule establishes the first valid application of a name, all names subsequently published to apply to the same unit becoming synonyms.

The selection of names for species is practically unrestricted. They are Latinized in their application to scientific uses but they may be derived from any language and may be descriptive or not. Custom imposes a limitation in some groups, as in a family of moths with specific names ending in *-ana* and another with the ending *-ella*. Names of species are written with a small initial letter and are italicized in text.

The names of genera are chosen with equal freedom, but it is provided that no name shall be used a second time in the same kingdom. If this is inadvertently done, the second application is said to be preoccupied and is replaced by a new name when the duplication is discovered. Names of genera are single words, written with an initial capital and italicized in text.

Subfamily names are formed of the stem of the name of the type genus plus the ending -inae, family names of this stem with the ending -idae, and superfamily names with the ending -oidea. These and all names of higher divisions are capitalized but are not placed in italics.

Procedure in botanical taxonomy differs in detail. Here the International Rules of Botanical Nomenclature, adopted and later revised by the International Botanical Congresses of various years, correspond as an authoritative guide to the zoological rules. Their provisions are in general harmonious. A few important points of difference follow: 1. The starting point of botanical nomenclature for most groups is Linnaeus' *Species Plantarum*, Edition I, 1753, but for certain mosses and fungi other pioneer works have been adopted. 2. A list of generic *nomina conservanda* has been adopted to render certain established usages immune from strict application of the rules. 3. The rules specify the ending -ales for orders, -ineae for suborders, -aceae for families, -oideae for subfamilies, -eae for tribes and -inae for subtribes. 4. The specifications for the establishment of types of genera are much less detailed and precise.

In modern botany there is no single set of rules constituting a code for the selection of names for the various taxonomic categories. Two distinct codes are in use in the United States, one of which, the American Code, corresponds closely to the International Rules of Zoological Nomenclature. Each International Botanical Congress has made progress in the formulation of acceptable rules governing the selection of appropriate names, priority rights, adequate publication, and other matters, but general agreement has not yet been reached.

All botanists agree on the use of the system of binomial nomenclature for species. Each species is given a name consisting of the name of the genus followed by the specific name and the official abbreviation of the name of the author of the combination. In common practice the latter item is usually omitted.

The central problem of nomenclature lies in the selection of the generic name. Each must be different and different from any name used for a genus of animals. It is always a Latin or Latinized noun in the nominative singular. It may be masculine, feminine, or neuter; the most practical method of determining the gender is that of consulting a manual for the gender of an adjective which designates a species in the genus. The generic names of trees and of genera named for persons are

always feminine. The name is always printed in italics with an initial capital.

Species names are usually Latin or Latinized adjectives which must agree in case and gender with the generic name. Such adjectives are italicized but never capitalized. If the specific name is an appositive noun or a proper noun in the genitive case it is usually capitalized. In rare cases the name is a common noun in the genitive case, singular or plural, and is not printed with a capital. These rules for capitalization lead to confusion and there is a growing tendency among botanists, especially horticulturalists, to follow the lead of the zoologists by omitting the capital from all species names.

An apparent exception to the system of binomial nomenclature is the use by botanists of a third name for varieties within species. The practice is especially common in the naming of marketable new varieties of cultivated plants. Varietal names follow the rules for specific names. They may be written after the specific name to form a trinomial or, more commonly, may be separated from the specific name by the abbreviation for the word variety (var.). The abbreviation is not italicized.

Family names are usually made from the root of the name of the principal genus within the family by adding the ending -aceae. The names of six large families constitute an exception to this rule. The names of these families follow with, in parentheses, the new names which have been proposed for them: Compositae (Asteraceae), Cruciferae (Brassicaceae), Gramineae (Poaceae), Labitae (Menthaceae), Leguminosae (Fabaceae), and Umbelliferae (Apiaceae).

Related families are collected into orders. The ordinal name has the ending -ales. Names of sub-families have the ending -eae. Names of families, sub-families (tribes), and orders are never italicized. (See **Taxonomy.**) (A.W.L., P.A.W.)

NOMOGRAM. **Alignment Chart.**

NONCALCAREA. A division of the sponges (Porifera) used by some zoologists to include the species without calcareous spicules. Equivalent to **Hexactinellida** and **Demospongiae** of this work. (A.W.L.)

NONCONFORMITY. **Unconformity.**

NON-EUCLIDEAN GEOMETRY. A non-Euclidean geometry is a geometry in which not all the axioms and postulates of Euclid are assumed. In particular, the classical non-Euclidean geometries are obtained by replacing the parallel postulate of Euclidean geometry by other assumptions.

In the hyperbolic geometry, usually credited to the Russian mathematician Lobachevski, all of Euclid's axioms are accepted with the exception of the parallel postulate, which is replaced by the assumption that through any point there are two or more lines which do not intersect a given line in the plane. In hyperbolic geometry, many theorems are the same as in Euclidean geometry, but many are different; for example, in hyperbolic geometry, the sum of the three angles of a triangle is less than two right angles.

In elliptic geometry, the parallel postulate of Euclid is replaced by the assumption that through a given point there are no lines which do not intersect a given line in the plane. (L.L.S.)

NON-FERROUS METALS. Metals and alloys in which iron is absent or present only as an impurity or alloying addition. (See **Brasses and Bronzes, Light Alloys, Solder, Nickel Alloys, Babbitt,** etc.) (R.H.H.)

NON-INDUCTIVE RESISTANCE. A resistance constructed in such a manner that the inductive effects are reduced to a minimum. Such construction is often required for high-frequency work. (L.R.Q.)

NONPAREIL. Aves, Passeriformes. The painted bunting, *Passerina ciris,* of the southern United States, a small bird brightly colored with red, blue, and green. (A.W.L.)

NON-SINUSOIDAL WAVE. This is any periodic wave which is not a pure sine wave. Such waves may, however, be analyzed into numerous sine components and often circuits may be analyzed by considering these one at a time. (L.R.Q.)

NORDMARKITE. The term proposed by Brögger, in 1890, for an **alkali syenite** containing free **silica** in the form of **quartz**, the principal femic minerals being **biotite** and **aegirine.** This type locality is at Nordmaken, Norway. (R.M.F.)

NORITE. **Gabbro.**

NORM. Used by **petrologists** to describe **igneous** rocks according to their standard, or normative **mineral molecules** as calculated in terms of **oxides.** (Contrast with **Mode.**) (R.M.F.)

NORMAL. A perpendicular; in descriptive geometry, a normal view of a line is one in which the direction of sight is perpendicular to the line, and shows the true length of the line. (H.C.H.)

NORMAL CURVE. The normal curve is given by

$$y_x = \frac{1}{\sqrt{2\pi}}\sigma_x \exp. -\frac{(x-m)^2}{2\sigma_x^2}.$$

m = population mean, σ_x = standard deviation. It is often given in standard units $y_t = \dfrac{e^{-\frac{t^2}{2}}}{\sqrt{2\pi}}$. (See **Normal Probability Function; De Moivre-Laplace Theorem.**) (L.A.A.)

NORMAL DISPERSION. A series is said to have normal dispersion if D, the **coefficient of dispersion,** is 1. The Bernoulli series of trials, a series of trials in which the trials are independent and the **probability** of success is constant from trial to trial, has $D = 1$. (See **Bernoulli Probability Function.**) (L.A.A.)

NORMAL FAULT. **Fault.**

NORMAL LINE TO A PLANE CURVE. **Tangents and Normals to Plane Curves.**

NORMAL LINE TO A SURFACE. **Tangent Plane to a Surface.**

NORMAL PROBABILITY FUNCTION. The equation of the normal probability function is in **standard units**

$$P_t dt = \frac{1}{\sqrt{2\pi}} e^{-\frac{t^2}{2}} dt, \quad t = \frac{x-m}{\sigma_x},$$

m = mean of the population, σ_x = **standard deviation** of the population. It occurs frequently in **statistics** particularly as a limiting distribution. The distribution of sample means and sample variances approach the normal probability function as the size of the sample increases, under very general conditions. **Snedecor's F distribution,** the **χ^2 distribution, Fisher's z distribution** and **Student's t distribution** are others which ap-

proach a normal distribution as the **degrees of freedom** approach infinity. The distribution function

$$H(t) = \int_{-\infty}^{t} P_t dt,\ P_t, \text{ and} \int_0^t P_t dt$$

have been tabulated. The ordinates of the normal probability function, P_t, form a symmetrical curve with mean zero and variance 1. It has 2 points of inflection at $t = \pm 1$. Approximately 68% of the area under the curve lies between $t = \pm 1$, 95% between $t = \pm 1.96$, and 99.7% for $t = \pm 3$. Sometimes the normal probability function is called the Gaussian function or the **normal curve.** (L.A.A.)

NORMAL SOLUTION. **Concentration.**

NORMALIZING. **Annealing.**

NORMALLY DISTRIBUTED. A variate is said to be normally distributed if it is distributed in a **normal curve** or a **normal probability function.** (L.A.A.)

NORTH. For many centuries, north has been the fundamental direction used by navigators and surveyors. During this long period a loose usage of the term has become prevalent. It seems desirable to set down certain standard meanings accepted by the majority of modern navigators and astronomers.

True north (unless a qualifying adjective is used with north, true north is to be assumed) is the direction along the geographical **meridian** of the observer, in the plane of the observer's **horizon,** toward the north pole of rotation of the earth. Compass north is the direction in the plane of the horizon toward which the north-seeking end of the **compass** points. Unless otherwise stated, compass north refers to north defined by the magnetic compass, if another type of compass is used it should be clearly indicated, e.g., **gyro-compass** north, etc. Magnetic north is the direction in the plane of the observer's horizon toward the north magnetic pole of **terrestrial magnetism.** For methods of conversion from any one of these three "norths" to any other see **Compass Corrections.** (W.K.G.)

NORTH POLAR SEQUENCE. **Stellar Magnitude.**

NORTH STAR. **Polaris.**

NORTHFIELDITE. The term proposed by Emerson in 1915 for an exceedingly quartz-rich **granite** containing 83% of **quartz** and 13% of **soda—orthoclase feldspar.** The type locality is at Northfield, Mass. (R.M.F.)

NOSE. A protuberance on the face of air-breathing **vertebrates** through which the respiratory passages lead. It is also associated in these passages with the sense of smell through the presence of the sensory olfactory epithelium.

A term used by **structural geologists** to define the end of a pitching **anticline.** Usually topographically expressed as a small open fold. (A.W.L., R.M.F.)

NOSE HEAVINESS, AIRPLANE. The condition of an airplane in which the nose tends to sink when the longitudinal control is released in any given attitude of normal flight. (See tail-heavy.) (F.T.M.)

NOSE LEAF. Complicated folds of skin, sometimes very extensive, on the snout of some **bats.** They are supposed to be provided with delicate sensory organs akin to the organs of touch. (A.W.L.)

NO-SEE-'EM. **Black Fly.**

NOSTRIL. The external orifice of a respiratory passage in the air-breathing **vertebrates.** There are usually two nostrils, but in some of the whales the respiratory system opens by a single aperture, called the nostril or blow-hole. External **naris.** (A.W.L.)

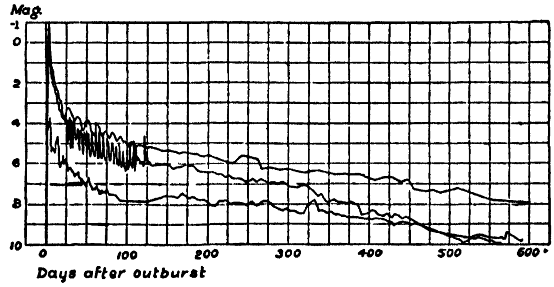
NOTCH SENSITIVITY. **Fatigue.**

NOTOCHORD. A longitudinal stiffening rod found in all **embryonic** chordates and in the adults of some of the lower members of this phylum (**Chordata**). It lies between the central **nervous system** and the alimentary tract (**digestive system**) and is the axis around which the spinal column develops. As the bony structure forms, the notochord is almost crowded out of existence. In the human body small remnants of it form the nuclei pulposi in the intervertebral disks. (A.W.L.)

NOTOPODIUM. The dorsal portion of the **parapodium** of **annelid** worms. (A.W.L.)

NOVA. There is probably no class of stars that attracts so much popular attention as the novae or "new stars." These objects suddenly appear in the sky at unpredicted time and place, in some cases becoming the brightest object in the sky for a few days. They then fade away and disappear from naked-eye observation, but may be followed telescopically for indefinite lengths of time. Many novae which do not attained naked-eye brilliancy are discovered and studied telescopically. It is impossible to give a definite estimate of the total number of novae which appear each year, for undoubtedly many escape detection. Bailey has estimated that 10 or more reach a brightness of the ninth **stellar magnitude** or greater each year. During the first 35 years of the present century there were 5 novae which reached conspicuous brightness.

In the accompanying figure we have represented the **light curves** of three of the bright novae of the present century. The ordinate scale of brightness is expressed in



Light curves of Nova Aquilae, 1918; Nova Persei, 1901; and Nova Germinorum, 1912. They are designated in order of decreasing height. (*Harvard College Observatory Annals.*)

stellar magnitude, and, since magnitude 6 is the limit of naked-eye visibility, the length of time that each was visible to the naked eye may be determined from the time scale at the bottom. These curves are characteristic of most novae, with the very rapid rise to maximum and then the relatively slow and irregular decline. Examination of photographic records indicates that novae are not actually "new stars" at all, but rather are faint stars which, for some unexplained reason, suddenly increase in intensity. An increase of 10 magnitudes is by no means uncommon, and this represents an increase of light intensity amounting to 10,000 fold.

Coupled with the increase in light intensity of a nova there is a correspondingly remarkable change in **spectral characteristics.** While the spectral changes in different novae vary to a considerable extent, nevertheless, there are certain stages of development which are more or less characteristic of them all. During the period of rise, in the few cases where increasing novae have been

detected in time for observation, the star is of the hot, blue A-type, with the absorption lines displaced very strongly to the violet. As the star starts to decline the color changes from white to yellow, and bright lines, particularly of hydrogen and ionized iron, appear. The bright lines then broaden out to bands of irregular structure which soon completely mask the continuous spectrum of the star. A few days later dark lines again make their appearance, and these are displaced far to the violet. Soon bright lines again appear, frequently of the type which are characteristic of the gaseous **nebulae**, except that they are broad. As the brightness of the star further decreases it eventually settles down to a peculiar O-type spectrum with bright lines superimposed on a continuous and dark line absorption spectrum.

There has been a great deal of research on the novae during the present century. The best theory is that, for some completely unexplained reason, a relatively faint star explodes and blows off an outer shell of gaseous material. Since this shell would rapidly expand after leaving the surface of the star, the displacement of the spectral lines to the violet may be explained as a **radial velocity** shift. There is further confirmation of the possibility of the expanding shell of gas in the fact that a nebulous envelope has actually been observed in certain novae. While the explosion and expanding shell hypothesis is by far the best of any thus far proposed, there is no explanation available as to what causes the terrific explosion necessary to drive the material out of the star against the enormous gravitational attraction. Other theories for the formation of novae from the collisions or very close approach of two stars have been advanced. In view of the approximately known distribution of stars in space and the average **space velocities** of the stars, the probability of a collision can be computed and is found to be far too small to account for the large number of novae which are observed.

Novae have been observed telescopically in some of the **extra-galactic** nebulae such as the great spiral in Andromeda. Since the distances of some of these objects are at least very approximately known, it is possible to get an approximation to the **absolute magnitudes** at maxima of the novae observed in them. For these extra-galactic novae we find absolute magnitudes of the order of -4, a value which compares favorably with those determined for the few cases where the distance of a galactic nova is known. (W.K.G.)

NOVACULITE. The term proposed by Cordier, in 1868, for a fine-grained or **crytocrystalline, cherty, metamorphic** rock essentially composed of **quartz** and other forms of **silica**. Accessory minerals are **feldspar** and **garnet**. Used for whetstones. (R.M.F.)

NOVOCAINE. Anaesthesia; Cocaine.

NOZZLES. A nozzle is a converging or converging-diverging tube attached to the outlet of a pipe, hose, or pressure chamber, the purpose of which is to convert efficiently the pressure existing in a fluid into velocity. Examples may be cited of nozzles for liquids, gases, and vapors. It may or may not be necessary to take compressibility of the fluid into consideration. Water in a hose or pipe at a pressure measured by a head of h ft. should, theoretically, spout freely from the pipe with a velocity equal to $\sqrt{2gh}$, in which g = **acceleration** due to gravity. However, unless a nozzle were applied, there would be a tendency of the water to begin to increase in velocity far enough back in the pipe so that a great deal of the head would be consumed in overcoming friction. A nozzle throttles the discharge down to a smaller stream, and allows a pressure to be carried in the pipe or hose adjacent to the nozzle. The percentage of ideal jet velocity actually obtained in a nozzle is known as the velocity coefficient. This coefficient ranges between .85 and .98 for nozzles of different shapes and designs. The discharge of water from a nozzle needs to be further corrected by allowing for the velocity of approach. As the water moves through the converging section of the nozzle towards the tip, it is increased in velocity, resulting in some tendency to offset reduction by velocity coefficient. Multiplying the computed velocity by

$$\sqrt{\frac{1}{1-\left(\frac{\text{tip diameter}}{\text{root diameter}}\right)^4}}$$

allows for this velocity of approach and gives the actual velocity at the tip of the nozzle.

The flow of air through nozzles may or may not involve compression. For example, compressed air jets used for cleaning have considerable expansion in the nozzles, from which high velocity is derived. Another case of an air nozzle is the entrance cone of a wind tunnel, in which an air stream is restricted in cross-sectional area, and increased in velocity. Here compressibility is not generally taken into account.

Steam nozzles are very definitely based upon expansion of steam. The nozzles of a steam turbine have to change the heat contained in steam into work, and direct the course of the steam onto the blades. The liberation of heat during the adiabatic expansion which occurs in steam nozzles increases the velocity of flow. Heat is liberated by a drop of pressure made possible by proper design of nozzle areas. The velocity attained by steam through **adiabatic** expansion can be found by application of the law of conservation of energy. The sum of the heat energy and kinetic energy in steam approaching a nozzle is equated to that leaving the nozzle, since there is no work done on the nozzle itself. This yields the formula:

$$V_2^2 - V_1^2 = 50{,}200H.$$

Here the V's are the velocity of approach and emergence from the nozzle, and H is the heat released by adiabatic expansion. When v cu. ft. of steam are flowing with a velocity of V ft. per sec., they require a flow area of $\frac{v}{V}$, so at any point of a nozzle the area is determined by the density of the steam and its velocity, both of these being determined by the pressure. The physical phenomena attending the variation in velocity and volume with change of pressure create a condition of a converging nozzle, that is, diminishing area, until the pressure becomes 58% (55% for superheated steam) of the initial pressure, after which the nozzle diverges. The final velocity, that is, the velocity at the mouth of the steam nozzle, is slightly less than that given by the above equation, because (1) reversible adiabatic expansions are not obtained, (2) there are frictional losses on the nozzle walls. (See **Jet; Pressure Vessels.**) (F.T.M.)

NUCELLUS. Flower.

NUCLEAR PARTICLES. Particles of atomic or sub-atomic mass, supposed to enter into the structure of the nuclei of atoms. Listed among these at present are the **alpha particle**, the **electron**, the **mesotron**, the **neutrino**, the **neutron**, the **positron**, and the **proton**. Some writers go so far as to include the photon, or quantum of **radiation**, under this head, since in some circumstances photons emerge from atomic nuclei and behave in certain respects like particles. Photons differ, however, from the other entities mentioned in that they have various masses (because they have various quantum energies), but always the same speed in a vacuum, whereas each of the others always has the same mass but may move with various speeds. (L.D.W.)

NUCLEIC ACIDS. Aminoacids, Polypeptides, and Proteins.

NUCLEOLUS. These are small rounded bodies found in the **nucleus** of the cell. Generally each nucleus contains a single nucleolus, but in many cases there are several. The function of the nucleolus is unknown. It seems to be a mass of accumulated material which is used in the **metabolic** processes going on in the nucleus. (R.M.W.)

NUCLEUS. 1. **Cell.** 2. A group of cell bodies in the central **nervous system** of vertebrates.

Examples are the red nucleus in the mid-brain, through which impulses are routed for the control of subconscious muscular movements, and Deiter's nucleus, lying at the junction of the medulla with the **hind-brain.** Through this center impulses pass for muscular action involved in the maintenance of equilibrium. (A.W.L.)

NUDA. Comb jellies (ctenophores) of large size and ovate or conical form, without tentacles. They constitute a class of this name in the phylum **Ctenophora.** It contains the single family Beroidae. (A.W.L.)

NUDIBRANCHIATA. Gasteropoda.

NULL HYPOTHESIS. The null hypothesis is the hypothesis which is being tested under the assumption that it is true. (L.A.A.)

NULL METHOD. Physical Measurement.

NUMBER. Historically, the various types of numbers of algebra were introduced gradually, step by step, as the need for them arose.

In the early stages of the development of man, the process of counting gave rise to the natural numbers or positive integers, 1, 2, 3, 4, 5, etc. These numbers serve to answer the question "How many?"

The process of measurement of quantities led naturally to the introduction of the positive rational fractions, examples of which are $\frac{1}{2}$, $\frac{2}{3}$, $\frac{5}{7}$, etc. These numbers are needed to assist in answering the question "How much?" From an algebraic viewpoint, the positive rational numbers were introduced in order to make division always possible. Positive rational fractions can be expressed as quotients of positive integers.

The positive irrational numbers were introduced through the incommensurable quantities which occur frequently in geometry; for example, the diagonal of a square is incommensurable with its side. Examples of such numbers are: $\sqrt{2}$, $\sqrt[3]{2}$, $5 + \sqrt{7}$, π, etc. From an algebraic viewpoint, the positive irrational numbers were introduced in order to help to make the extraction of roots always possible.

Quantities that could be measured in two opposite senses suggested the idea of the negative numbers; for example, temperature is measured above and below zero, and latitude is measured north and south of the equator. Algebraically, the negative numbers were introduced in order to make subtraction always possible. The negative numbers consist of several types: the negative integers -1, -2, -3, -4, etc., the negative rational fractions, such as $-\frac{3}{4}$, $-\frac{8}{5}$, $-\frac{1}{7}$, etc., and the negative irrational numbers, such as $-\sqrt{3}$, $-\sqrt[6]{6}$, $-1-\sqrt{2}$, etc.

The number zero, 0, is often used to indicate absence of quantity. Algebraically, zero is introduced to indicate the result of subtracting a number from itself.

The positive integers, the negative integers, zero, the positive rational fractions, and the negative rational fractions are grouped together to form the system of rational numbers.

The numbers of the rational number system together with the positive and negative irrational numbers are grouped to form the real number system.

Comparatively late in the historical development of algebra, the pure imaginary numbers and the complex numbers were introduced in order to make the extraction of roots of negative numbers and the solution of certain types of equations always possible. Examples of pure imaginary numbers are $\sqrt{-1}$, $\sqrt{-5}$, $-3\sqrt{-1}$, etc.; examples of complex numbers are $2 + 3\sqrt{-1}$, $-1 - \sqrt{-2}$, $\frac{1}{2} - \frac{1}{2}\sqrt{-3}$, etc.

The square of any real number is always a positive real number. But the pure imaginary numbers have the property that their squares are negative real numbers; thus, the square of the imaginary number $\sqrt{-3}$ is -3. Any complex number may be expressed as an indicated sum of a real and a pure imaginary number, as for example $2 + \sqrt{-3}$. The term "imaginary number" is sometimes used to mean complex number.

An irrational number cannot be expressed as a quotient of positive integers nor as a quotient of rational fractions. It may, however, be represented approximately by rational fractions, to any degree of approximation desired. Thus, the irrational number $\sqrt{2}$ may be represented approximately by the rational numbers 1.4, or 1.41, or 1.414, or 1.4142, etc. In fact, any irrational number can always be inclosed between pairs of rational numbers whose differences are as small as we please. Thus, $\sqrt{2}$ lies between 1.4 and 1.5, between 1.41 and 1.42, between 1.414 and 1.415, etc.

The absolute value (or numerical value) of a positive number is the number itself, while the absolute value of a negative number is the number with its sign changed. The absolute value of a number a is denoted by the symbol $|a|$. Thus, $|5| = 5$, $|-8| = 8$.

Real numbers may be represented graphically by points on a straight line, whose distances from some arbitrarily selected origin are the corresponding real numbers.

An algebraic number is a number which satisfies a **polynomial equation** in one variable with integral coefficients. A transcendental number is a number which is not algebraic, i.e., is not a root of a polynomial equation in one variable with integral coefficients.

Irrational numbers are either algebraic, as $\sqrt{2}$, $\sqrt[3]{5}$, $1 - \sqrt{3}$, etc., or transcendental, as π, e, etc.

Any type of number may be regarded as contained in the complex number system. If in the complex number $a + bi$, we have $b = 0$, the number is a real number a; if $a = 0$, the number is purely imaginary. (L.L.S.)

NUMBER SIZE DRILL. Drilling; Gauge Number.

NUMERICAL INTEGRATION. Approximate Integration.

NUNATAK. A topographic or physiographic term of Eskimo origin and meaning the top of a hill or mountain which projects above an ice sheet or continental glacier. (R.M.F.)

NUSSELT GROUP. Heat Transfer.

NUT. Screw Fastenings; Fruit.

NUTATION. For the use of this term in botany, see **Movements in Plants.**

Nutation in astronomy is a short periodic change in **precession.** Precession is caused by the attracting force of the sun and the moon tending to pull the equatorial bulge of the earth into the plane of the **ecliptic.** The amount of this force is changing throughout the year as the **declinations** of the sun and the moon change. For example, twice during each year both the sun and the moon are on the equator, and at those times their precessional forces are zero. The principal nutation is due to the periodic change in the plane of the moon's orbit, and has a period of about 19 years. Most of the nutation effects are periodic in character, but a complete account of them is beyond the scope of this work. (W.K.G.)

NUTCRACKER. Aves, Passeriformes. Birds (**Aves**) related to the crows and jays. The few species are confined to the northern parts of the northern hemisphere. The Clarke nutcracker, *Nucifraga columbiana,* lives principally at higher altitudes in the mountains of western North America. It is associated with coniferous forests. (A.W.L.)

NUTHATCH. Aves, Passeriformes. Small climbing birds (**Aves**) which cling in any position to the bark of trees as they search for food. They eat both insects and seeds. The most common North American species is the white-breasted nuthatch, *Sita carolinensis,* found throughout the United States east of the Rockies. The red-breasted nuthatch, *S. canadensis,* is more common in Canada and the mountains but migrates in winter as far as the southern states. The pigmy nuthatch, *S. pygmaea,* is a western species. Nuthatches are found on all other continents except South America, although in Africa they are confined to the north. (A.W.L.)

Nuthatch.

NUTMEG. *Myristica fragrans.* Myristicaceae. Nutmegs are the seeds of a tree native to the Molucca Islands. The tree grows 60′ tall, and has pointed **lanceolate** leaves. The trees are **dioecious,** pistillate (see **Pistil**) and staminate (see **Stamen**) flowers being borne on separate trees. Since the trees are frequently grown in cultivation, especially in favorable localities, it is necessary to plant some of both sexes to insure cross-pollination and seed formation. The flowers are pale yellow, the fruit a dark orange-colored berry containing a single large brown seed. Surrounding the seed is a branched deep red **aril,** which on drying becomes pale brown. The seed is the nutmeg of commerce, the aril is mace. Both the seed and the aril contain an aromatic oil, but only poor quality seeds are used for the oil. Both nutmeg and mace are well-known spices used in great quantities in the United States. (R.M.W.)

NUTRITION. The process of incorporating in the body the substances necessary for growth, repair, and energy. Constructive **metabolism.** Anabolism.

In the usual sense the term designates certain aspects of the entire process of securing food and incorporating it in the body, hence words describing the manner of nutrition indicate fundamental relations of the animals involved. All organisms which ingest animals or plants as food, as is true of most animals, carry on holozoic nutrition. They are also described as zootrophic or heterotrophic organisms. Those which have chlorophyll and are able to synthesize food from inorganic materials like the green plants and some one-celled animals, have holophytic nutrition, or are called autotrophic or phytotrophic organisms. Animals which absorb dissolved organic materials have saprozoic nutrition and those which live in another organism and use its materials carry on parasitic nutrition. No exact line can be drawn between parasitic and saprozoic animals for some parasites merely absorb food from the contents of the alimentary tract in which they live and so are, in the strict sense, saprozoic. The bodily association and dependence of parasitism also enter into the definition of this condition. (A.W.L.)

NUX VOMICA. Strychnine.

NYALA. Mammalia, Artiodactyla. An African harnessed **antelope,** *Tragelaphus angasi,* related to the bongo and nakong. It is blue-gray with faint white stripes. Found in swampy jungles of eastern Africa. (A.W.L.)

NYLON. This is a generic term applied to "any long-chain synthetic polymeric amide which has recurring amide groups as an integral part of the main polymer chain, and which is capable of being formed into a filament in which the structural elements are oriented in the direction of the axis." A typical reaction mixture is 14.8 parts of pentamethyleneamine, 29.3 parts of sebacic acid, and 44 parts of mixed xylenols. The filament nylon is silky in appearance, relatively insensitive to moisture and mildew, and of superior elastic recovery (better than silk) and tensile strength (better than silk and rayon). Nylon is specially adapted for hosiery, knitted and woven goods, shoe laces, bristles for brushes, and transparent wrapping film; also for parachute fabrics, glider tow-ropes, and as fabric for airplane tires. (R.K.S.)

NYMPH. An immature insect of the forms which have gradual metamorphosis (**Paurometabola**). Nymphs resemble adults but have wings in the developmental state. (A.W.L.)

NYMPHAEACEAE. Water Lilies.

NYMPHOMANIA. Abnormal degree of sexual desire in the female. (R.S.M.)

NYSTAGMUS. An involuntary rapid movement of the eyeball which may be from side to side, up and down, circular, or a combination of these movements. It may be due to incoordination of the eye muscles, disturbances of the nerves of the eye, or to disturbances of the vestibular canals in the ear. (R.S.M.)

O

O SERIES. X-ray Spectra.

OAKS. *Quercus* sp. Fagaceae. The oaks are trees and shrubs of the north temperate region. All the more northern species are **deciduous** plants. Many of those in the southern part of the range have evergreen leaves, and are often called live oaks. In Asia and the Pacific coast of North America, oaks are found in regions approaching tropical conditions.

The 300 species of this genus have simple alternate leaves. The flowers are of two kinds, borne on the same tree. The pistillate (see **Pistil**) flowers are borne singly and are surrounded by an **involucre** of many scales beyond which the **stigmas** protrude. The staminate (see **Stamen**) flowers are borne in long slender pendant **catkins.** Pollination is by wind. The fruit is an acorn, a **nut** of characteristic cylindrical shape, capped by the small persistent style-base, and seated in the scaly involucre, which forms a cup partially or almost wholly surrounding the nut.

Many of the oaks are valuable trees, yielding woods which have a variety of uses. In early times, before the day of the sawmill, oaks were much used in the construction of buildings. Often the oaks used for this purpose were split into thin planks, a method of preparation which served well to bring out the attractive grain of the **wood.** This grain is due partly to the numerous large vessels which are formed periodically every spring and appear as very evident dark lines or streaks in the wood, and partly to the large **vascular** rays which appear as irregular flakes, especially when the wood is split in a radial plane. In modern construction oak is often used as paneling or flooring. To obtain the best grain, the wood is quarter-sawed, that is, cut in such a way that the flat surfaces shall be as nearly radial as is possible. Because of its beauty and also its durability, oak wood is also much used in furniture making. In America the principal species used for wood is white oak, *Quercus alba.* In Europe several species are used, among them the British oak, *Quercus Robur.* Often these European oaks are trees of remarkable size, and are preserved because of their rugged beauty. The wood is very strong and durable, and finds considerable use in ship construction. Formerly much more was used for this purpose.

Accidents sometimes cause the formation of oak wood of special properties and value. The trunks of fallen trees may lie buried for long periods of time in bogs or elsewhere. Sometimes, when removed, these logs are found to be perfectly sound and to have developed a rich dark brown or nearly black color, which makes them especially sought after for furniture making. Such oak is known as bog oak. Living trees frequently develop large irregular growths, known as burls, in which a very irregular much-contorted grain is found. The custom of cutting back the top of the tree, causing the development of numerous **adventitious buds,** a practice known as pollarding, causes a similar irregular grain. These burls are used for making **veneers.** Another species of oak, *Quercus Suber,* yields **cork.**

Oaks are valuable sources of **tannin.** In many species the bark is the source of the tannin, but in *Quercus Aegilops,* a native of eastern Europe and Asia, a tannin known as valonia is obtained from the cup and the young acorns.

African oak, a strong, heavy wood, comes from African trees of other genera than *Quercus.* This wood is rarely used, due to the difficulty of removing the heavy wood from its native forest. (R.M.W.)

OATS. *Avena sativa.* Gramineae. Oats are annual cereal grasses native in temperate regions of the Old World. The several species of oat plants are characterized bv their closed leaf-sheath, a wide-branched **panicle,** and by a special type of **inflorescence.** In the **florets** of wild oat plants the **lemma** has the midrib prolonged as a prominent **awn,** the basal portion of which is spirally twisted. In many cultivated forms this awn has been eliminated. The grain of oats is not easily separated from the surrounding husk, composed of the lemma and **palea,** which are neither palatable nor digestible.

Oats are principally adapted to growing in a climate having cool summers and abundant moisture. However, the plants are very hardy and tolerant of adverse conditions. Oats are used principally for grain. The straw is used either for bedding livestock or as a rough cattle food. The grain is an important article in horse feeding. A comparatively small part of the total oat harvest is used for human consumption in the form of rolled oats and oatmeal. In manufacturing rolled oats the grain is first carefully cleaned and graded according to size, then passed between two millstones so placed that by the revolution of one against the other the husks are removed and withdrawn by suction. The cleaned grains are steamed, and in the case of "Quick Oats," partially cooked, and then passed between heavy rollers and dried, after which they are ready for the market. (R.M.W.)

OBESITY (Adiposity). A state of the body in which excessive fat is stored in the tissues. This is one of the most common disorders to which the human race is subject. The prevention and treatment of obesity are important, not only for the sake of appearance, but also because obesity decreases human efficiency, shortens life and predisposes the subject to many disorders.

The fundamental cause of obesity is the absorption of a greater number of calories than is necessary for the total amount of energy expended by the body. It is also true that, while two persons may eat the same amount of food, one may gain and the other lose weight. This difference is due to factors regulating the amount of energy expended. One who gains weight and who does not apparently eat to excess (such a person usually eats more than he realizes or admits) is usually phlegmatic, reacts slowly to outside stimuli, is not easily worried, dislikes exercise or expenditure of energy in any form, sleeps longer and more soundly, and relaxes more completely than either the thin person or the one of normal weight. A few people who fall in the overweight group have disturbances of the endocrine glands, especially the **thyroid** or **pituitary** or both. But most obesity is due to the one factor of simply liking to eat large quantities of fattening food—carbohydrates, starches and fats.

Marked obesity can cause shortness of breath and fatigue on slight exertion. It also seems to predispose to certain diseases or accentuate their symptoms. An individual with heart disease may develop heart failure sooner than a thin person with the same degree of cardiac disease. Arthritics having pain in the legs or back notice considerable improvement in their symptoms, as a rule, with reduction in weight. Obesity is a factor in **diabetes.** Obese patients seem to be unable to cope with such diseases as **pneumonia** as well as the normal individual.

Prevention of obesity is simpler than its treatment. Treatment lies along two lines. First, the amount of

food must be reduced and at the same time a balanced diet, adequate in minerals and vitamins, achieved. The rapid loss of weight by radical diets is harmful. Second, increase in exercise, which unfortunately increases the appetite. (D.M.H.)

OBJECTIVE. **Optical Instruments; Telescope; Microscope; Camera.**

OBJECTIVE PRISM. In the ordinary laboratory **spectrograph** a collimating lens is necessary in order that the light from the narrow slit may be sent through the **dispersing** agent in a parallel beam. At the principal focus of the camera lens the images of the slit in the different radiations are commonly known as the **spectral lines.**

The stars are at such tremendous distances that they subtend infinitesimal angles and the light from them reaches the earth in parallel beams. Hence the slit and collimating lens of the laboratory spectrograph are unnecessary and the dispersing agent, usually a prism, may be placed directly before the objective lens of the telescope or astrographic camera. With such an instrument, commonly known as an objective prism, instead of single-point images of the stars, there appear on the photographic plate a series of dots, each of them in some particular radiation from the stars, or, in other words, the **spectra** of the stars. In order that the spectra may have appreciable width or that the spectral lines may have length instead of appearing as mere dots, the refracting edge of the prism is set parallel to the spherical coordinate of **right ascension** and the telescope driven a bit too fast or too slow, slightly "trailing" the images.

The objective prism has certain important advantages over the slit spectrograph for astronomical purposes. On each plate taken with the instrument we obtain spectra of a great number of different stars. Furthermore, the loss of light at the narrow slit is obviated and the exposure time necessary to obtain a good spectrogram will be greatly diminished. In contrast to the advantages in speed of the objective prism there is the serious disadvantage that it is impossible to obtain good comparison spectra with such an instrument, and the determination of accurate wavelengths of the different radiations is practically impossible.

The objective prism is used primarily for the determination of the **spectral classes** of the stars and to determine the relative intensities of the different lines and regions of the spectra. Within recent years attempts have been made to determine **radial velocities** of the stars with this instrument and results obtained are of sufficient accuracy for statistical purposes. The **flash spectrum** is often obtained by use of the objective prism. (W.K.G.)

OBLIQUE COORDINATES IN A PLANE. Let any two non-perpendicular intersecting lines in a plane be chosen as reference axes; let P be any point in the plane, and through P draw lines parallel to the axes. The distances, parallel to the axes, from the axes to the point P are called oblique coordinates of the point. (L.L.S.)

OBLIQUE REPRESENTATION. **Orthographic Projection.**

OBLIQUE TRIANGLES. **Triangles.**

OBLIQUES (PAIRED). **Photogrammetry.**

OBSEQUENT STREAMS. **Consequent Streams.**

OBSIDIAN VOLCANIC GLASS. Highly acidic lavas (those containing a preponderance of **silica**), when chilled very rapidly and congealed, without appreciable crystallization, into a rigid liquid solution. Such a solid is called a glass to distinguish it from a crystalline substance. Pure obsidian is hard, with conchoidal fracture and vitreous luster. Thin chips appear smoky-gray or red in transmitted light. The exceptionally dark color of obsidian, as compared with chemically related crystalline rocks (**rhyolite and granite**) is due to the fact that a small amount of coloring matter is much more effective in a solution than when segregated in a few dispersed dark-colored minerals. (R.M.F.)

OBSTETRICS. The branch of medicine and surgery which has to do with the management of **pregnancy,** labor and the complications and disorders arising from them. (R.S.M.)

OCCIPITAL BONE. A bone of the vertebrate **skull** located at the posterior end of the dorsal wall. It is a median unpaired bone. (A.W.L.)

OCCLUSION. **Adsorption; Wave Cyclones; Minerals, Rocks.**

OCCULT MINERALS. A term proposed by Iddings, in 1913, for mineral compounds which, because of the chemical composition of an **igneous rock,** should be either potentially or actually present, but which cannot be detected by the **petrographic** microscope. (R.M.F.)

OCCULTATION. When the **moon** passes between a star and the earth, the light of the star is cut off and the star is said to be occulted. The term **eclipse,** which is technically correct for this phenomenon, is reserved for circumstances involving the **sun, earth,** and **moon,** and for such things as **eclipsing binaries, satellites of Jupiter,** etc. As the moon passes between the earth and a star in its revolution about the earth the star disappears behind the eastern edge of the moon and reappears again at the western edge. The disappearance and reappearance are practically instantaneous; proving both that the moon has no sensible atmosphere and that the star appears sensibly as a point of light. The interval between disappearance and reappearance depends fundamentally upon how closely the center of the moon appears to pass across the star.

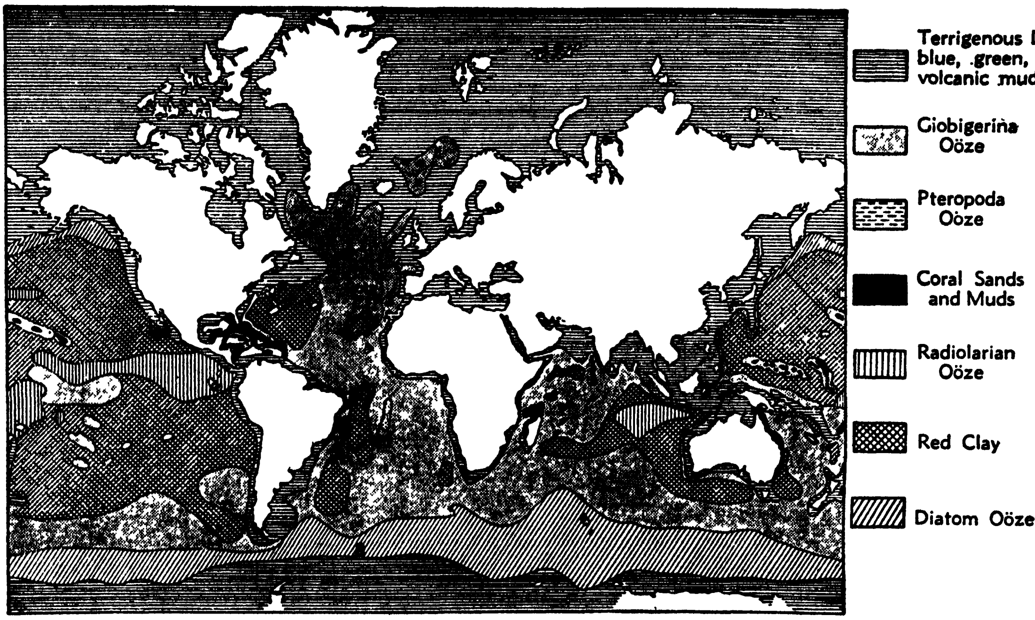
Since the disappearance and reappearance are practically instantaneous, the times of the phenomena can be determined with great precision. Observations of the instants of occultation of stars by the moon may be used to determine the position of the moon with great precision. A large number of such occultations are observed both by professional and amateur astronomers, and the results used to verify and correct the theory regarding complicated motions of the moon. The differences in the time of occultation of a given star, as observed by widely separated observers, may be used both to determine the distance of the moon and also to determine the difference in terrestrial **longitude** of the two observers. This method of determination of difference in longitude was the most accurate available before the development of modern methods for distribution of Greenwich **Time.** (W.K.G.)

OCEANIC DEPOSITS. The map on the facing page shows the distribution of the different types of deep-sea or oceanic sediments. (R.M.F.)

OCELLUS. 1. The simple **eye** of **arthropods.** Usually very small. 2. An eye-like spot. The wings of many butterflies and moths bear such markings. (A.W.L.)

OCELOT. Mammalia, Carnivora. A moderately large South American **cat,** *Felis pardalis,* which ranges north to the Rio Grande. It is tawny or reddish, marked with black spots and blotches.

This species has been recorded from southern Texas (A.W.L.)



Distribution of marine-continental and oceanic deposits. (*After Scott. After Collet.*)

OCTAHEDRITE. The mineral octahedrite, **titanium** dioxide, TiO_2, is a rare mineral crystallizing in the **tetragonal** system. It has the same chemical composition as **rutile** and **brookite**. It commonly occurs in **octahedral** crystals, either acute or obtuse, hence the name. (See **Rutile.**) (E.S.C.S.)

OCTANE NUMBER. Detonation.

OCTANE RATING. Gasoline.

OCTOPUS. Mollusca, Cephalopoda. A genus of marine **mollusks** commonly called **devil fishes** but also known by the anglicized generic name. They have a large head bearing eight similar arms or tentacles, each with many suckers. The arms are webbed at the base, and in a related genus the webs unite them almost to the tips. (See also **Invertebrate Paleontology.**) (A.W.L.)

ODONATA. The **dragon flies** and **damsel flies**, an order of insects containing moderate to large species with slender bodies and four narrow net-veined wings. Their flight is powerful and they are well adapted to take their insect prey on the wing. The mouth is formed for biting. In the immature stages these insects are aquatic. Commonly called devil's darning needles. The order contains about 2700 species and is represented in all parts of the world. (A.W.L.)

ODONITE. The term proposed by Chelius, in 1892, for a basic **igneous rock** with a **porphyritic** texture whose **phenocrysts** are **labradorite** and **augite** in a matrix composed of **feldspar** and **hornblende.** (R.M.F.)

ODONTOCETI. The toothed whales, an order of marine mammals containing the **dolphins, narwhal, porpoises,** etc. A few species live in the large tropical rivers, including the Ganges and the Amazon. (A.W.L.)

ODONTOLITE. Turquoise.

OENOCYTE. A kind of large **cell** found in clusters associated with the **tracheae** and fat bodies of insects. Larval oenocytes have been interpreted as **endocrine glands** and those of adults are apparently for the storage of waste products. (A.W.L.)

OERSTED. The practical unit of magnetic intensity. The term oersted, prior to 1932, was used to designate the practical unit of magnetic reluctance (see **Magnetism**). By international agreement, however, it now replaces the term **gauss,** which formerly denoted a unit of magnetic field intensity; while the unit of magnetic reluctance is left without a name. The value of the oersted of magnetic intensity may be expressed in the same way as that used in defining the gauss of magnetic induction; but it is simpler to state that if a unit north magnetic pole is placed in a vacuum traversed by a magnetic field of intensity 1 oersted, the pole is urged in the direction of the field with a force of 1 **dyne.** (L.D.W.)

OERSTED EXPERIMENT. Electromagnetism.

OGIVE. The graph of the **cumulative frequency distribution,** or the graph of the **distribution function** in the case of a **continuous variate.** (L.A.A.)

OHM. The practical unit of electrical **resistance.** It is defined in two ways. The absolute ohm is that resistance which causes a potential drop of 1 absolute **volt** when a steady current of 1 absolute **ampere** flows through it; it is equal to 10^9 abohms (see **Electrical and Magnetic Units**). The international ohm is based upon a specified conductor; viz., it is the resistance of a uniform thread of mercury in a capillary tube of such diameter that the thread is 106.3 cm. long and weighs 14.4521 grams, its temperature being 0° C. (This gives the thread a cross section of almost exactly 1 sq. mm.) Unfortunately the two units are not quite equal, the international ohm being larger by about 46 parts in 100,000. In more familiar terms: a No. 16 copper wire (0.05″ in diameter), having a resistance of 1 ohm, would be about 264′ long. The resistance of a 110-volt, 50-watt lamp in full operation is 242 ohms. Occasional use is made of the megohm (1,000,000 ohms) and the microhm (0.000001 ohm). (L.D.W.)

OHMMETERS. The accurate measurement of resistance is somewhat tedious, and various instruments

have been devised to make direct readings in ohms. For example, one may send a current from a source of known electromotive force E and known internal resistance R through an unknown resistance R_x, a voltmeter being placed across the terminals to register the resulting potential drop V. From these the resistance can be calculated; for, using Equation 3 under **Electric Circuits** and substituting therein V for $V_A - V_B$, R_x for R_{AB}, $R_i + R_x$ for R, and zero for E_{AB} (since the terminals A, B are here the terminals of the unknown, inactive resistance R_x), we obtain

$$V = \frac{R_x}{R_i + R_x} E,$$

from which

$$R_x = \frac{VR_i}{E - V}.$$

Obviously, for a given, fixed electromotive force, the voltmeter scale might be graduated directly in ohms. But the reliability of such an instrument requires a strictly constant electromotive force. The more approved types of ohmmeter use the slide-wire **bridge** principle, with the slide-wire scale graduated in ohms. These instruments, though accurate, are necessarily somewhat restricted in range. A form of high-resistance ohmmeter, designed by Evershed, is graduated in megohms and is known commercially as a "megger." This is a type of differential, moving-coil galvanometer, in which part of the coil is in series with the unknown resistance, while another part, carrying current from the same source, is independent of that resistance. The galvanometer reading depends upon the relative currents in the two parts, and hence upon the unknown resistance. (L.D.W.)

OHM'S LAW. This very familiar law of electric **conduction,** stated by George Simon Ohm in 1827, is expressible in various forms, of which the following is typical: The steady electric current in a metallic circuit is proportional to the constant total electromotive force operating in the circuit: $I = KE$. The constant K, known as the "conductance" of the circuit, is the reciprocal of the **resistance** R; so that the equation may be written in the more usual form

$$I = \frac{E}{R}.$$

Emphasis must be placed on the constancy of the electromotive force and the current. For, if the current varies, the effects of **inductance** and **capacitance** set up extra electromotive forces, positive or negative, which render the law expressible in general only by a differential equation. (See **Transients, Alternating Currents,** and **Electric Circuits.**) Also there are certain kinds of conduction for which the law is not valid; notably that of **ionized gases, thermionic vacuum tubes** and **photoelectric cells.** (L.D.W.)

OIL. Volatile Oils; Fixed Oils; Paints; Hydrocarbons; Lubrication; Lubricants.

OIL HOLE DRILL. Drilling.

OIL POOLS. Petroleum.

OIL SANDS. Petroleum.

OIL SHALE. A general term applied to a group of fine black to dark brown **shales** rich enough in **bituminous** material (called kerogen) to yield **petroleum** upon appropriate distillation. Oil shales are only of economic importance in those countries which are notably deficient in petroleum. The United States has vast reserves of oil shales. (R.M.F.)

OIL WELLS. Petroleum.

OILLESS BEARING. The term is really a misnomer, but refers to a device used to replace the usual metallic, oil-lubricated bearing where lubrication is difficult or likely to be overlooked. One form of oilless bearing is made of maple, impregnated with 40% grease; in another, a bushing is made by the powder metallurgy process, and impregnated with oil by immersing it in a hot bath of the lubricant. (H.C.H.)

OILS, ESSENTIAL. Perfumes; Volatile Oils.

OILS, FATTY. Esters.

OILS, PETROLEUM. Hydrocarbons.

OILS, VOLATILE. Volatile Oils.

OKAPI. Mammalia, Artiodactyla. *Okapia.* An African forest animal related to the giraffe but smaller and with shorter legs and neck. They are dark brown with white stripes on the hind quarters. (A.W.L.)

OKRA. *Hibiscus esculentus.* **Mallow Family.**

OLD MAN. 1. The great gray **kangaroo,** *Macropus giganteus.* 2. Aves, Cuculiformes. A Jamaican name for a cuckoo, also called the rain bird. (A.W.L.)

"OLD RED" SANDSTONE. Devonian.

OLD SQUAW, OLD WIFE. Aves, Anseriformes. A small **duck,** *Clangula hymenalis,* of the northern latitudes of the northern hemisphere, migrating into the United States in winter. It is chiefly black and white and the male has a long slender tail. Also called the long-tailed duck. (A.W.L.)

OLDHAMS COUPLING. Coupling.

OLEFIN. Hydrocarbons.

OLEIC ACID AND OLEATES. Oleic acid ($H \cdot C_{18}H_{33}O_2$ or $C_{17}H_{33} \cdot COOH$ or $CH_3(CH_2)_7CH{:}CH(CH_2)_7 \cdot COOH$), is a colorless liquid, melting point 14° C., boiling point 286° C. at 100 mm. pressure, insoluble in water, miscible with alcohol or ether in all proportions. Oleic acid differs from **stearic acid** chemically by possessing 33 instead of 35 hydrogen atoms in the radical ($C_{17}H_{33} \cdot COOH$ (oleic acid), $C_{17}H_{35}COOH$ (stearic acid)). It is possible to convert oleic acid and oleate esters into stearic acid and stearate esters by treatment with **hydrogen** gas in the presence of finely divided **nickel** as a **catalyzer** at 250° C. under pressure as in the **hydrogenation** of oils and fats. Either by careful oxidation, or by addition of ozone (see **Oxygen**) and splitting, oleic acid yields products of 9 carbon atoms, thus leading to the conclusion that the double bond is in the center of the carbon chain. Oleic acid adds **bromine** or **iodine** in definite amounts to confirm the conclusion that one double bond is contained. **Nitric acid** converts oleic acid into elaidic acid ($C_{17}H_{33}COOH$), melting point 51° C. (oleic and elaidic acids are related, cis- and trans-, as maleic and fumaric acids).

Oleic acid may be obtained from glycerol trioleate, present in many liquid vegetable and animal non-drying oils, such as olive, cottonseed, lard, by **hydrolysis.** The crude oleic acid after separation of the water solution of **glycerol** is cooled to fractionally crystallize the stearic and **palmitic acids,** which are then separated by filtration, and fractional distillation under diminished pressure. Oleic acid reacts with **lead** oxide to form lead oleate, which is soluble in ether, whereas lead stearate or palmitate is insoluble. From lead oleate oleic acid may be obtained by treatment with **hydrogen sulfide** (lead sulfide, insoluble solid, formed). With **sodium**

oleate, a soap is formed. Most soaps are mixtures of sodium stearate, palmitate, and oleate.

Representative esters of oleic acid are: methyl oleate ($C_{17}H_{33}COOCH_3$) boiling point 190° C. at 10 mm. pressure; ethyl oleate ($C_{17}H_{33}COOC_2H_5$) boiling point 205° C. at 10 mm. pressure; glyceryl trioleate (triolein) ($(C_3H_5(COOC_{17}H_{33})_3)$) boiling point 240° C. at 18 mm. pressure.

Oleic acid is used in the preparation of metallic oleates, such as aluminum oleate for thickening lubricating oils, for water-proofing materials, and for varnish driers. As the glyceryl ester oleic acid is one of the constituents of many vegetable and animal oils and fats. (R.K.S.)

OLEO SHOCK ABSORBER. **Shock Absorber.**

OLFACTORY ORGAN. Organs of the sense of smell. These organs are stimulated by minute quantities of material such as diffuse through the air in the form of gases or vapors. In a broad sense they sample materials in the animal's environment in the form of gases or vapors, although these substances probably dissolve in the body fluids before they act on the sensory ending. Like the organs of taste, olfactory organs are chemoreceptors, reacting to chemical properties, and in some animals it is difficult to distinguish accurately between the two senses. The fact that they are activated by minute concentrations, sometimes as low as one part in one million of air, gives them a wider range of perception. Whereas taste demands actual contact with a solid or liquid material, the volatile products may diffuse rapidly and over long distances from such a source and are readily carried by air currents.

Sense organs of many lower animals which live in water are more logically interpreted as organs of taste or as more primitive chemoreceptors, since materials must reach them in solution. Some aquatic insects and fishes, however, have olfactory organs enclosed in cavities which open to the exterior. Whether reached by water or not, they are classed as olfactory organs from their resemblance to such organs in related terrestrial forms.

The olfactory organs of insects are most abundant on the **antennae.** They consist of blunt processes or flat plates, associated with sensory nerve endings. In some cases they are grouped in the lining of depressions. As many as 39,000 have been reported on a single antenna and five or six thousand are frequently present.

In the **vertebrates** the olfactory cells lie in the epithelium lining a pair of olfactory pits which form in the embryo as depressions at the anterior end of the head. These cells are connected with the brain by the fibers of the olfactory nerves, the most anterior pair of cranial nerves of known function. In the air-breathing vertebrates the olfactory epithelium becomes part of the lining of the nasal passages.

The keenness of smell and its varied uses are well illustrated by dogs. Man has very nearly abandoned the sense through depending more on vision for distant perception, although he is usually more aware of odors when he cannot see. The sense is keener in man than we usually realize, but it is much less keen than in other animals. (A.W.L.)

OLIGOCENE. A geologic period of the **Tertiary,** of the Lower **Cenozoic** era of the **geologic time-scale.** The term was proposed by Beyrich in 1854. Type locality near Paris, France. Maximum thickness of strata in Italy. This period began approximately 36,000,000 years ago and lasted for about 16,000,000 years. In the United States marine sediments overlap the Cretaceous and earlier Tertiary sediments of the Atlantic border of South Carolina and the Gulf of Mexico. Marine sediments also occur on the Pacific Coast. Terrestrial sediments are well developed in the easterly Great Plains and Oregon (John Day Basin). The "Bad Lands" of South Dakota, eastern Wyoming, and North Dakota (Black Hills) are important collecting localities for the fossil mammals of this period. In the Paris Basin occur fresh and brackish water deposits, which contain numerous **fossil vertebrates, invertebrates,** and plants (see **Paleobotany**). The Oligocene formations are also well developed in Germany, and in the Alps. The marine invertebrates and fishes of the Oligocene are similar to those in the Eocene. Among the mammals the true carnivores have replaced the **creodonts.** The principal types of mammals are the Archaeotherium (giant pig), Poebrotherium (ancestor of the camels), Mesophippus (early horse), Hyracodon (cursorial rhinoceros), and Hoplophoneus (progenitor of the sabertoothed cats). (See also **Fossil Mammals.**) For mineral resources of this period see the **Tertiary.** (R.M.F.)

OLIGOCHAETA. **Chaetopoda.**

OLIGOCLASE. **Feldspar.**

OLIGOTRICHIDA. **Ciliophora.**

OLIVE. *Olea europaea.* Oleaceae. The olive is a small tree indigenous to the eastern Mediterranean region. It has **lanceolate** evergreen leaves, small inconspicuous flowers, and a purplish **drupe,** the flesh of which is very bitter in the natural state. Cultivation of the tree has continued through many centuries, gradually spreading not only to all Mediterranean countries, but abroad to suitable regions both in the Old and the New Worlds. In the United States, olive growing is largely restricted to California, and even there it is not a major crop. The wood of the tree is used to a limited extent.

The principal product is the oil, which is expressed from the flesh of the fruit. To obtain this oil the fruit is picked when ripe and usually allowed to dry a bit to remove some of the water contained in the flesh. Pressing freshly picked fruits yields a much higher grade of oil. Pressing is often done in a rather primitive machine. The fruit is first crushed and then firmly pressed The best grade of oil is known as virgin oil.

Olive oil is widely used as a food or in the preparation of food, owing to its lack of objectionable taste. Cheaper grades are used in soap-making. Sardine packers require large quantities for packing their product. In recent years olive oil has been much adulterated with cottonseed, sesame, peanut, and other oils. (See **Esters.**) (R.M.W.)

OLIVENITE. The mineral olivenite is a complex basic **arsenate** of **copper** with the formula $Cu_3As_2O_8 \cdot Cu(OH)_2$. It appears as prismatic, sometimes acicular **orthorhombic** crystals or may be fibrous to granular and earthy. It is brittle; hardness, 3.; specific gravity, 4.1–4.4; luster, vitreous; color, usually some shade of green but may be brownish, less frequently yellowish or grayish; translucent to opaque. Olivenite is a rare secondary mineral found associated with other copper minerals in various localities in France, England, South West Africa, and in the United States in the Eureka and Tintic mining districts of Utah. The name olivenite is derived from its olive-green color. (E.S.C.S.)

OLIVINE. The mineral olivine is an **orthosilicate** of **magnesium** corresponding to the formula $(Mg,Fe)_2SiO_4$, in which the ratio of magnesium to iron is found to vary considerably. Olivine crystallizes in the **orthorhombic** system in somewhat flattened forms but may occur massive or granular. It has a conchoidal **fracture** and is rather brittle; the hardness is 6.5–7; specific gravity, 3.27–3.37; luster, vitreous; color, olive-green; may be reddish from the oxidation of the iron. It is transparent to translucent. Olivine occurs both in **igneous rocks** as a primary mineral as well as in certain

rocks of **metamorphic** origin. It has also been discovered in **meteorites**.

Olivine crystallizes from **magmas** that are rich in magnesia and low in silica which form such rocks as **gabbros, norites, peridotites** and **basalts**. The metamorphism of impure **dolomites** or other sediments in which the magnesia content is high and silica low seems to produce olivine.

Transparent olivines of good color are sometimes used as a gem, often called *peridot,* the French word for olivine; it is also called chrysolite from the Greek meaning gold, and stone. Olivine occurs in the lavas of Vesuvius and Monte Somma and in the Eifel district of Germany. Gem material comes from St. John's Island in the Red Sea, Upper Burma, and from Minas Geraes, Brazil. In the United States olivine localities are Orange County, Vermont; Webster and Jackson Counties, North Carolina. Arizona and New Mexico have also furnished some gem material. (E.S.C.S.)

OLM. Amphibia, Urodela. A European **salamander** with a long snake-like body, very small legs, and tufted external gills. It is found in subterranean waters, and in correlation with this habitat has rudimentary eyes. (A.W.L.)

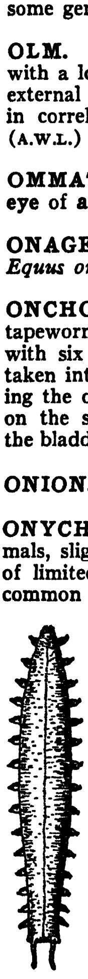
OMMATIDIUM. The structural unit of the compound **eye** of **arthropods.** (A.W.L.)

ONAGER. Mammalia, Perissodactyla. A wild **ass,** *Equus onager,* of western India. (A.W.L.)

ONCHOSPHERE. An early embryo or **larva** of the tapeworm (**Cestoda**). It is a small rounded organism with six hooks which hatches from the egg after it is taken into the alimentary tract of a host. After hatching the onchosphere lodges in various tissues, depending on the species to which it belongs, and develops into the bladder worm or another intermediate stage. (A.W.L.)

ONION. **Allium.**

ONYCHOPHORA. Small, soft-bodied, creeping animals, slightly like caterpillars in appearance. They are of limited distribution in warm countries and have no common name. The name of one genus, *Peripatus,* is sometimes applied indiscriminately to all members of the group.



Peripatus.

These animals form a class of the phylum **Arthropoda** characterized as follows: 1. The body is metameric but segments are not distinctly marked externally. 2. The head consists of three segments but is not distinctly separated from the body. 3. The first segment bears a pair of **antennae.** 4. The mouth is provided with a pair of jaws and a pair of oral **papillae.** 5. Each segment of the body bears a pair of legs which are fleshy protuberances ending with a pair of claws. 6. Each leg contains an excretory tubule. 7. Respiration is carried on by air tubes or **tracheae** whose external orifices are irregularly placed. 8. Unlike other arthropods, these animals have cilia in the alimentary tract and reproductive system.

Onychophora are regarded as the most primitive of the terrestrial arthropods. Their structure suggests the ancestral form of the insects. (A.W.L.)

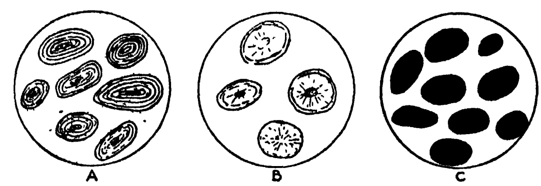
ONYX. **Agate.**

ONYX MARBLE. A trade term for a variegated, crystalline **limestone** which resembles the cryptocrystalline variety of **quartz** called **onyx.** Not a true **marble** since it is not a **metamorphosed** limestone. Onyx is usually formed as encrustations around springs which are particularly rich in **calcium** carbonate. Much used for interior ornamental purposes. (R.M.F.)

OOECIUM. A brood pouch in which the **embryo** develops in **bryozoans.** Nourishment is supplied during this period by specialized cells in the walls of the ooecium. Regarded as a modified **zooecium** and also called the ovicell. (A.W.L.)

OÖGONIUM. **Gamete.**

OÖLITE. The term is from the Greek meaning egg and stone. Oölites are well-rounded sand-like particles, originally formed of calcite but sometimes subsequently altered to either dolomite, or entirely silicified. Structure typically concentric about a nucleus, and often with radial lines. In the accompanying figure, A and B (typical oölites) and C are probably the excrement of worms. Oölites are relatively common constituents of



Different types of oölites. *A* and *B* typical oolites, *C* probably the excrement of marine worms. (*Field, Outline of Geology, Princeton University Press.*)

limestones, often forming distinct beds. Oölites are now forming on the shores of Great Salt Lake, but no authentic cause is known of marine oölites being formed at the present time. Coarse-grained oölites, in which the particles are about the size of peas, are called pisolites, from the Greek, meaning pea and stone. (R.M.F.)

OÖLOGY. A division of biology which deals with the eggs of birds. It is scarcely a science, but is rather a part of **ornithology.** (A.W.L.)

OÖSPORE. An oöspore is a thick-walled plant cell formed by the union of two unlike **gametes.** It is therefore a fertilized egg surrounded by a special protective coating. Certain **algae** such as Vaucheria have oöspores. (R.M.W., B.S.M.)

OÖTYPE. A region of the genital passages of flatworms (**Platyhelminthes**) at the junction of the oviducts and vitelline ducts. At this point the walls are thickened and a special secretion aids in forming the shell of the egg. (A.W.L.)

OOZE. Ooze is a general term used to designate the mud found on the ocean bottoms at abyssal depths and composed largely of the calcareous and silicified shells of minute surface living marine organisms, called **plankton.** (R.M.F.)

OPAH. Pisces, Teleostei. A beautifully colored Mediterranean and Atlantic fish (**Pisces**), *Lampris luna,* also called the sunfish. It reaches a length of 4′. (A.W.L.)

OPAL. The mineral opal is amorphous hydrated **silica,** the water content being sometimes as much as 20%. It has, of course, no crystal form, occurring as irregular **veins** and masses. It has a conchoidal fracture; hardness 5.5–6.5; specific gravity 2.1–2.3; luster, vitreous or greasy to dull; color, very variable, colorless, white, milky-blue, gray, red, yellow, green, brown and black. Often a beautiful play of colors may be observed in the gem varieties. These interference colors result from

minute cracks in the opal which are filled with secondary silica. It has also been suggested that this effect is due to the physical arrangement of thin lamellae in the opal during its solidification. Besides the gem varieties which show the delicate play of colors, there are other sorts of common opal such as the milk opal, a milky bluish to greenish kind; resin opal, which is honey-yellow with a resinous luster; wood opal, resulting from the replacement of the organic matter of wood by opal, and **hyalite,** a colorless glass-clear opal sometimes called Muller's Glass. Opal is a mineral gel, which is deposited at relatively low temperatures and may occur in the fissures of almost any type of rock. Hungary, Australia, Honduras, Mexico and in the United States, Nevada and Idaho, have been the sources of gem opals. Hyalite comes from Czechoslovakia, Mexico, Japan and British Columbia. Other common varieties of opal are widespread in their occurrence. The word opal is derived from the Latin *opallus.* (R.M.F.)

OPEN DELTA. This is a three-phase transformer connection using two single-phase **transformers** connected to form a V or open **delta** across the three lines. Such a connection has about 58% of the capacity of full delta using transformers of the same rating. It is often used for temporary work anticipating a later completion of the delta or for emergency service when one transformer of the complete delta requires servicing. (L.R.Q.)

OPEN HEARTH PROCESS. The open hearth process developed by Sir William Siemens is the principal method for making **steel** in the United States. This process is briefly described as follows: A rectangular covered furnace is provided with a hearth in the shape of a large shallow dish in which is charged **pig iron,** which may be either cold "pigs" or molten pig iron direct from a blast furnace, scrap, and iron ore, together with limestone. The charge is heated and melted at a very high temperature. The source of this high temperature is the combustion of fuel which may be oil, powdered coal, natural gas, coke-oven gas, or producer gas, for which the air supply has been highly preheated. The high temperature in the furnace, coupled with the oxidizing ore, and the presence of considerable excess air in the furnace, brings about the oxidation of part of the carbon and of other elements which are to be removed from the iron. In this respect the action of the open hearth furnace is seen to be the same as the **Bessemer** process, which is one of oxidation. The chemical reactions are under better control in the open hearth process, and a greater variety of steels can be produced than in the Bessemer furnace. The loss of iron is lower, and the product is of higher quality. For these and other reasons, the open hearth process is the leading method of steel-making in the United States.

The secret of obtaining the high temperatures necessary for the successful operation of an open hearth furnace lies in the regenerative heating of the air for combustion. The furnace is equipped with ports at both ends, through which the preheated air enters the melting chamber. The fuel, either gas or oil, is introduced through high-pressure burners located in the ends of the furnace. The furnace is fired from one end at a time, and the heated gases pass out of the ports at the other end into heat exchangers, which are large chambers in which is set up a checker work of brick. An open hearth furnace is fired alternately from either end at about 15-min. intervals, and there are two sets of the checker-work chambers, in one of which air is being heated and brick being cooled, while in the other bricks are being heated by the products of combustion of the fuel.

There are two modifications of the open hearth process which differ in the kind of materials used for refractories, the composition of the charge, and the slag produced. The basic open hearth process uses raw materials high in sulfur and phosphorus which are removed by a "basic" slag composed mostly of lime, iron oxide, and silica, the lime being usually at least twice the silica content. The refractories in contact with the molten bath and slag are predominately magnesia. In the acid open hearth process, the raw materials are low in sulfur and phosphorus. The "acid" slag formed is low in lime and high in silica. The furnace refractories are predominately silica.

The furnace itself is made of brick having steel reinforcement on the sides and ends. The hearth is made of basic or acid materials laid on a concrete foundation, and may be either stationary or tilting. The open hearth furnace may have a capacity of 15–350 tons of metal, a common size being 200 tons. It is about 80′ long by 20′ wide, and the pool of metal is generally about 3′ deep. The side walls are laid up with first quality silica brick, as is also the arched roof. In addition to the ports previously mentioned, the walls are pierced by several charging doors, with slag holes, and by a tapping hole. The slag holes are placed at the normal upper level of the bath, and the tap holes at the bottom so that all of the iron may be drained.

The manufacture of steel by this process requires, in addition to the furnace, a large amount of other equipment. There must be calcining cupolas to produce the calcined dolomite used for lining ladles and hearths; storage bins for limestone, ore, pig iron, scrap; conveyor systems; machines for dumping measured amounts of materials into the furnaces; ladles and cranes; ingot molds; ingot stripping machines; hot metal mixers; blast furnaces for producing molten pig iron; hot metal mixers in which molten pig iron may be held until needed; and frequently, gas producer plants.

The actual making of steel by the open hearth process can be described as follows. When the furnace is ready for the heat, the limestone is charged, then the scrap, ore, and cold pig iron. The combustion is stepped up to its maximum rate, and the melting down of the charge begins. If the heat is one in which some of the charge is molten iron which has been obtained from an auxiliary cupola, blast furnace or mixer, it is not added until the melting is nearly finished. After a few hours the charge lies molten on the hearth, and the purification of the iron is carried out by oxidation. Due to the presence of the iron oxides, the limestone, and the excess oxygen in the combustion region, the action of the ore definitely precedes that of the limestone, and the reaction in the furnace has two definite stages, the one known as the ore boil, the other as the lime boil. During the ore boil, usually occuring shortly after the addition of hot metal from the blast furnace, considerable slag is "flushed" from the furnace by the violence of the reaction of the ore with carbon to form carbon monoxide. When the carbon is nearly oxidized out of the bath, the furnace men take samples of the metal, which are cast in small molds. These test bars are broken, and the experienced melter can tell from the appearance of the fracture what the approximate carbon content was at the time of sampling. More accurate control of the carbon content is obtained by rapid chemical analysis or by special magnetic tests on a rod-shaped sample.

There are two methods of making steel. One is to estimate the rate of elimination of the carbon and to tap the heat when the carbon content has dropped to that which is desired in the steel. The other is to reduce the carbon content to about .10% and recarburize in the ladle with Spiegel, coal, or graphite. When the iron approaches the final state desired, the temperature of the pool of metal must be raised to that which is proper for pouring. This should be possible by controlling the furnace carefully during the period just preceding the tapping, but sometimes it is necessary to add pig iron, whose carbon content will give some slight boil which will increase the temperature to that suitable for pouring (about 2900° F.). The heat (molten metal) is then

tapped into a large crane ladle, and additions of manganese, carbon, and other alloys are made in the ladle, depending on the type of steel desired. Exceptions to this procedure are to be noted in the case of nickel and copper, both of which are added in the furnace. After thus finishing the steel, the ladle is carried over the mold track, and a train of cars, each carrying an ingot mold, is brought up under it. The molten steel is then teemed into the ingots one by one, after which the ingot train moves off to the stripper, which removes the molds from the red hot ingots. (F.T.M., R.H.H.)

OPEN TRAVERSE. **Traverse.**

OPEN-BILL. Aves, Ciconiiformes. *Anastomus.* Birds (**Aves**) of Indian and African species related to the storks. The upper **mandible** is straight and the lower curved, so that complete closure is impossible. (A.W.L.)

OPERA GLASS. **Telescope; Binocular.**

OPERATIONAL DIVISIBILITY. The segregation or division of simultaneous operations on an automatic or semi-automatic chucking machine to obtain approximately equal processing time on all work or tool stations. To illustrate, suppose a part machined on an automatic turret lathe involves facing, drilling, and boring operations requiring one minute each, and a turning operation that requires two minutes. Since the total time per piece on a machine of this character is based upon the time of the longest operation, the turning operations would probably be handled at two adjacent work stations in two stages of one minute each, thus making the actual production time one minute per piece, instead of the two minutes that the turning operation would necessitate. (See **Screw Machine.**) (H.C.H.)

OPERCULUM. A flap covering an opening. 1. An enlarged branch of a tentacle found in some of the marine **annelid** worms. It closes the mouth of the tube when the animal is retracted. 2. The margin of the **zooecium** of **bryozoans** which closes in when the body is retracted. 3. A horny plate which fits into and closes the shell aperture of certain **gasteropod** and cephaloped mollusks when the body is retracted. 4. A plate formed of a pair of rudimentary appendages which covers the external apertures of the genital ducts of **scorpions.** 5. A hinged flap on the side of the head in most fishes (**Pisces**). It covers the entire series of gill slits. Also called the opercle. 6. The lid of the capsule in the mosses. (A.W.L.)

OPHICALCITE. An old, but still consistently used term, proposed by Brongiart in 1813, for a variety of crystalline **calcite** and **serpentine.** Frequently used as a decorative **marble.** (R.M.F.)

OPHITIC TEXTURE. A term proposed by Michel-Levy, in 1877, for the characteristic texture of **dolerites,** in which the **pyroxene** crystals are penetrated by laths of **plagioclase** feldspar. This type of texture differs from poikilitic in that in the latter type of texture the pyroxene crystals entirely enclose a number of laths of plagioclase. (R.M.F.)

OPHIURAE. **Ophiuroidea.**

OPHIUROIDEA. The brittle stars, a class of **echinoderms** resembling starfishes with a well-marked disk and slender arms. The class is distinguished chiefly by this sharp demarcation of disk and arms, which accompanies the restriction of visceral organs to the disk. In addition the tube feet are without suckers and the madreporite lies on the oral surface. (A.W.L.)

OPHTHALMIA. Conjunctivitis. Acute infection of the **eye** or the membrane around the eye. Ophthalmia of the newborn is a very severe form caused by **gonorrhea.** Until measures were taken for applying **antiseptics** to the eyes of all infants directly after **birth,** it was one of the great causes of blindness. (R.S.M.)

OPHTHALMOSCOPE. An instrument made up of lenses, and producing a beam of light by means of which the retina of the eye can be seen. It is one of the valuable diagnostic instruments as in many diseases significant findings are present in the eye grounds. (R.S.M.)

OPIATE. Any **drug** derived from **opium** or, as the term is commonly used, any drug which produces sleep. (R.S.M.)

OPISTHOBRANCHIATA. **Gasteropoda.**

OPISTHOSOMA. The abdomen of **arthropods.** (A.W.L.)

OPIUM. The dried milk-juice obtained from incising the unripe **poppy.** The principal opium-producing countries are in Asia Minor, India and China.

Opium contains a series of closely related **alkaloids,** but only three of these are of medical importance. These are (1) **morphine** and its related compounds marketed as dilaudid, dionine, heroin, pantapon, (2) **codeine,** and (3) papaverine. Morphine and codeine are central nervous system depressants. Papaverine relaxes smooth muscle, particularly that of blood vessels.

Opium is used as a powder, a tincture (laudanum), and a camphorated tincture (paregoric). Its main actions are those of morphine. It has a marked constipating effect which is made use of in the treatment of **diarrhea.** The smoking of opium is common in the Far East. This is the least pernicious form of opium addiction. (See **Poppy.**) (D.M.H.)

OPOSSUM. Mammalia, Marsupialia. Pouched **mammals** of moderate size, with long scaly tails and sharp noses. With the exception of the water opossum they are arboreal animals which eat insects or a general diet. The pouch is rudimentary in some species.

The common opossum, *Didelphys virginiana,* ranges from the Great Lakes to the Gulf and westward to Oklahoma. Other species range from Mexico to southern Brazil. The water opossum or yapock, *Chironectes,* of this region is a swimming animal which lives on fishes and other aquatic animals. (A.W.L.)

OPPOSITION. **Planetary Motion.**

OPTIC AXIS. **Double Refraction.**

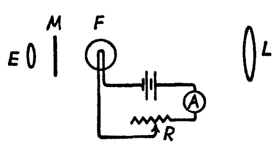
OPTICAL ACTIVITY. **Isomerism; Polarized Light.**

OPTICAL INSTRUMENTS. Optical instruments may be divided into two general classes: (1) those used for optical projection, such as the stereopticon and the **camera;** and (2) those used as an aid to natural **vision,** such as the **telescope** and the **microscope.** In the first class, a real image of the object to be represented is formed on a screen or photographic plate by means of a lens system or a mirror. In the second, the eye of the observer is placed so as to view a virtual image formed by the optical system as a whole, which may or may not involve the formation of a real image in the interior of the instrument. In either type there is an objective lens or mirror, and in the second class the final virtual image is formed by an **eyepiece** or **ocular.** There are also usually one or more "stops," which are

opaque screens with circular openings serving to limit sharply the field of view and incidentally to intercept stray light. Some cameras and projectors have stops of adjustable diameter. (See **Geometrical Optics, Magnifying Power, and Vision.**) (L.D.W.)

OPTICAL LEVER. A common device for amplifying and measuring small rotations. The object rotated carries a small mirror, which, reflecting a beam of light, deflects it through twice the angle of rotation to be measured. Light from a lamp is thus reflected as a bright spot moving along a scale, or the image of a fixed scale is viewed in the mirror by means of a reading telescope. The most common applications are to **galvanometers, electrometers,** etc., using a torsion suspension; but the principle is also often adapted to devices such as that used for measuring Young's modulus, and in situations where a **micrometer** might otherwise be used. (L.D.W.)

OPTICAL PYROMETER. Several **pyrometers** have been devised, by means of which the temperature of a very hot surface is determined from its incandescent **brightness.** One commercial type is illustrated in the figure. The hot body is viewed through a sort of tele-



Arrangement of parts of optical pyrometer. (Diagrammatic.)

scope, whose objective L produces at F a real image of the glowing surface. At this point F is placed a lamp filament, which is thus viewed through the eyepiece E against the hot surface as a background. A monochromatic filter M is interposed before both, so that their brightness is compared in one spectral region only. The current in the filament is so adjusted by means of the rheostat R that the filament becomes invisible against the bright background. The ammeter A then gives the current, from which the temperature may be deduced; or the ammeter scale may be graduated to read temperatures directly. In another type the balance is secured by keeping the current constant and introducing an absorbing wedge between the filament and the objective, as in a **wedge photometer.** In still others, the temperature is determined, not by the total brightness, but by the relative brightness at two selected wavelengths. (L.D.W.)

OPTICAL ROTATION. Polarized Light.

ORAL CAVITY. The cavity usually called the mouth. It is formed in the **vertebrates** of an embryonic depression, the stomodaeum, which forms in the ectoderm of the under side of the head and unites with the embryonic gut just behind its anterior end. The depression is deepened by the growth of processes from the body wall at the level of the pharynx which form the upper and lower jaws. Later the olfactory pits break through to join it and in this stage, which persists in the **amphibians,** the cavity is common to the **respiratory** and **digestive systems.** In a more advanced stage shelf-like partitions grow out from the lateral walls and join to form the palate, which divides the cavity into respiratory and oral portions, as in man. Also called the buccal cavity. (A.W.L.)

ORAL FUNNEL. The depression leading to the mouth in the lampreys (**Cyclostomata**). (A.W.L.)

ORAL GROOVE. A shallow depression in the surface of the one-celled animals resembling *Paramecium.* It is lined with **cilia** which create a current along it toward the cytopharynx at the rear, where food particles are gathered together to be taken into the body. (A.W.L.)

ORANGE. Citrus Fruits.

ORANGITE. Thorite.

ORANG-UTAN. Mammalia, Primates. A large man-like **ape** found in Borneo and Sumatra. It reaches a height of less than 5′ and a weight of about 150 lbs. The sharply depressed bridge of the nose accentuates the prominence of the rounded muzzle. This feature, together with the weak legs, long arms, and prominent abdomen, gives the species a grotesque appearance.

Orangs have been kept in captivity more successfully than gorillas but they also are delicate in the severe climates of Europe and America. They have been found very intelligent, but they are less desirable subjects for study than chimpanzees because of their uncertain temper. This is especially true of older males.

The name is Malayan for man of the woods. (A.W.L.)

ORBICULAR STRUCTURE. The term proposed by Delesse, in 1849, for concentric shells of different minerals, frequently formed around a **xenotithic** nucleus, in **granites, diorites** and other granitoid, intrusive **igneous rocks.** Synonyms for orbicular (in the above sense) are spheroidal and nodular. (R.M.F.)

ORBIT. In anatomy the orbit is the bony depression in the **vertebrate** skull in which the **eye** is seated.

The path which a celestial object follows in its motions through space, relative to some selected point, is known as the orbit of the object. The solution of the **two body problem** indicates that, in the case of two objects moving under the influence of their mutual gravitational attractions, the relative orbit of one to the other will be a **conic section.** The character of the conic will depend upon initial conditions. In the case of members of the **solar system,** because of the relative very large mass of the sun in comparison with any of the other members, the orbits of the members may be conveniently represented as ellipses with the sun at one focus. In the case of the **satellites** of the various members the orbits of the satellites may be represented as ellipses with the primary object at one focus. Any deviations from the two body problem may be treated as departures of **perturbations** from the simple conic.

To define completely the orbit of an object at any particular instant and to permit the determination of

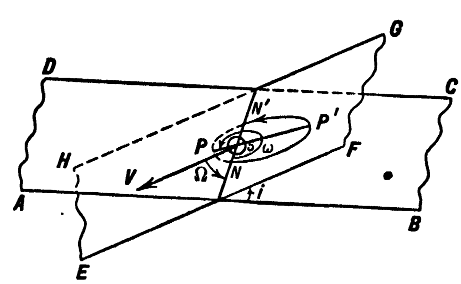


Diagram of orbit of member of solar system.

the position of the object in this orbit at any future time, six quantities are necessary, known as the seven elements of the orbit. In the accompanying figure we have a diagram of a planetary orbit about the sun. The plane $ABCD$ represents the plane of the ecliptic, and the plane $EFGH$ represents the plane containing the orbit. These two planes must intersect in a line, NN', which must pass through the sun since both the earth (the plane of the ecliptic being the plane of the earth's orbit) and the planet are revolving about the sun. The

elliptical orbit of the planet is represented by $PNP'N'$ with the direction of motion of the planet as indicated, PP' representing the major axis of the ellipse, and P the point where the object is closest to the sun (the **perihelion** point). The line SV represents, in the plane of the ecliptic, the direction to the vernal equinox. We will assume that we are looking down on the plane of the ecliptic from the direction of its north pole. The points N and N', where the planet is on the ecliptic, are known as the nodes; the point N, where the planet is passing from south to north of the ecliptic, being the ascending node and the point N' the descending node. To define the orbit plane the orbital element, i, the inclination, gives the angle between the orbit plane and the plane of the ecliptic; while the element, Ω (the angle VSN), gives the celestial **longitude** of the ascending node. The size and shape of the orbit in its plane are given by the orbital elements, a, semi-major axis (usually expressed in **astronomical units**) and, e, the eccentricity of the **conic**. To locate the position of the conic in the orbit plane we use either ω (the angle NSP measured in the direction of motion of the planet), or, more commonly, $\bar{\omega}$, the longitude of **perihelion** which is the sum of the two angles, Ω and ω. It should be noted that Ω is measured in the plane of the ecliptic while ω is measured in the orbit plane so that $\bar{\omega}$ is not strictly a longitude. To locate the position of the object in its orbit the element, T, which is some epoch or date when the object is at perihelion and the rate at which the object is moving in the orbit are necessary. Occasionally we find the rate of motion of the object given as an orbital element, but it is strictly not an independent element, since it may be derived from a. Listing the six elements as defined above we have, i, Ω, a, e, $\bar{\omega}$, and T. Unfortunately, several different systems of symbolic notation have been used by different authors and great care must be exercised in interpreting any symbolic description of an orbit.

In describing the orbits of satellites the plane frequently used is the plane of the planet's orbit about the sun and the inclination, i, of the satellite orbit is referred to it. Also, instead of locating the position of the orbit in the plane by perihelion, the point where the satellite is closest to the planet is used (in the case of satellites of Jupiter the point is known as perijove). In the case of **binary star** orbits, i gives the inclination of the orbit plane to the plane perpendicular to the line of sight, and instead of perihelion the point where the smaller star is closest to the primary, the periastral point, is used.

The problem of orbit computation is far too complex to be included in a work of this character. In general three observations of an object, giving the **spherical coordinates** of the object and the times of observation, are sufficient to compute a set of preliminary elements. From these preliminary elements subsequent positions of the object may be computed and compared with observed positions. From the differences between observed and computed positions the preliminary elements are corrected until a satisfactory representation of all observations is obtained. Before a definitive orbit can be obtained (i.e., an orbit which will give accurate positions for a long period of time), the perturbations due to other objects must be computed. (A.W.L., W.K.G.)

ORBITAL MOTION. Two Body Problem.

ORCHID FAMILY. Orchidaceae. The Orchids, which form the second largest family of plants, are the highest development of the **Monocotyledons**, just as the **Composite Family** marks the highest point of evolution reached by the **Dicotyledons**. But between the two families a most striking contrast exists. The Composites are most beautifully formed to enjoy a more abundant life; the numerous small flowers are massed in compact heads, so pollination is almost certain of accomplishment. The reduction of the fruit to a single ovule and the presence of various barbs or scales or bristles, called the pappus, greatly favor the probability of successful continuance of the species. In the 9000-10,000 species of Orchids, the individual flowers are usually very conspicuous objects often of bizarre form and rare beauty. But they depend entirely on insects for **pollination** and often exhibit elaborate modifications to insure successful insect pollination. The seeds are minute and borne in tremendous numbers, few of which germinate and grow to maturity. As a result, orchid plants are relatively rare, a fact which has contributed not a little to the zeal with which collectors have sought these plants.

Originally orchids were known only from the reports brought back by travelers from the tropics who spoke of the brilliant colors, the curious forms and the delightful fragrance and also of the mystery and folk-lore which often attached to orchids. Later botanists gained a wider knowledge of the family from dried specimens, in which color, fragrance, and, to a considerable extent, form, were lacking. In time, however, living plants were obtained by collectors and carried to western lands. There they were grown, usually without much success, since it was assumed that they could grow only in a very hot humid atmosphere. Only the most tolerant species stood this, and they only partially. Gradually, however, better understanding of the plants' requirements was obtained, and successful culture followed, so that during the first third of the nineteenth century orchids became popular. Necessarily they are expensive to collect, they are not easy to transport, and they can be grown only in glass houses under fairly uniform conditions of temperature and humidity.

Orchids are primarily plants of the tropical rain forests, where they grow in greatest abundance. In these forests they are found mostly as **epiphytes**, plants growing on other plants. Such plants grow attached to the branches of large trees, or massed in a crotch of the tree, or even attached to the trunk. Often they occur high up on the topmost branches of lofty trees, where they are inaccessible except when the supporting tree falls, bringing all its attached plants to earth. Other species of orchids, including nearly all those found in extra-tropical regions, are terrestrial. All orchids, wherever they grow, are herbaceous perennials. A few species are **saprophytes**, lacking **chlorophyll** entirely, and obtaining their food by absorption from the soil of complex organic substances.

In terrestrial orchids the roots are rather coarse and sparsely branching. In many species one of these roots becomes greatly swollen with food, as the growing season advances, forming a tuberous body which will be used to promote rapid growth in the following season. n epiphytic orchids two kinds of roots are found. One of these grows tightly appressed to the supporting plant, is not affected by gravity but is negatively **phototropic**, growing into crevices in the supporting plant. The other roots are the aerial roots, coarse branching objects which hang down, often in conspicuous masses, from the base of the plant. The epidermis and the outer portion of the **cortex**, which is called the velamen, are composed of dead cells with perforated walls which readily absorb any water which may come to them and retain it tenaciously. The inner tissues of the cortex are green and capable of carrying on **photosynthesis**. In some orchids slender absorbing branches grow out from the base of the other roots and penetrate the mass of debris which frequently collects at the base of the plant.

The stems of terrestrial orchids are erect and leafy, and terminated by the **inflorescence**. In many epiphytic forms the leaves are dropped at the end of the growing season, the bare stem remaining. The internodes of such stems are often conspicuously swollen, forming pseudobulbs in which are stored water and food

reserves. In other epiphytic species the leaves are fleshy and serve for storage.

The most characteristic and in many species the most conspicuous part of the plant is the flower. In all orchids the flowers are irregular but formed on a very uniform pattern. In all there is a 6-parted **perianth** composed of two groups of three members each. One of the inner three differs from all the others and is designated the lip or labellum. This becomes variously fringed in some orchids, broadly expanded in others, and even saccate (slipper-like), as in the Lady's Slipper. It is commonly much more brilliantly colored than the other five parts and gives to the flower its showiness. It serves as a landing place for insects, and is often a definite factor in bringing about pollination. Often various outgrowths such as spurs add further complexity to the flower. The essential organs of the flower, the **stamens** and **pistil**, are united into a single body, the column, which is a characteristic feature of the orchid flower. Its structure varies somewhat in the different groups of the family. In orchids there are only one or in some species, two, **anthers** present. The greater number of species have a single anther, which has two lobes, each filled with a mass of pollen grains held together by fine elastic threads. Such a mass is called a pollinium. The threads all unite to form a slender stalk which ends in a sticky mass resulting from the breaking down of certain cells in the rostellum. The latter is a special organ which represents one of the **stigmas** of the flower.

An insect comes to the orchid flower seeking the nectar which it contains. In getting this nectar the insect comes in contact with the sticky mass of cells which become firmly cemented to some part of the body, often the eyes, or the **antennae.** When the insect leaves the flower, it drags the pollinium out. The latter may be in a position so that when the insect enters the next flower, the pollen comes directly in contact with the stigma and pollination is accomplished. In many cases, however, a striking change occurs. The stalk of the pollinium, due to changes in its water content, bends through an angle of 90°, and so brings the pollen mass into a position which will insure its reaching the surface of the stigma of the next flower visited by the insect. There are many, often complex, variations in this process of pollination in orchids, all on this general method. In the second group of orchids the pollen is not combined into masses.

The **ovary** of the orchid flower is inferior; that is, all the floral organs are borne at the apex of the ovary, which contains an immense number of ovules attached to its walls. After fertilization, the ovules develop into very minute, light seeds, which are easily blown about by air currents.

Raising of orchids from seed is a very difficult problem, in which the ordinary grower is seldom successful. Development from seeds is very slow, several years being required to bring the plants to maturity. Propagation is usually by means of cuttings. Orchids are commonly grown for the beauty of the flowers, or for the weird shapes and striking colors which the latter often show. Only one of them, **Vanilla,** is of any great importance commercially. In times past many orchids were reputed to have medicinal value.

Common orchids found in the United States are the *Cypripediums* or Lady's Slippers, the *Habenarias* or Fringed Orchids, *Spiranthes* or Lady's Tresses, *Epipactis,* the Rattlesnake Plantain, and *Pogonia,* the Grass Pink. (R.M.W.)

ORCHITIS. Inflammation of the **testicle.** This may occur in **mumps, gonorrhea, syphilis** or **tuberculosis** or it may result from injury. The disease is marked by **pain,** a sense of weight or fullness, and swelling of the scrotum. (D.M.H.)

ORDER. A taxonomic division of the class. (See **Classification** and **Nomenclature.**) In this work the orders of the animal kingdom are listed with brief notes or for reference to the larger groups under which they are discussed.

Orders are characterized by important details of structural development and are the least of the major taxonomic divisions. The families into which they are divided are in many cases determined by minor evolutionary trends. (A.W.L.)

ORDINARY DIFFERENTIAL EQUATIONS. An **equation** which connects a **function** y of a single **independent variable** x with its **derivatives** of the first n orders, of the form:

$$F\left(x, y, \frac{dy}{dx}, \frac{d^2y}{dx^2}, \cdots, \frac{d^ny}{dx^n}\right) = 0,$$

where F is a polynomial function, is called an ordinary differential equation and its order is defined to be n.

If several functions $y, z, \cdots$ are connected with one another and their derivatives by as many equations as there are functions, we have a system of ordinary differential equations; as for example,

$$\frac{dy}{dx} = f(x, y, z) \quad \text{and} \quad \frac{dz}{dx} = \phi(x, y, z)$$

By a solution or a primitive or an integral of an ordinary differential equation in x and y is meant a function $y = f(x)$ which satisfies the equation.

The most general function which satisfies a differential equation of order n contains n arbitrary constants. A solution containing n arbitrary constants is called the general solution. If special values of the constants are used in the general solution, we obtain particular solutions. An equation may sometimes have a singular solution, which is a solution of the equation which cannot be obtained from the general solution for any particular values of the constants; a **singular solution** contains no arbitrary constant.

In applied problems, we are in most cases concerned with particular solutions. The determination of the general solution is usually a necessary preliminary step, after which the required particular solution is found by determining the arbitrary constants by using given initial conditions.

The order of a differential equation is the order of the highest derivative that occurs in it.

When an ordinary differential equation is rational and integral with respect to all the derivatives that occur in it, its degree with respect to the derivative of highest order is called the degree of the equation.

The geometric interpretation of an ordinary differential equation of the first order is as follows: Any differential equation $F(x, y, y') = 0$, of the first order and n^{th} degree, represents an infinite set of curves, n of which (real or imaginary) will pass through any assigned point (x_1, y_1), and will there have the n slopes obtained by solving the differential equation algebraically for y'. (L.L.S.)

ORDINARY DIFFERENTIAL EQUATIONS OF FIRST ORDER AND FIRST DEGREE. A differential equation of the first order and degree $\frac{dy}{dx} = f(x, y)$ may be written in the differential form $M\,dx + N\,dy = 0$, where M and N are functions of x and y.

The simplest type of equation here is the separable case. If it is possible to separate the variables and write the equation in the form $f(x)\,dx = g(y)\,dy$, it may be integrated at once.

If in the differential equation $M\,dx + N\,dy = 0$, the functions M and N are **homogeneous functions** of x and y, the equation may be solved by making the substi-

tution $y = vx$, for the resulting equation in v and x is then separable.

To solve an equation of the form

$$(ax + by + c)\,dx + (\alpha x + \beta y + \gamma)\,dy = 0,$$

make the substitution $x = x' + h$, $y = y' + k$, choose h and k so that $ah + bk + c = 0$, $\alpha h + \beta k + \gamma = 0$, then the equation becomes homogeneous, unless $a/b = \alpha/\beta$, in which case the substitution $z = ax + by$, or $z = \alpha x + \beta y$ will give rise to an equation in which the variables are separable.

A linear differential equation of the first order is an equation of the form

$$\frac{dy}{dx} + Py = Q,$$

where P and Q are functions of x (but not of y). Such an equation may be integrated by multiplying through by $e^{\int P dx}$ (an integrating factor). The solution may be written

$$ye^{\int P dx} = \int Qe^{\int P dx}\,dx + c.$$

The equation $\frac{dy}{dx} + Py = Qy^n$ may be reduced to a linear equation by the substitution $z = y^{1-n}$; it becomes

$$\frac{dz}{dx} - (n-1)Pz = -(n-1)Q.$$

A differential equation $M\,dx + N\,dy = 0$ is called an exact differential equation if the left member is an exact differential of some function of x and y.

The necessary and sufficient condition that $M\,dx + N\,dy = 0$ be exact is that $\frac{\partial M}{\partial y} = \frac{\partial N}{\partial x}$.

If the differential equation is not exact, it may be possible to find a function, in general involving x and y, such that when both sides are multiplied by it, the equation becomes exact; such a factor is called an integrating factor. (L.L.S.)

ORDINARY DIFFERENTIAL EQUATIONS OF FIRST ORDER AND HIGHER DEGREE THAN THE FIRST. In dealing with these equations, it is customary to abbreviate the derivative by the letter p.

We may denote the given equation, of the first order, by $F(x, y, p) = 0$.

There are three cases that may be considered separately, depending on whether the equation $F(x, y, p) = 0$ can be solved algebraically for p in terms of x and y, or for y in terms of x and p, or for x in terms of y and p.

If $F(x, y, p) = 0$ can be solved for p in terms of x and y, we obtain thus several **differential equations of the first order and first degree,** which may each be solved for y in terms of x. If these solutions are $f_1(x, y, C) = 0$, $f_2(x, y, C) = 0$, $\cdots$, the general solution of $F(x, y, p) = 0$ may be written

$$f_1(x, y, C)\cdot f_2(x, y, C)\ \cdots = 0.$$

If $F(x, y, p) = 0$ can be solved for y in terms of x and p, we obtain one or more equations of the type $y = \psi(x, p)$. If we differentiate each such equation $y = \psi(x, p)$ with respect to x, we obtain a differential equation of the first order in p which does not involve y, and may be solved for p in terms of x, say $\phi(x, p) = C$. For any particular value of C, the equations $y = \psi(x, p)$ and $\phi(x, p) = C$ may be interpreted as **parametric equations** of a curve in terms of the parameter p; the set of all such curves represents the solution of the equation $y = \psi(x, p)$.

In a similar manner we may treat the case when $F(x, y, p) = 0$ can be solved for x in terms of y and p. Having found x in terms of y and p, we differentiate with respect to y and replace $\frac{dx}{dy}$ by $1/p$. We may then proceed as before.

In differential equations of the first order and higher degree than the first, singular solutions may occur. Let $F(x, y, p) = 0$ be such an equation, and let $f(x, y, C) = 0$ denote its general solution. The equation $f(x, y, C) = 0$ represents a family of curves, which may have an **envelope,** i.e., a curve $\phi(x, y) = 0$ which is touched at each of its points by one of the curves of the preceding family. Then $\phi(x, y) = 0$ will be a solution of the differential equation, but it will not generally be included among the particular solutions obtained by assigning particular values to C in the general solution $f(x, y, C) = 0$. Such a solution $\phi(x, y) = 0$ is called a **singular solution** of the given differential equation.

A differential equation of the form $y = px + f(p)$ is called a **Clairaut equation.** Its general solution is $y = Cx + f(C)$. Another solution is $x = -f'(t)$, $y = tx + f(t)$, which is a singular solution. (L.L.S.)

ORDINARY DIFFERENTIAL EQUATIONS OF THE SECOND ORDER. An ordinary differential equation of the second order may in general be written in the form

$$\frac{d^2y}{dx^2} = F\left(x, y, \frac{dy}{dx}\right).$$

We shall here consider only very briefly several important special types, in which one of the variables is absent from the equation.

If the function y is lacking in the differential equation, put $\frac{dy}{dx} = p$, then $\frac{d^2y}{dx^2} = \frac{dp}{dx}$, and the differential equation takes the form $\frac{dp}{dx} = \phi(x, p)$, which is an **ordinary differential equation of the first order** in p as a function of x. After finding p as a function of x, we may replace p by $\frac{dy}{dx}$, and again solve a first order differential equation to express y as a function of x.

If the independent variable x is lacking in the differential equation but y is present, put $\frac{dy}{dx} = p$, so that $F\left(x, y, \frac{dy}{dx}\right)$ becomes a function $\psi(y, p)$; then since $\frac{d^2y}{dx^2} = \frac{dp}{dx} = \frac{dp}{dy}\cdot\frac{dy}{dx} = p\frac{dp}{dy}$, the given differential equation becomes $p\frac{dp}{dy} = \psi(y, p)$, which is a first order equation with p a function of y. After finding p as a function of y, we replace p by $\frac{dy}{dx}$ and solve another first order differential equation for y as a function of x.

A special device for differential equations of the type: $\frac{d^2y}{dx^2} = f(y)$ is the following: Put $\frac{dy}{dx} = p$, then the equation becomes

$$\frac{dp}{dx} = f(y).$$

Multiply both sides by $2p$, then since $2p\frac{dp}{dx} = \frac{d}{dx}(p^2)$, and $2pf(y) = 2f(y)\frac{dy}{dx}$, we have $\frac{d}{dx}(p^2) = 2f(y)\frac{dy}{dx}$. Integrating, we get $p^2 = 2\int f(y)dy + c = \phi(y)$, say. Extract the square root, replace p by $\frac{dy}{dx}$, and integrate again by separation of variables, obtaining finally y as a function of x. (L.L.S.)

ORDINATE OF A POINT. Rectangular Coordinates in a Plane.

ORDOVICIAN. A period of the **Paleozoic Era.** Type locality, border of Wales and Shropshire, England.

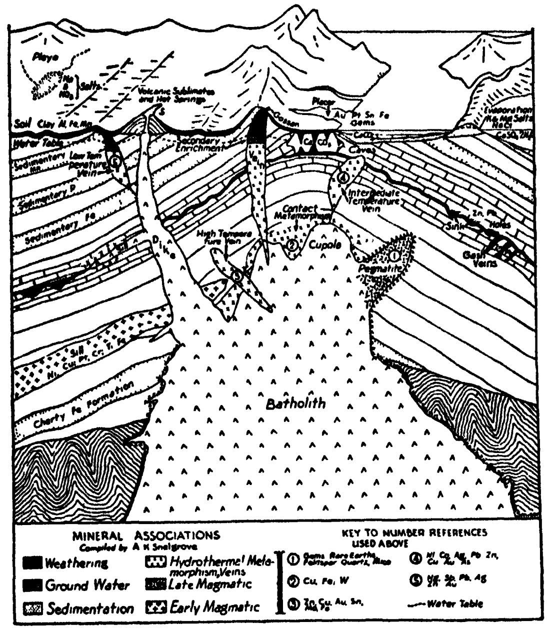
The formations of this system were first studied and described by Charles Lapworth in 1879. The Ordovician period began 440 million years ago and lasted for 60 million years. In 1874 J. D. Dana had already proposed a post-**Cambrian** system, the **Canadian.** This system has only been recently recognized in Britain (Northwest Highlands of Scotland) where it is still considered as upper Cambrian by some British geologists (1937). In 1911, E. O. Ulrich proposed a new system (period) called the Ozarkian, to include some of the upper Cambrian and some of the lower Canadian. There is still considerable doubt as to the systemic importance of the Ozarkian, especially as it appears to be absent in Great Britain. Ordovician formations are well exposed in North America due to the fact that a large part of the continent was submerged during this period. The marine sediments are of two principal types, **limestones** and **shales,** the former contain "shelly **fossils**" and the latter, principally **graptolites.** Thus the American Ordovician covers an enormous area and has an endless variety of local developments, for during the vast lapse of time which is included in the period, the shallow **epeiric seas** were continually shifting their positions, outlines and depths. The United States Ordovician contains no **igneous rocks** with the exception of volcanic ashes, called bentonites. The formations of this system are well exposed in Portugal, Switzerland, Bohemia, Austria, Hungary, Ireland, eastern Asia, China, Manchuria, Siberia, Himalayas, Burma, Morocco, Australia, New Zealand, northern Argentina, Bolivia, and eastern Peru. The maximum thickness of Ordovician strata, 40,000 feet, occurs in Australia. All classes of marine invertebrates occur as fossils, a number of which classes are now extinct. The principal types are **graptolites, corals, echinoderms, bryozoans, pelecypods, nautiloids, trilolites** and **ostracods.** (See also **Invertebrate Paleontology**). The strata of eastern North America are an important source of petroleum. Be cause of the wide surficial distribution of the Ordo vician limestones they are much quarried for foundation structures, road metal, flux for the reduction of iron ores, and especially for the lime used in mortar, whitewash, fertilizers and Portland cement. In Vermont and Tennessee occur valuable deposits of **marble.** Lead and zinc ores in rocks of Ordovician age are mined in Iowa, southern Wisconsin and northern Illinois. Phosphates of the same age are mined in central Tennessee. In eastern North America the Ordovician closed with a period of mountain building named the **Taconic Revolution** by J. D. Dana, in 1895. (R.M.F.)

ORE. A mineral aggregate in which the valuable metalliferous minerals are sufficiently abundant to make the aggregate worth mining. Types and origins of ore deposits are illustrated at the top of the page. (R.M.F.)

ORFE, GOLDEN ORFE. Pisces, Teleostei. A domesticated variety of the ide, a European fish of the carp family. This form is golden-yellow. Introduced into England during the 19th century. (A.W.L.)

ORGAN. A multicellular structure made up of various **tissues** for the performance of some complex function. The stomach, for example, contains in its walls tissues of all of the five principal divisions. Its function is the digestion of food and this end is gained by the cooperative exercise of the simpler functions of all of the tissues composing it. (A.W.L.)

ORGANELLE. A specialized structure of the single cell composing the body of the **protozoans.** Organelles are comparable with the **organs** of **multicellular animals**



Diagrammatic illustration of the origin of the ore deposits. (*Field, Outline of Geology, Princeton University Press.*)

in their relation to individual life but differ in their simplicity of structure. Also called cell organs. (A.W.L.)

ORGANIC CHEMISTRY. Chemistry.

ORGANIC DISEASE. In contrast to a functional disease, an organic disease is one in which definite structural changes take place in some organ or tissue. These changes may be temporary or permanent in character. (D.M.H.)

ORGANIZATION. The association of specialized parts in the body of an organism for the coordinated performance of various functions for the welfare of the entire individual. All living things, no matter how simple, show some degree of organization, hence it is regarded as a distinctive property of living matter. Some of the details of animal organization are taken up under **anatomy** and others under the various organ systems. (A.W.L.)

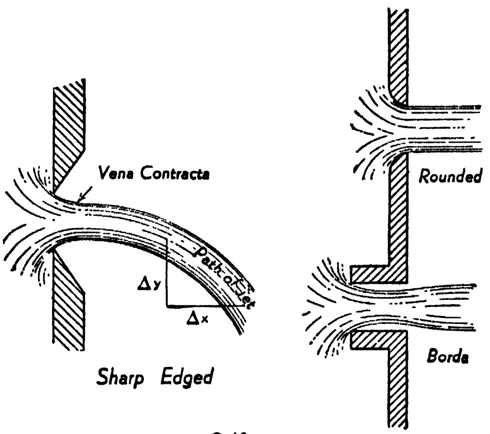
ORGANIZATION CHART. A graphical representation of the coordination, rank and function of industrial organization. An organization chart usually shows the varied personnel of an industry or plant by means of rectangular blocks, arranged in order of rank, with "leaders" or connecting lines or links to show their functional relationship. Flow sheets are similar in appearance to organization charts, but are usually employed to show the relationships and continuity of the various steps of industrial processes. (H.C.H.)

ORGANOGENY. The formation of **organs** in the **embryo.** After the formation of the **germ layers** and their initial stages of differentiation, each layer or its subordinate parts gives rise to certain of the organs characteristic of the adult by processes described under **embryology.** (A.W.L.)

ORIBI. Mammalia, Artiodactyla. *Ourebia.* South African **antelopes** of dainty build. They are less than 2′ high, with sharply pointed horns 4 or 5″ in length The color is tawny above and white below. (A.W.L.)

ORIENTATION. Metallography.

ORIFICE. An orifice is an opening having a closed perimeter through which a fluid may discharge. The orifice may be open to the atmosphere, which is the case of free discharge, or it may be partially or entirely submerged in the discharged fluid. The standard orifice is the sharp-edged orifice shown in the illustration but



Orifices.

other types, such as the well-rounded orifice, the partially rounded orifice, the Borda mouthpiece, and the short tube orifice, have their special uses. An orifice may be very small, as in the case of those used for leak ports or for calibration, or large, as illustrated by sluice gates in a dam. The head of water on the orifice is measured from the water level surface to the center line of the orifice. Should the head above the orifice be so small as to be less than approximately the vertical dimension of the orifice, the following remarks will not apply, as this would come under the special case of large orifices under low heads.

The streamlines in water approaching a sharp-edged orifice converge on the orifice from all directions, and so continue to converge for approximately one-half of the orifice diameter downstream. The jet contracts to a section somewhat smaller in diameter than the orifice, after which it increases in size. The contracted section is known as the *vena contracta*. The ratio of the cross-section of the jet at the vena contracta to the area of the orifice is known as the contraction coefficient. Friction in the orifice slows the velocity to somewhat lower value than the ideal free spouting velocity which is $\sqrt{2gh}$. The ratio of actual to spouting velocity is the velocity coefficient. Since the discharge is the product of velocity and area, the discharge coefficient is the product of velocity and contraction coefficients. It has a numerical value of 61% for the average sharp-edged orifice. The discharge from an orifice of area a is

$$Q = .61a\sqrt{2gh}.$$

The path taken by a jet discharging freely horizontally under head of h is parabolic in shape due to the pull of gravity acting on a particle having, originally, horizontal motion only. The equation

$$x^2 = 4K_v^2hy$$

gives a curve of the center of the path of the jet. K is the velocity coefficient which averages 98% for sharp-edged orifices. Suppression of the contraction of a jet increases the discharge from an orifice. An orifice on the side wall of a tank near the bottom has a higher coefficient of contraction than one which is located farther away from the bottom. Similarly an orifice with the upstream edges rounded has a higher coefficient of contraction than one with sharp edges. The discharge may be as much as 30% greater for well-rounded orifices. Orifices which are submerged, orifices which are squared instead of circular, and orifices in which the water approaches with a high velocity, cannot be treated by the equation given above without corrections being made for these special conditions.

The above discussion relates to the flow of water through an orifice. Orifices are much in use for measuring flows of vapors and gases. The method employed is to place an orifice of some type in the pipe or duct carrying the fluid. By means of a **manometer,** or pressure gauge, the upstream and downstream pressures are measured, and the discharge can be determined from those readings coupled with the known area of the orifice. The flow of a gas through an orifice depends on the area of the orifice, the upstream pressure, the temperature, and a factor which involves gas constants, such as the ratio of the specific heats at constant pressure and constant volume, and the ratio of the upstream and downstream pressures. The formula for the weight of gas flowing is $\frac{C_1C_2aP}{\sqrt{T}}$ (pounds per second). C_1 is the constant just mentioned, C_2 the velocity of approach correction, P the upstream pressure, a the area of the orifice, and T the absolute temperature. Many steam flow meters are based on the principle of the orifice. A sharp-edged, or thin-plate, orifice is clamped between the flanges at some joint of a flanged steam line. Pressure leads are taken from upstream and downstream sections to an instrument which is a pressure-measuring device, but which may be calibrated to read steam flow. (See **Flow Meter.**) (F.T.M.)

ORIGINATION. In mechanical terminology, origination is the process of developing or producing a part without reference to any previous or existing standard. By reference to the definition of a straight-edge, it may be seen that three straight-edges may be originated by cutting and scraping; once the standard is established, however, any number of straight-edges may be made by machining and finishing them by reproduction, or comparison with the existing standard. (See **Lapping.**) (H.C.H.)

ORIOLE. Aves, Passeriformes. Brightly colored birds (**Aves**) of the family Oriolidae, found in all parts of the Old World. The North American birds to which this name is applied belong to the family Icteridae and are more closely related to the blackbirds than to the true orioles. The orchard oriole, *Icterus spurius,* and the Baltimore oriole, *I. galbula,* are the most widely known species of the latter group. (A.W.L.)

ORION. (Map, page 380.) This **constellation** is, on the whole, the richest and most impressive of all of the constellations. The "belt and sword" of Orion are frequently referred to in both ancient and modern literature and even found recognition as the shoulder insignia of the 27th division of the United States Army during both World Wars, probably because of the fact that the division was commanded by General O'Ryan. Despite the wide area covered, the physical characteristics of many of the stars are so similar that there is considerable evidence in support of the theory that they have a common origin.

The star Betelgeuse must be considered as an exception to this class for it is quite different from the other bright members of the constellation. Its color is a distinct yellow-orange as contrasted with the blue-white tint of the typical "Orion star." It is a **giant star,** its diameter, as measured with the interferometer, being about 300 times that of the **sun.**

The middle "star" of the sword is not a star at all, but is a huge gaseous **nebula.** This is one of the very few nebulae that can be seen with any satisfaction in a small instrument. Of course the larger the instrument the finer the view.

Several of the bright stars in the constellation are multiple objects, and the possessor of a 4-in. telescope will find the stars of Orion worth more than a passing glance. (W.K.G.)

ORNITHOLOGY. The biological science which deals with facts relating to birds (**Aves**). The large number of species and the great range of habits of birds have furnished abundant material for purely scientific studies, and the beauty and general interest of the group have made bird study a hobby of many persons. Economically birds are important as destroyers of insect pests, as game, and less frequently as predators. In these roles they have commanded the attention of the Biological Survey and of the many conservation boards and commissions of fish and game of the various states. (A.W.L.)

ORNITHOPTER. Ornithopters are the natural result of man's attempts to gratify his desire to fly. An ornithopter is a flying machine which, like a bird, flies by flapping its wings. It is quite logical that efforts should have been made to copy bird flight. The first attempts to fly were with ornithopters. One is recorded as having been built by Leonardo da Vinci in 1490, but, like the many ornithopters which have been built since that day, it was not a success. The ornithopter is too complicated mechanically, and there is not a close enough resemblance between the flight of birds and that with which man must be content to permit much success in the field of the flapping wing machine, even though flying ornithopter models have been built. (F.T.M.)

ORNITHORYNCHUS. **Fossil Mammals.**

OROGENY. **Epeirogeny.**

OROGRAPHICAL WEATHER PHENOMENA. Any weather phenomena caused by the flow of air over prominent features of the terrain. Air flowing uphill undergoes certain changes because of this orographical lifting.

1. As long as the air is unsaturated, it cools at the dry-adiabatic rate of approximately 5.5° F. per 1000′.
2. As soon as the air is saturated, it cools at the pseudo-adiabatic rate which depends on the amount of water being condensed by cooling, but in any event less than the dry-adiabatic rate.
3. Clouds, rain, or snow are often formed in this orographically lifted air. Thunderstorms occur if the air is unstable.

Down-slope warming such as occurs on the eastern slopes of the U. S. Rockies is thus of orographic origin. The Indian monsoon rains and the rains of the U. S. and European northwest coasts are large-scale orographic phenomena. (P.E.K.)

ORPIMENT. This mineral, like realgar its frequent associate, is an **arsenic** sulfide. Orpiment, however, is the trisulfide corresponding to the formula As_2S_3. It is **monoclinic** with a resinous to somewhat pearly luster; color, various shades of lemon yellow; translucent to nearly opaque. Orpiment is found in association with **realgar**, although a somewhat rarer mineral. It is believed to be formed from the alteration of other arsenic-bearing minerals. It occurs in Czechoslovakia, Rumania, Macedonia, Japan, and in the United States in Utah, Nevada, and Wyoming. The name orpiment is derived from a corruption of the Latin *auripigmentum*, meaning golden paint, because of its color as well as the belief that it contained gold. It was formerly much used as a dye, but its place has been largely taken by an artificial product of similar composition. (E.S.C.S.)

ORRIS ROOT. **Volatile oils.**

ORSAT ANALYSIS. **Flue Gas Analysis.**

ORTHITE. **Allanite.**

ORTHOCHROMATIC REPRODUCTION. The word orthochromatic is derived from the Greek roots *ortho* (correct) and *chroma* (color) and orthochromatic is loosely defined as the proper (or correct) reproduction of color in monochrome. However, since only one characteristic of color, i.e., brilliance, can be reproduced in monochrome, orthochromatic photography is more properly described as the correct reproduction of the brilliance characteristic of color into monochrome. For orthochromatic reproduction, the variation in the sensitivity of the photographic material to color should correspond with that of the eye. In other words, the distribution of sensitivity with wavelength of the film or plate should be the same as that of the eye, which, of course, is represented by the color-brilliance curve. It is obvious that, except for a limited color range, orthochromatic reproduction can be obtained only with a film or plate which is sensitive throughout the visible region, or from a wavelength of approximately 400 mμ to 700 mμ. Such materials are termed panchromatic: pan (all) color. Therefore, "orthochromatic films," which are widely used in photography, do not rightfully deserve this designation because, as they are insensitive to red, they do not reproduce red color values correctly. While considerable progress has been made in such materials within the last decade, it is not possible as yet to produce a film or plate whose variation in sensitivity with wavelength corresponds at all closely to that of the eye. The principal difficulty lies in the predominant sensitivity of the silver halides in the short-wave region, but many of the most useful dye sensitizers sensitize too powerfully in the long-wave region to produce the desired result. It is necessary, therefore, to employ light filters if orthochromatic reproduction is to be obtained. Orthochromatic filters are generally yellow since the principal requirement is to absorb violet and blue, but some sensitive materials and light sources necessitate green filters. In all cases in which orthochromatic reproduction is required, the filter recommended by the manufacturer of the sensitive material should be used.

It should be noted that the filters recommended do not in fact result in true orthochromatic reproduction as this would involve greatly increased exposures and the danger of insufficient detail in colors at both ends of the spectrum, namely the violet and deep red, but only in what may be regarded as a satisfactory approach to it.

Orthochromatic reproduction is not always the end in view. In many cases the visual effect of color is reproduced more accurately if orthochromatic reproduction is departed from and one or more of the colors rendered relatively lighter, or darker, than its color brilliance would justify. Color contrasts, for example, which depend upon hue rather than the brilliance characteristic must be distorted to produce a difference in tone which will reproduce the visual contrast adequately in monochromate. (See **Light Filters.**) (C.B.N.)

ORTHOCLASE. **Feldspar.**

ORTHOGENESIS. A theory of organic **evolution** which assumes the occurrence of progressive change in living things along definite lines of development.

In **fossil** series it is always possible to see orderly progression or retrogression from form to form. According to some evolutionists this type of development has taken place under the impulse of unknown controlling factors as a directive tendency. Others point out that one result of evolution is certain to be an ancestral series which, if isolated, appears to be orthogenetic.

Since every heritage must have certain potentialities, the evolution of any group must proceed along the lines

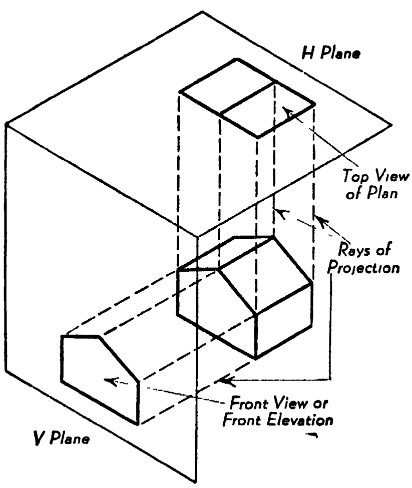
made possible by these potentialities. To this extent orthogenesis is an established principle. No comprehensive theory of evolution, however, fails to admit the existence of other factors, at least in a directive capacity, and so orthogenesis is not to be regarded as an explanation of organic evolution. (A.W.L.)

ORTHOGNEISS. **Gneiss.**

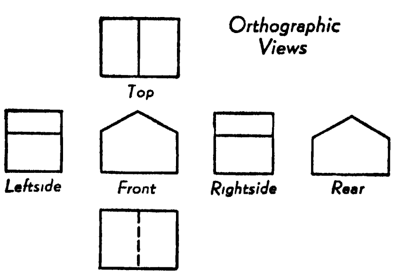
ORTHOGONAL CIRCLES. **Circles.**

ORTHOGRAPHIC PROJECTION. A method of representing solid objects on a plane surface, using parallel rays or projectors, in contrast to a cone of rays as used in **perspective.** The rays are perpendicular to the plane of representation, in contrast to oblique representation or projection, in which the rays are parallel, but at an angle to the plane of representation. In auxiliary projection, the plane of representation is inclined with respect to the principal axis of the object, although the rays are perpendicular to the plane of representation, and usually perpendicular to an inclined face of the object.

Six principal orthographic views are possible, although usually only four, the top view or plan, the front view or front elevation, and the left-side and right-side views or side elevations are employed. The usual arrangement of views in American practice is shown in the figure; in



Orthographic Projection



Orthographic Views

Europe, a view arrangement in which the top view is below the front view, and the so-called right-side view is to the left of the front or top view, referred to as first angle projection, is extensively used. (H.C.H.)

ORTHOPEDICS. A division of surgery having to do with the diagnosis and treatment of the diseases of bones and joints. (D.M.H.)

ORTHOPTERA. **Insects** of many forms with many common names, constituting one of the larger orders. The principal members of the group are the **grasshoppers, crickets, mantises, stick insects,** and **cockroaches.** Locusts are grasshoppers. Some authorities place these major forms in separate orders, but the general tendency is to group them together.

The order is characterized by biting mouth parts and gradual metamorphosis (**Paurometabola**). When wings are present there are two pairs, the front wings somewhat thickened as tegmina and the hind pair broad and membranous, folding beneath the tegmina when at rest.

These insects have a wide range of habits and occupy many terrestrial habitats. The locusts are important crop pests in some areas and cockroaches are common household pests. (A.W.L.)

ORTHORHOMBIC SYSTEM. **Crystallography.**

ORTHOSILICATE. **Silicon; Garnet.**

ORTHOSITE. The term proposed by Turner, in 1900, for a rock of granitic texture but composed almost entirely of the feldspar, **orthoclase.** (R.M.F.)

ORTOLAN. Aves, Passeriformes. A European bird, *Emberiza hortulana,* whose flesh is regarded as an unusual delicacy. Many of the birds are caught in nets and fattened for the market. One of the **buntings.** (A.W.L.)

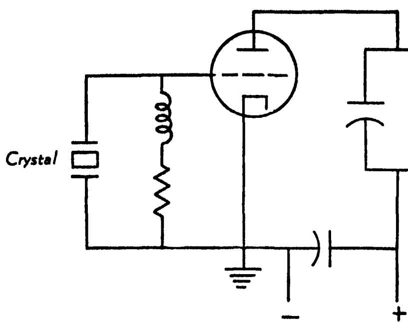
ORYX. Mammalia, Artiodactyla. A genus of **antelopes** found in the desert regions of Africa and thence to Syria. The name is also anglicized as a common name of some species. All species have very long horns, straight or slightly recurved. The **gemsbok, beisa,** leucoryx and beatrix antelope are oryxes. (A.W.L.)

OSAZONES. **Hydrazines, Hydrazones and Osazones.**

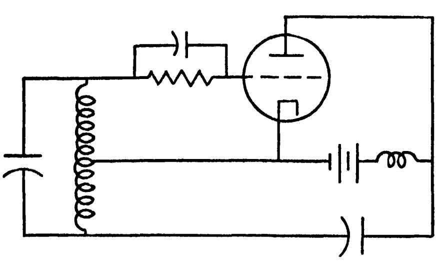
OSCILLATION. An oscillation is to and fro, or vibratory motion, of an object, a wave, electrons, etc. Mechanical oscillation is exemplified in the **pendulum,** by its regular swing back and forth. The center of oscillation of a pendulum is one of its conjugate points. (See **Kinetics.**) Electrical oscillation occurs in a circuit in which electricity surges back and forth. Electromagnetic waves are oscillatory in nature, and can be produced by **oscillators.** The number of oscillations per second is known as the **frequency** of oscillation, and its reciprocal is the period. (F.T.M.)

OSCILLATOR. The oscillator is the heart of the radio **transmitter** since it generates the high-frequency carrier signal essential for this type communication. The early oscillators used in radio consisted of inductance-capacitance circuits to which a surge of electrical energy was applied by the breakdown of a spark gap or an arc. This energy then surged back and forth between the inductance and capacitance until it was all dissipated as radiation and as circuit losses. This type oscillator produced damped oscillations and is no longer used. Modern oscillators use **vacuum tubes** in various circuit arrangements. Since the ordinary vacuum tube is inherently an amplifying device, it can be used as an oscillator by feeding back some of the output energy to the **grid** so the tube effectively drives itself. The various oscillator circuits in common use are utilizations of different means of doing this. For stable frequency characteristics crystal-controlled oscillators are used in most stations. In these a quartz **crystal** is connected in the grid circuit of the vacuum tube so the voltages produced by the crystal when it vibrates mechanically control the grid and hence the plate output of the tube.

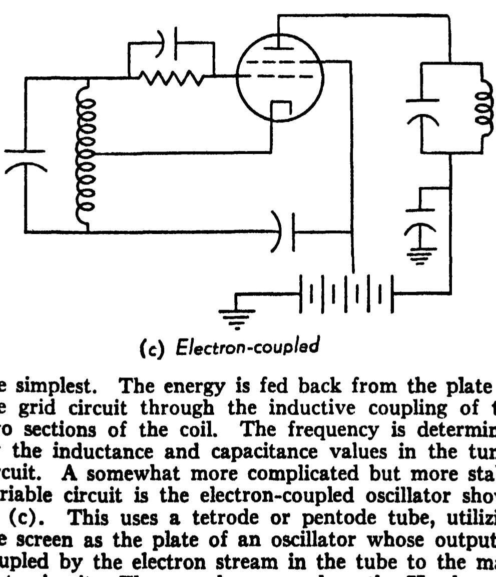
Enough energy is fed back, usually through the grid-plate capacitance of the tube, to keep the crystal in a steady state of vibration. Because of the high frequency stability of the mechanical vibrations, the output frequency of the circuit is remarkably stable, in some cases where extreme care is exercised amounting to 1 part in 20,000,000. In modern broadcast stations the crystals maintain the frequency accurately to 2 or 3 cycles. Where continuously adjustable frequency output is needed some type of self-controlled oscillator is needed. The Hartley, shown in the figure, is one of



(a) Crystal



(b) Hartley



(c) Electron-coupled

the simplest. The energy is fed back from the plate to the grid circuit through the inductive coupling of the two sections of the coil. The frequency is determined by the inductance and capacitance values in the tuned circuit. A somewhat more complicated but more stable variable circuit is the electron-coupled oscillator shown at (c). This uses a tetrode or pentode tube, utilizing the screen as the plate of an oscillator whose output is coupled by the electron stream in the tube to the main plate circuit. The one shown employs the Hartley circuit. At very high frequencies the oscillator frequency is often controlled by a resonant transmission line. At **ultra high frequencies** special tubes and types of circuits must be used. In these the frequency is largely determined by the transit time of the electrons in the tube. (L.R.Q.)

OSCILLOGRAPH. This name applies to a variety of instruments, including certain vibration **galvanometers**, which automatically trace, or at least render visible, curves representing variable currents, electromotive forces, or other electrical quantities. For example, the electric oscillations in a circuit may cause the electromagnetic vibration of a filament bearing a small mirror which, reflecting a beam of light, leaves a trace on a moving photographic film; or a diaphragm may be vibrated through electrostatic forces controlled by varying potential. The most generally adaptable forms are of the **cathode-ray** type, originated by Braun. In these, a slender stream of cathode particles, usually from a hot-filament cathode, issues from a small anode opening (like negative **canal rays**), and is deflected by means of a rapidly varying magnetic or electric field or both, so that its far end oscillates in faithful reproduction of the currents or voltages responsible for the fields. The stream may fall on a fluorescent screen where its vibrations become visible (in which case the instrument is often called an oscilloscope), or may leave its trace on a photographic plate or moving film. In one form, the motion along the time axis, called the "sweep," is secured by causing the stream to deflect under the influence of an increasing electric field controlled by a slowly charging **condenser**. (L.D.W.)

OSCILLOSCOPE. Oscillograph.

OSCULATING ORBITS. Orbit.

OSCULUM. The opening of the central cavity (paragaster, gastral or paragastric cavity) of **sponges**. Water passes into this cavity through the small pores in the body wall and flows out of it by the osculum. (A.W.L.)

OSE. Esker.

OSMETERIUM. A scent gland found in some **insects**. A common example is the forked eversible organ just behind the head of the caterpillars of swallowtail butterflies. This organ is thrust out when the insect is alarmed. It is brightly colored and gives off a powerful odor, usually reminiscent of the animal's food plant but too strong to be agreeable to the human nose. (A.W.L.)

OSMIUM. Symbol: Os. Atomic number: 76. Atomic weight: 190.2. Density: 22.48. Hardness: 7. Melting point: 2700° C. (**Isotopes**, page 290.)

Compact osmium is a bluish-white metal, and is not attacked by acids. Discovered by Tennant in 1804.

Finely divided osmium is a **catalyzer** for the reactions, (1) **hydrogen** plus **oxygen** at 50° C. forming water, (2) hydrogen plus **nitrogen** at high pressures and 400–500° C. forming **ammonia**.

Osmium occurs native with **platinum**, and with **iridium** (osmiridium, 20–40% Os). By boiling finely divided osmium-containing material with **aqua regia**, volatile, poisonous osmium tetroxide distills over, and is absorbed in **sodium** hydroxide solution. The resultant red solution, containing sodium osmate (Na_2OsO_4), is later acidified, and reduced to osmium metal by zinc metal.

Osmium tetroxide is used in preparing microscopic slides, where it stains selective portions of tissues black.

Chlorides: Osmium dichloride ($OsCl_2$); osmium trichloride ($OsCl_3$); osmium tetrachloride ($OsCl_4$).

Hydroxide: Osmium hydroxide ($Os(OH)_4$), brown precipitate, by solutions of hydroxides, e.g., **sodium** hydroxide.

Oxides: Osmium monoxide (OsO); osmium sesquioxide (Os_2O_3); osmium dioxide (OsO_2); osmium tetroxide, or osmic acid (OsO_4). The last compound has melting point 40° C., boiling point 100° C.

Sulfides: Osmium disulfide (OsS_2), brown precipitate, in acid solution by **hydrogen sulfide**; osmium tetrasulfide (OsS_4), in neutral solution.

Osmium tetroxide is reduced by **ferrous** sulfate solution to osmium dioxide. Osmium compounds are reduced to osmium metal by ignition in hydrogen. (R.K.S.)

OSMOSIS. The passage of liquids or gases from solution through membranes. When solutions of different degrees of concentration are separated by a membrane (a common form of membrane for experiment is a very thin sheet of collodion) substances diffuse through from the solution in which they are more concentrated to that in which they are less so, provided that the membrane is permeable to them. The term osmosis is restricted to such movements of the solvent, which in organisms is usually water. Dissolved substances may dialyze if the membrane is permeable to them. (See **Diffusion of Fluids.**) (A.W.L.)

OSPHRADIUM. A branching sensory organ of mollusks, supposed to be olfactory in function. It sometimes resembles a **ctenidium.** (A.W.L.)

OSPREY. Aves, Falconiformes. A large bird of prey of almost worldwide distribution. It is a skillful fisher and is known in North America as the fish hawk, *Pandion haliaëtus.* (A.W.L.)

OSSICLE. 1. The calcareous plates in the body wall of **echinoderms.** In some species, notably the sea urchins, they are connected to form a shell and in others, especially the sea cucumbers, they are small and scattered. 2. A small bone, such as the chain of three auditory ossicles (hammer, anvil and stirrup) in the middle **ear** of mammals. (A.W.L.)

OSSIFICATION. The formation of bone, or the conversion of tissue into bone or a bone-like substance. (R.S.M.)

OSTEITIS. A low-grade inflammation of bone marked by tenderness, pain and enlargement of the bone. (R.S.M.)

OSTEITIS FIBROSA CYSTICA. **Parathyroid Gland.**

OSTEO-ARTHRITIS. **Arthritis.**

OSTEOLEPIS. **Fossil Fishes.**

OSTEOLOGY. A division of vertebrate anatomy which deals with the **skeletal system.** The study of bones. Comparative osteology is the study and comparison of the bones of different races and different species of organisms. (A.W.L., R.S.M.)

OSTEOMYELITIS. An acute or chronic infection of bone, most commonly due to hemolytic *Staphylococcus aureus* but occasionally to the *streptococcus, pneumococcus,* or to *B. typhosus.* The organisms often reach the blood from an insignificant **furuncle** or other infection on the skin, and are carried in the blood stream to the bone. Previous injury at the site of infection seems to play a part in lowering the resistance of the bone and allowing the organisms to gain a foothold.

Osteomyelitis is a disease of childhood, most of the cases occurring between the ages of 2 and 12 years. It is commoner in boys than in girls. The bones most frequently involved are the femur (thigh), tibia (leg), and humerus (upper arm). When fully developed, the infection may involve the covering of the bone, the bone itself, and the marrow cavity. Widespread destruction and **necrosis** may occur.

Acute osteomyelitis is usually sudden in onset with a chill and high fever, pain, tenderness, redness and swelling of the involved bone. The child is extremely sick, dehydrated, and may be delirious or even comatose. Staphylococci can often be found in the blood stream by **culture.** The treatment of acute osteomyelitis has been improved enormously since the introduction of the **sulfonamides** and **penicillin.** Penicillin, administered early, will sterilize the blood stream and control the bone infection with remarkable rapidity. If the infection has gone on to the stage of pus and **abscess** formation before the drug is begun, surgical drainage may be necessary in addition to drug therapy.

Chronic osteomyelitis, which may go on for many years, has been in the past a common end-picture for the patient with acute disease. It is now much less common in penicillin-treated patients. Chronic osteomyelitis is characterized by the persistence of bone infection, draining pus, and recurrent acute flare-ups Although treatment with penicillin does not produce as dramatic results as in the acute disease, it is the most successful means, when combined with adequate surgical measures, of healing the diseased bone. Chronic osteomyelitis is seen also as a complication of compound **fractures** and other bone injury. (D.M.H.)

OSTEOPATHY. A system of treatment in which diseases are treated by manipulations of bones and joints with intent to restore to normal the disturbed mechanism of the body. It places the chief emphasis on the structural integrity of the body as being the most important single factor in maintaining the well-being of the organism in health or disease. (D.M.H.)

OSTIUM. The terminal opening or mouth of a duct and other openings of hollow organs. The slits in the wall of the tubular heart of **insects,** the opening of a radial canal into the central cavity of **sponges,** and the opening of the **vertebrate** oviduct into the abdominal cavity are specific examples. (A.W.L.)

OSTRACODA. **Crustacea.**

OSTRACODERMS. **Fossil Fishes.**

OSTRICH. Aves, Struthioniformes. *Struthio.* An African bird (**Aves**) of one or possibly two or three closely related species. These large birds are widely known because they have long been kept in captivity for their plumes and are readily maintained in zoos. They attain a height of 8′ and a weight of 300 lbs. The neck and legs are long, the feet bear a single large toe and one much smaller, and the wings are very small.

Ostriches are at home in hot arid country. They run very rapidly and when cornered defend themselves chiefly by powerful kicks. The nests are mere hollows in the ground and in warmer regions the eggs are not incubated during the day.

Ostriches have been kept in large numbers in Africa and in the warmer parts of North America. When their plumes were in great demand the industry is said to have attained a value of about $10,000,000 annually.

The **rheas** are called American ostriches. (A.W.L.)

OTITIS MEDIA. Infection of the middle ear commonly due to staphylococci and streptococci. This condition is very common, and is most frequently seen in children. It often led to **mastoiditis** in the days before **sulfonamides** were in use. The infection reaches the middle ear through the **Eustachian canal** from the **pharynx.** It usually occurs secondary to an acute upper respiratory infection such as **coryza, pharyngitis,** or acute **tonsillitis.** Children with adenoids and large tonsils are more subject to ear infections. Coughing, hard blowing of the nose, and the use of nasal douches or sprays often spread the infection from the throat to the ear. As soon as there is sufficient pus in the cavity of the middle ear to cause pressure, the pain

becomes excruciating. Rise in temperature and loss of hearing in the affected ear are present.

The treatment in certain cases is with **sulfonamides.** Later, when there is pressure on the ear drum from the accumulated pus, incision of the drum is necessary as well as chemotherapy. Most cases recover shortly and heal within 2 weeks with little or no impairment of hearing after 2 months. When the symptoms and discharge continue for a longer period, mastoid involvement is usually present. (R.S.M., D.M.H.)

OTOCYST. Lithocyst.

OTOPORPA. A protuberance extending upward from the base of a **lithocyst** in some of the jellyfishes. (A.W.L.)

OTTER. Mammalia, Carnivora. Elongate animals with short legs, broad head, and webbed toes. They are excellent swimmers, even catching fish apparently for the pleasure of the pursuit.

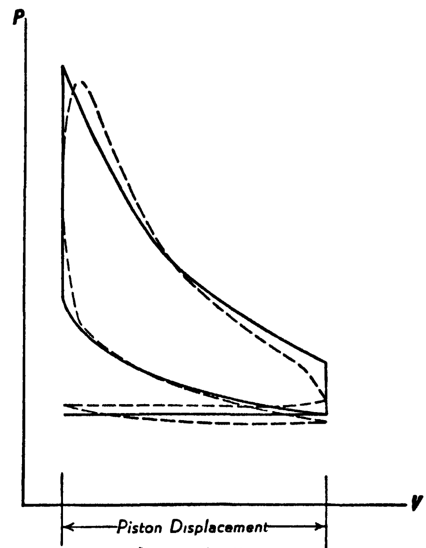
Otters are found on every continent except Australia. Different species vary from two to three feet in length, exclusive of the long tail, but there is relatively little difference in their general appearance. *Lutra canadensis* is found in North America.

Otter fur is thick, soft and glossy, and is among the most valuable commercially. The fur of the sea otter, *Latax lutris,* one of the largest species, is regarded as the most valuable of all furs. The species inhabits the northern Pacific, in both Asiatic and American waters, where it feeds on marine invertebrates. It was once abundant but through indiscriminate trapping it has become very rare. (A.W.L.)

OTTO CYCLE. The possibilities of an **internal combustion engine** which would operate on the **four-stroke** cycle were analyzed in the nineteenth century by de Rochas. The action of an engine, which was at that time described only, is in all fundamental respects the same as that used today. Shortly after this internal combustion engine analysis was made, the German Otto built an engine which operated on the four-stroke cycle, and which has come, since, to be called the Otto cycle. The Otto cycle is carried out by a series of operations, namely, and in order:

1. Suction during outward stroke of the piston.
2. Compression during inward stroke of the piston.
3. Expansion during outward stroke of the piston following ignition at inward dead center.
4. Exhaust during inward stroke of the piston.

Although the first engines built by the Otto works were four-stroke cycle (**four-cycle**) engines, the Otto engine can be adapted to a two-stroke cycle (**two-cycle**). An engine which operates on the Otto cycle has considerable clearance volume (when the piston is on dead center) into which the air and fuel drawn in on the suction stroke are compressed. As the piston pauses instantaneously on dead center position, the charge is **ignited** and **combustion** of the charge occurs at constant volume. The heat added by this combustion greatly increases the pressure. During the expansion stroke, this pressure is lowered, and a considerable amount of the heat is taken from the gas to be converted into work. At the end of expansion, the pressure is dropped to the exhaust point, and the exhaust gases are pushed out of the cylinder, which is thus cleared for the next suction stroke. In the figure which illustrates the Otto cycle in theory and in practice, the cycle is shown on the pressure-volume plane. The ideal cycle is shown solid, and departures from it, made by actual cycles, are shown dotted. The ideal four-stroke cycle is made up of two isovolumetric changes, one representing the combustion of fuel at constant volume, the other the rejection of heat to the exhaust at constant volume, and two **adiabatic** changes, one representing the compression of the charge, the other the power stroke. Finally, there are two coincident constant pressure changes, representing the ideal exhaust and suction



Otto cycle diagram.

strokes. An actual working cycle will not have quite the same processes. Combustion of a fuel is not instantaneous in nature. That occurring in the gasoline engine occupies an appreciable length of time compared to piston motion, so that isovolumetric pressure rise is not possible. The point of ignition must be advanced before inward dead center, or there will be considerable loss of work by delayed combustion. An exchange of heat between cylinder cooling water jackets and cylinder contents tends to destroy the adiabatic relationship assumed for the ideal cycle. The exhaust cannot be at constant pressure because of the inertia of gases leaving the cylinder and the definite rate of valve action of mechanically driven valves. Furthermore, the exhaust and suction lines cannot be coincident, since exhaust must be above atmospheric pressure by the amount of friction losses through the ports and manifolds, while suction must be below atmospheric pressure for the same reason. The cylinder horsepower of an engine operating on this cycle is $\frac{PLAN}{33{,}000}$, wherein P is the mean effective pressure, and N is the number of power strokes per minute. The N of a four-stroke cycle, single-acting engine is one-half the number of revolutions per minute multiplied by the number of cylinders per engine. L and A are the stroke in feet and piston area in units corresponding to those of P.

The ideal efficiency of this cycle is expressed by the equation

$$E = 1 - \frac{1}{r^{y-1}}$$

r is the compression ratio, and y the ratio of the specific heats at constant pressure and constant volume. This air standard efficiency is higher than the actual efficiency because it neglects cooling losses and friction losses. The actual efficiency of the Otto cycle is usually between 20 and 25%. The compression ratios employed have been steadily raised by manufacturers in order to increase the efficiency of their product, for, as is seen in the above equation, an increase of r will increase the efficiency of the Otto engine. Modern motor cars are built having r as large as 7, but only by the use of aluminum cylinder heads, which conduct the heat from the cylinder

more rapidly. An average value of *r* for the Otto cycle would be 5. (F.T.M.)

OTTO ENGINE. The **Otto cycle** is described in another section. The **internal combustion engine,** which operates on that cycle, is of importance because of its widespread use for both stationary and motive service. The advantages which have established the Otto engine as an important prime mover are its high average effective pressure, its high rotative speed, its ease of starting, and its adaptability to production methods of manufacture. The Otto engine, acting as a heat engine, is supplied with a gaseous or liquid fuel which is burned explosively in its cylinder with a liberation of heat, some 25% of which will eventually find its way into useful horsepower output. The principal parts of the Otto cycle machine are as follows:

1. **Cylinder.** That part in which the combustion is made to occur, and in which the heated gases expand.
2. The mechanical linkage of members, by means of which a gas pressure is converted to a useful torque on a shaft. These parts consist, ordinarily, of a **piston, connecting rod,** and **crankshaft.**
3. **Ignition system.**
4. **Carburetion** and fuel system.
5. **Lubrication.**
6. **Manifolds.**
7. **Valves** and **valve gear.**
8. Frame and bedplate.
9. Combustion chamber cooling system.

The piston, cylinder, connecting rod, and crankshaft form the principal parts. These are integrated and aligned by being fastened to a frame or bedplate, which is often of the fully enclosed type, so that spray lubrication may be used. Valves operated by the valve gear provide the function of admitting and releasing the working medium to and from the cylinder, while manifolds distribute or collect the gases in the multi-cylindered engines. The two auxiliary systems of carburetion and ignition are essential in the gasoline engine, the carburetion to prepare the fuel, and ignition to ignite it. An average heat balance for this type engine would be as follows:

Output	25%
Cooling	36%
Exhaust	34%
Friction	5%
Total	100%

A typical multi-cylindered engine is arranged with cylinders in line or in banks, or radially. The cylinders are aligned so that the connecting rods may bear on the same crankshaft. This crankshaft drives the necessary auxiliaries, and delivers the remaining power as useful output at a coupling, pulley, or clutch. Each cylinder has at least one inlet and one exhaust valve mechanically operated and synchronized with the cycle. The ignition apparatus is located in the combustion chamber either as an igniter head or a spark plug. The openings to the cylinder, which are opened and closed by the valves, lead to ports, to which manifolds are connected. Auxiliaries which must be driven by the engine, and which consume part of its gross output, are the aforementioned valves, the lubricating oil pumps, cooling water circulating pumps, the **generator** for current to the ignition system, the igniters or timers of the ignition system, and sometimes an air fan. The cylinders are mounted on a crankcase, which provides alignment and also supports the crankshaft bearings.

The operation of an Otto engine may be described beginning with the suction stroke. At the beginning of the suction stroke, the inlet valve will be open, and will remain so until the outward stroke is completed, drawing in through the carburetor and manifolds a mixture of gasoline and air in explosive proportions. The quantity drawn in per stroke depends on the **volumetric efficiency** created by the induction system. On the succeeding inward stroke of the piston the inlet valve remains open for possibly 10 to 15 degrees of crankshaft travel because there is a certain inertia of the gas column moving in the manifolds and ports, and the flow will not immediately reverse upon reversal of the piston travel. The inlet ports should remain open as long as any gas will flow into the cylinder, so that the volumetric efficiency will be maximum. After closure of the inlet valve, the gas is compressed into the clearance space at the extremity of the cylinder. This clearance space is the combustion space, and its shape has been given a great deal of study in connection with **detonation.** In this space is located the **spark plug** which receives the high-voltage impulse from the ignition system when the crank pin is still 10 to 15 degrees (sometimes even more) before dead center. The advance of this spark before dead center is variable, so that it may be advanced more at high rotative speeds, thus aiding completion of the explosion before expansion begins. On the outward stroke, which is the power stroke, both valves remain closed until the crank is about 30 degrees before outward dead center, when the exhaust valve begins to open. The valve is given this lead on the piston position in order that it may be fully open at the dead center position, so that on the inward exhaust stroke a complete scavenging of burned gases from the cylinder can be a possibility. In fact, the exhaust valve remains open until after the piston is slightly past inward dead center position.

Power is nearly maximum at rated speed. The power strokes per minute in a four-stroke cycle engine of a single-acting type is one-half the number of revolutions per minute times the number of cylinders. In a two-stroke single-acting engine it is the number of revolutions per minute times the number of cylinders. In the double-acting engine, it is always twice that of the corresponding single-acting engine. Thus a two-cycle, double-acting engine would have four times as many power strokes for the same rotative speed as a four-cycle single-acting engine. The amount of power developed by the Otto engine may be varied in several ways, among which are the following:

Quantity Governing. In quantity governing, the amount of air mixed with a unit of fuel is kept the same, but the quantity fed per cycle is decreased for decreased power, and vice versa. This system is the type ordinarily employed on the automobile engine, where the quantity is governed by interposing an artificial resistance between the carburetor and the cylinder in the form of a valve, which may be opened or closed by the driver. The disadvantage of quantity governing is that it reduces the efficiency because the full compression pressure is not reached when the engine is operating throttled.

Quality Governing. With this the full compression pressure is reached at the end of the compression stroke because the amount of air charged per cycle remains constant. Power is varied by altering the mixture of fuel and air. This system of governing is faulty in that unexplosive mixtures are produced at very light loads, causing a hit and miss type governing. It is suitable to gas, but not gasoline, engines.

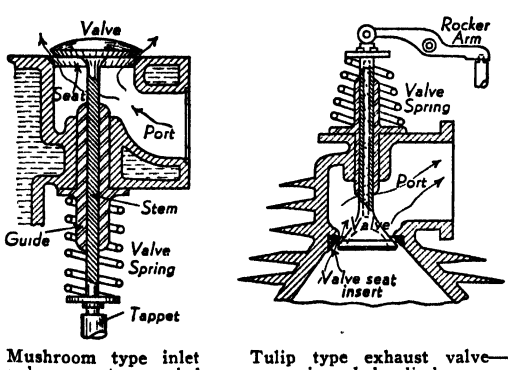
Hit and Miss Governing. An inexpensive simple form of constant speed governing used on light portable and stationary engines, is known as hit and miss governing. It is governing by means of varying the number of power strokes per minute by causing some normal power strokes to be missed. This can be done by one of three ways:—by opening the switch in the ignition circuit, causing failure to ignite; by holding the exhaust valve open during the suction stroke; and by leaving the inlet valve closed during the suction stroke.

The combustion of gasoline in the Otto engine is as follows: (**Gasoline** is a mixture of many hydrocarbons, for which the formula C_8H_{18} is taken as a fair average composition.)

$$C_8H_{18} + 12.5O_2 = 8CO_2 + 9H_2O.$$

Calculations based on this equation show that 15.2 lbs. of air are required for the complete combustion of each pound of gasoline. A deficiency of air results in the formation of **carbon monoxide** and **hydrogen**, but if there is only a small deficiency, the hydrogen may be assumed as being completely burned. Theoretically, **oxygen** and carbon monoxide should not be present in the combustion of a perfect mixture, but actually oxygen will be found in the combustion of lean mixtures, and carbon monoxide will persist in the products of combustion of rich mixtures. The limits of explosive mixtures of gasoline and air are between 12 and 19 lbs. of air per pound of gasoline. Maximum power is derived at about 13 lbs. of air, the ideal conditions call for 15.2 lbs., and maximum economy is obtained with even leaner mixtures.

There is no more critical part of the Otto cycle than the valves, for these are required to remain pressure-tight under the severe condition of high operating temperature. The exhaust valves of heavily loaded engines operate continuously in an atmosphere of flame, and become red hot. The valves, especially the exhaust valve, which has not the benefit of the cooling derived from an incoming charge, are sources of trouble in the Otto engine. By the use of special cooling and of alloy steels, these failures have been greatly reduced in number. The poppet valve is used on nearly all Otto engines. The only other type to be employed at all is the sleeve valve, in which a sleeve is placed between the piston and the cylinder. The piston slides smoothly in the sleeve, which has some slight motion relative to the cylinder walls. The sleeve is driven by eccentrics or cams, so that a slot in it registers with a fixed port on the cylinder wall when the cylinder is to be opened to the manifolds. Two concentric sleeves are used in the Knight sleeve valve design. Of much more importance from the standpoint of usage is the poppet valve. This valve has a disk-like head attached to a stem. The stem reciprocates in a valve guide under the action of a cam which bears against the end of the stem, or which operates a tappet which, in turn, bears against the valve stem. The head has a face which is a portion of a cone, and which sets in a conical seat in the cylinder, or combustion chamber. There is no sliding action between the valve and its seat. Mushroom and tulip type poppet valves are shown in the accompanying diagram. The mushroom type is the



Mushroom type inlet valve — water - cooled cylinder.

Tulip type exhaust valve—air-cooled cylinder.

Fig. 1. Poppet valves.

simplest, and is suitable for ordinary work. When valves run continuously at very high temperatures, and are made fairly large, the mushroom head has a tendency to break or warp, because its strength is derived by cantilever action, and there is a point of weakness at the attachment of the stem. The tulip valve is in tension instead of bending. It is less liable to leak and gives a better streamlining in the port. This type of valve, when constructed with a hollow stem, partially filled with metallic sodium, which assists in the transfer of heat from the head to the rest of the stem, has been able to perform satisfactorily in the high output aeronautical type engines. The materials which are used must be alloy steel to withstand the corrosion, abrasion, scaling, burning, and high stress met in service. While carbon steel may be used for inlet valves, chrome nickel or chrome silicon exhaust valves are required. The valve seats are often cut and reamed into the cast iron which comprises the cylinder block of small and medium duty engines. Large valved engines, and engines having aluminum cylinder heads, require inserts of aluminum bronze, stellite, or special alloys, to form the valve seats.

Valves are actuated by an operating gear deriving its motion ultimately from the crankshaft. Since the motion of a poppet valve is a reciprocation of short throw, the **cam** is the most practical intermediary between the rotative motion of the crankshaft and the reciprocating motion of the valve. Due to the fact that the valve needs to reciprocate only once during the two revolutions of a four-stroke cycle, the cam shaft must be a half-speed shaft driven from the crankshaft by gears or chain. The cam bears against a follower, which may be of roller type, or flat face. This follower may be the end of the valve stem, or it may be a tappet, push rod, or rocker arm between cam and valve stem, depending on the relative location of the cam shaft and valves. Any discussion of valve operating gear would necessarily be based on some knowledge of common cylinder head arrangements (Fig. 2). These might be classified as T, L, I, and F arrangements, these letters being symbolic of the shape of the

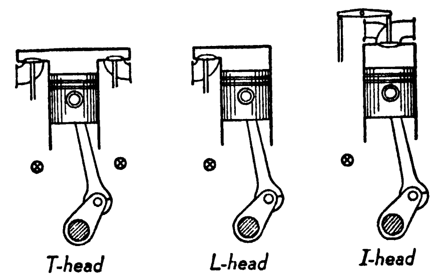


Fig. 2. Common cylinder shapes as governed by valve position.

cylinder head. In the T head, the combustion chamber has pockets on either side, in one of which is located the exhaust valve, in the other the inlet valve. Earlier engines were so built, but the construction has been abandoned because two cam shafts were necessary. The L head arrangement is the most common today. The valves are both located in the same pocket on the same side of the cylinder. In-line multi-cylinder engines, then, have all the valves in a single line, so that they may be driven by cams, all of which are machined on a common cam shaft. When the valves are located overhead in the top of the cylinder instead of in a special valve pocket, the arrangement is known as the I head. The valves open downward into the cylinder in the I head, whereas in the T and L they open upward. I head arrangement has advantages of more direct gas flow to the cylinder, thus promoting higher volumetric efficiency; but has the disadvantage of a more complicated valve gear. In the F head, which has been but little used, the exhaust and inlet valves are mounted one over the other in a valve pocket, one being similar to an L head valve, the other to an I head valve. (See **Valve Gear.**)

Valves in L head engines are set directly in line with the cam shaft, so that the cam either bears directly on the end of the valve stem, or indirectly, through a relatively short follower. As the cam provides positive motion in one direction only, the valve is opened against a spring pressure. The valve spring holds the cam follower against the cam. On I head engines, the cam shaft must either be placed above the cylinder, a somewhat awkward position, or motion must be transmitted from its crankcase location to the valve by push rod and rocker arm.

The high cylinder temperatures of internal combustion engines would quickly destroy any lubricating film if positive cooling of some sort were not adopted. By positively abstracting about one-third of the heat of combustion to a cooling system, a temperature gradient is maintained through the cylinder wall, and the moving parts can be adequately lubricated. The heat so abstracted is loaded on either air or water. In a great many cases air is also the final cooling medium for the water. The water is circulated through a **radiator**, where it is cooled by a current of air drawn through the radiator. Direct air cooling requires extending the outer surface of the cylinder, because computations show that a plain cylinder would have a temperature exceeding 1800° F. Cylinders are finned and flanged so that the external surface will be sufficient to dissipate the required amount of heat to a stream of air. A positive circulation of air over the fins is also necessary. This is accomplished by fans and by baffles which direct the air over the finned surface. Air cooling is most successful where the cylinders are individual, whereas liquid cooling is better suited to en-bloc construction. The liquid is contained in a thin layer held around the cylinder head, or completely around the cylinder, by the cooling **jacket**. This may be a metallic cover welded or otherwise fastened around the cylinder, leaving a water space between it and the cylinder, or the water space may be an opening in the casting made by cores. Most liquid cooling is with water, but special liquids, such as alcohol, glycerine, ethylene glycol, are added for several reasons, among which are to be noted low freezing temperatures, antirusting properties, and better heat transfer. The water used in a cooling system must be clean and relatively pure, so that scale will not accumulate inside the jackets. It can be used in a once-through system, or it can be recirculated. The heat may be absorbed as heat of the liquid, obtained by an increase of water temperature to a maximum of around 200° F., or it may be absorbed as latent heat in evaporating the water in the jacket. Usually the water-cooling system is of the recirculation type, the heat being ultimately given to the air by means of radiator, cooling tower, or spray pond.

The lubrication of this type of engine is of the utmost importance because of high speed, temperature, and pressure, coupled with the interdependence of all parts upon the proper functioning of the remainder. Parts needing lubrication are the piston and cylinder, the valve gear, the connecting rod bearings, the crankshaft, and camshaft bearings.

Auxiliaries such as fans, generators, starters, also have their points of lubrication. Three systems of lubrication most used are the splash, the semi-force feed, and the force feed, all of these relating to the enclosed crankcase type engine. In the splash system oil is pumped into troughs located so that the ends of the connecting rods dip into a pool of oil and splash it about inside the crankcase. The semi-force feed system has lubrication of the crankshaft bearings and the camshaft bearings by oil which is conveyed to them under pressure through tubes. The connecting rod bearings and cylinders are lubricated by splash. There is neither trough nor splash in the full force feed. Oil from the pump is carried to the crankshaft bearings through tubes, and to the connecting rod bearings through drilled passages in the webs of the crank. Centrifugal force throws it out of the connecting rod bearing as the latter revolves, so that the crankcase is filled with an oil mist which lubricates the piston and wrist pin. Occasionally one will find the connecting rod drilled in its entire length so that the piston end of the connecting rod also receives oil under pressure. The oil so delivered to the bearings drains into the crankcase, from which it is either taken as needed by the oil pump, or is immediately removed and placed in an external tank by a scavenging oil pump. These two systems are known as the dry and the wet sump systems.

During the operation of the engine there is a steady loss of oil. Some is burned in the combustion chamber, some leaks through gaskets and around shafts, and some is blown out of the crankcase breather as a mist. That which is burned in the combustion chamber accounts largely for the accumulation of carbon so often found there. The incomplete combustion of fuel, and dust and dirt from the air, contribute somewhat to combustion chamber deposits, but to a much lesser degree than does oil. Some oil in the combustion chamber is necessary if the piston is to be properly lubricated, but wear or sticking of the piston rings may cause the piston to assume some pumping action, and deliver to the combustion chamber a great deal more oil than would be necessary for cylinder lubrication, certainly more than is desirable from the standpoint of the condition of the combustion chamber. In addition to creating a carbon deposit, an excessive amount of oil may foul the sparking plug points, and cause sticking of the valves. Carbon in the cylinder head provides a black surface which initially aids heat transfer, but, as it thickens, greatly retards heat transfer, due to the low heat transfer coefficient of carbon. Then hot spots remain in the cylinder and preignition and detonation are liable to occur. The thicker the accumulation of carbon, the hotter the combustion chamber becomes, and carbon reaches a maximum thickness beyond which accumulations are burned off as rapidly as they are formed.

The foregoing remarks apply, in the main, to the four-stroke cycle engine. In some respects they apply to the two-stroke, but there are essential points of difference. The two-cycle engine is characterized by the absence of valve gear, since the piston moves to uncover ports in such a way that the events of admission and exhaust are

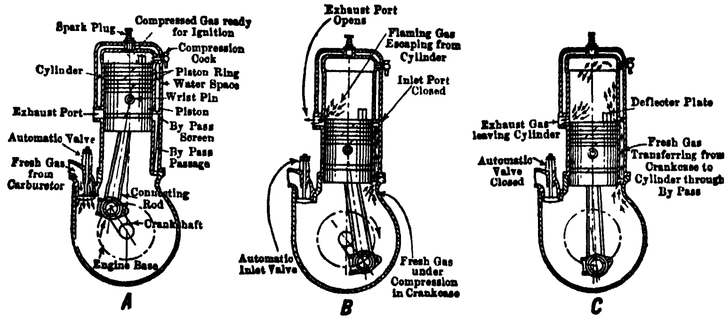

Fig. 3. Two port two-cycle engine.

accomplished without the use of valves. Fig. 3A represents the two-cycle engine nearing the inward dead center, with the compressed gas ready for ignition. Ignition occurs, and the resulting combustion raises the pressure and drives the piston outward on a power stroke. Near the end of the outward stroke the piston uncovers an exhaust port in the lower part of the cylinder wall, and the residual pressure drives the exhaust gas quickly out through this port (Fig. 3B). Further outward motion to the dead center position then uncovers a port leading from the crankcase to the cylinder. The crankcase is filled with a slightly compressed mixture of gasoline and air, which is rapidly passed through this port (Fig. 3C). Entering the cylinder, being deflected upwards, it tends to drive the remaining burned gas out through the exhaust port, which is still open. As the piston moves on its inward stroke, it closes these ports and compresses the gas into the clearance space. The same motion tends to create a vacuum in the airtight crankcase, with the result that a fresh charge is introduced into the crankcase to be compressed on the down stroke. The comparatively shorter length of time available in this engine for charging and scavenging the cylinder makes it impossible to attain volumetric efficiencies comparable with the four-stroke cycle, except for relatively small, slow-moving engines. (F.T.M.)

OTTRELITE. **Chloritoid.**

OUNCE. Mammalia, Carnivora. The snow leopard of Asia, *Felis uncia,* a moderately large cat found at high altitudes in the central part of the continent. The fur is long and thick, grayish or slightly tawny above with darker black-ringed spots. (A.W.L.)

OUTCROP. Everywhere beneath the **soil** at greater or less depths there exists the solid continuous masses of rock which make up the earth's crust. Wherever rock appears protruding through the soil cover it is spoken of as an outcrop. (E.S.C.S.)

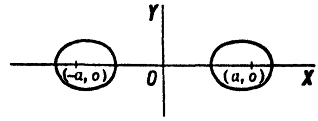
OUTLIER. A term used by **structural geologists** to define an area of younger rock strata which has been geographically separated by **erosion** from the principal area within the same region. Not to be confused with **klippe.** (See also **Inlier.**) (R.M.F.)

OUTPUT METER. This is an **instrument** used for measuring the output of audio **amplifiers.** It consists of a resistor coupled to the amplifier through an impedance-matching **transformer** and a rectifier voltmeter connected across the resistor. The voltmeter is usually calibrated so it indicates the watts dissipated in the resistor either directly in watts or in **decibels** above some reference value. (L.R.Q.)

OUZEL. Aves, Passeriformes. 1. The ring ouzel, *Turdus torguatus,* a mountain bird (**Aves**) of central and northern Europe. A thrush. 2. The **blackbird** of Europe and eastern Asia, also a **thrush.** 3. The water ouzel, or dipper. The name water ouzel applies to several species of the northern hemisphere which haunt rapid streams. Although not a swimming bird it wades into deep water, where it is said to make its way by using both feet and wings. The North American species, *Cinclus mexicanus,* is characteristically a western mountain bird. Its dull gray color is more than offset by its interesting habits and by a glorious song, heard all too rarely.

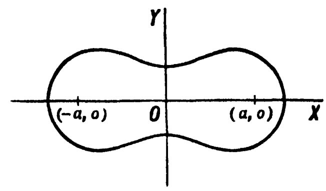
Sometimes spelled ousel. (A.W.L.)

OVALS OF CASSINI. This is the name given to the plane curve defined as the **locus** of a point that moves so that the product of its distances from two fixed points $(-a, 0)$ and $(a, 0)$ is equal to a constant k^2. (Figs. 1 and 2.)



$k<a$

Fig. 1.



$k>a$

Fig. 2.

Ovals of Cassini.

Its equation in **polar coordinates** is

$$(r^2 + a^2)^2 = 4a^2r^2 \cos^2 \theta + k^4.$$

If $k = a$, we get the **lemniscate.** (L.L.S.)

OVARIOLE. One of the tubular components of the insect ovary. It consists of regions in which the egg cells are formed and in which they grow and mature. (A.W.L.)

OVARY. The ovaries are the sex glands of the female. In humans they are two in number, 3–4 cm. in diameter, almond-shaped, and situated on either side of the **pelvis** in the folds of the broad ligament which supports the **uterus.** With the onset of puberty, cyclic changes take place in the ovaries; after the **menopause** they diminish in size and activity.

The function of the ovaries is the production of **ova,** and the elaboration of several hormones concerned in reproductive mechanisms. The ovaries are therefore glands of internal secretion, or **endocrine glands.** Two types of hormones are produced: the estrogenic group of which estrin is the most important, and corpus luteum hormone or progesterone. These substances are concerned with the changes characteristic of **menstruation,** those following impregnation which are necessary for the development of the fertilized ovum, and the changes in the mammary glands occurring during **pregnancy.** Further, the ovary produces **hormones** that cause development of the female genital organs and the secondary sex characteristics. The ovary is directly stimulated or inhibited by hormones from other endocrine glands, notably the **pituitary** and in a lesser degree by the **thyroid** and **adrenal glands.**

For the use of the term ovary in botany, see **Flower.** For its general use in zoology, see **Gonad.** (D.M.H.)

OVEN-BIRD. Aves, Passeriformes. 1. The European willow **wren,** *Phylloscopus trochilus,* and other birds which build domed nests. 2. A North American Warbler, *Seiurus aurocapillus,* also called the golden-crowned thrush. 3. South American birds of several species which build mud nests resembling old-fashioned ovens. Genus *Furnarius.* (A.W.L.)

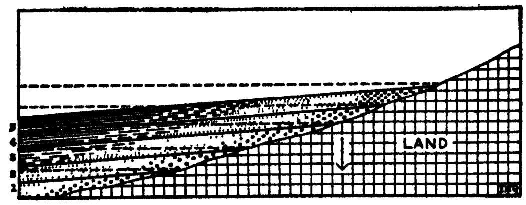
OVERCAST. When the sky is more than 9/10 covered with clouds. Viewed from on top (aircraft view) it is said to be an undercrest. (P.E.K.)

OVERFOLD. A term used by **structural geologists** to define an overturned **anticline** resulting in a recum-

bent fold often simulating a normal **stratigraphic** pile of strata for which it may be mistaken. (R.M.F.)

OVERHANGING BEAM. **Bending Moment; Shear.**

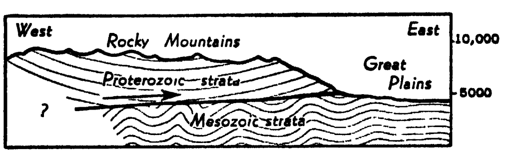
OVERLAP. This term refers to the gradual burial of the land mass or mountain slopes from which the **sediments** were derived. (R.M.F.)



This diagrammatic section shows the principle of overlap. Horizontal broken lines represent different stages of sea level relative to the land. As the sea encroached toward the right upon the subsiding land, deposition of the sediments 1, 2, 3, 4, 5, extended farther and farther to the right, later formed beds, thus overlapping earlier formed beds.

OVERSATURATED. As used by **petrologists,** this term, proposed by Shand in 1915, signifies **igneous** rocks containing free **silica of magmatic** origin, and in the form of **quartz** or **tridymite.** (R.M.F.)

OVERTHRUST. A low-angle **fault** of the thrust or compressional type frequently resulting in the translocation of a mass of rocks several miles. Because of



Diagrammatic structure section showing how the great body of Proterozoic strata has been thrust-faulted from the west for miles over upon Late Mesozoic strata in Glacier National Park, Montana. The Mesozoic beds were folded by action of the over-riding block. Length of section, about 25 miles. Vertical scale, much exaggerated.

the low angle of the thrust as well as the possible inversion of great piles of formations this type of faulting or failure of the **lithosphere** has led, and still leads, to considerable technical difficulties in determining the **stratigraphic** history in regions where low angle faulting predominates. (R.M.F.)

OVERTONES. **Vibrations and Waves; Musical Sounds.**

OVICELL. **Ooecium.**

OVIPOSITOR. An organ used by some of the **arthropods** to deposit their eggs. It consists of a maximum of three pairs of appendages formed to transmit the egg, to prepare a place for it, and to place it properly. In some of the insects the organ is used merely to attach the egg to some surface, but in many parasitic species (**Hymenoptera**) it is a piercing organ as well. It is used by the **grasshoppers** to force a burrow in the earth to receive the eggs and by **cicadas** to pierce the wood of twigs for a similar purpose. Both long-horned grasshoppers and sawflies cut the tissues of plants by means of the ovipositor. None of these examples is quite as remarkable as the **ichneumon flies** (parasitic Hymenoptera) which have a slender ovipositor several inches long, used to drill into the wood of tree trunks. These species are parasitic in the larval stage on the larvae of wood-boring insects, hence the egg must be deposited in the burrow of the host.

The sting of **wasps** and **bees** is also an ovipositor, in this case highly modified and associated with poison glands. (A.W.L.)

OVO-TESTIS. **Gonad.**

OVULE. **Flower.**

OVUM. **Gamete.**

OWL. Aves, Strigiformes. Nocturnal **birds** (**Aves**) of prey with hooked beaks and strong curved talons. They differ from the other birds of prey in having the eyes directed forward and surrounded by a more or less evident disk of small radiating feathers. Owls have soft thick plumage and are characteristically silent in flight as a result.

The North American species range in size from the 6-in. Acadian owl to the 2-ft. great horned owl, ***Bubo virginianus,*** and a similar range of size is noted in the rest of the world from the pigmy owls of the Old World to the great hawk-owl of Australia. The group is represented on all continents.

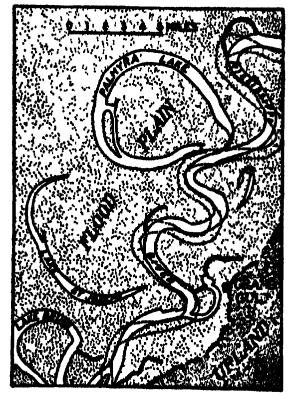
Although owls are characteristically predacious they do not disdain insects as food. The smaller species catch mice and other small animals, and larger owls prey upon animals as large as rabbits. The great horned owl is said to be an undesirable marauder in poultry yards at times. Certainly it catches birds, but owls in general probably do more good than harm in their destruction of small rodents. (A.W.L.)

OWLET MOTH. Insecta, Lepidoptera. A common name for the **moths** of the great family Noctuidae. Used chiefly in Europe. (A.W.L.)

OX, OXEN. Mammalia, Artiodactyla. Hoofed animals with two functional toes on each foot, with hollow horns in both sexes, and with a long tail, usually tufted at the end. The horns are never spiral as in sheep, goats, and some antelopes, but are usually curved. They are mostly of massive build, with a short head, broad muzzle, and short thick neck.

Most of the species of this group are indigenous to the Old World. North America has the **musk ox** and the **bison,** and South America and Australia are entirely without representatives. A number of species have been domesticated and are used in all favorable parts of the world as a source of meat, milk, and hides, and to a lesser extent as draft animals. The common ox is *Bos taurus.*

The group includes the **aurochs,** humped cattle or **zebu,** the **gaur, gayal, banting, yak, bisons, buffalos** and the **musk ox,** which is related to the sheep. The European bison is also called the wisent or zubr, and the Indian buffalo is sometimes known as the arna. In the Philippines the **tamarao** and **carabao** are the buffalos used for draft purposes. The **anoa** is a small species related to the buffalos and antelopes; it is found in Celebes. (A.W.L.)



Meanders and ox bow lakes of part of Mississippi River flood plain in 1883 (heavy lines) and 1896 (dotted lines). (*By William Davis, based upon Government Surveys.*)

OX BOW LAKE. The type of lake developed on the flood plains, especially in the delta regions, of large rivers. Ox bow lakes represent the detached or truncated former meanders of the main stream which, from time to time, straightens its course by forming cut-offs or short cuts. (R.M.F.)

OXALIC ACID AND OXALATES. Oxalic acid ($H_2 \cdot C_2O_4 \cdot 2H_2O$ or $COOH \cdot COOH \cdot 2H_2O$) is a white solid, melting point of crystals 101° C. (of anhydrous 180° C.), sublimes at 150° C., soluble in water, alcohol, or ether. **Calcium** oxalate, on account of its solubility characteristics (0.007 gram per liter of water), is of importance in the separation and recovery of oxalic acid. Calcium oxalate plus dilute **sulfuric acid** yields oxalic acid plus calcium sulfate, and the latter may be separated by filtration. Oxalic acid may be obtained by evaporation of the filtrate. With concentrated **sulfuric acid** heated, calcium oxalate, or other oxalate or oxalic acid, yields equal volumes of **carbon dioxide** and **carbon monoxide** gases. Oxalic acid (or oxalates), after being dissolved in dilute sulfuric acid, is readily oxidized to carbon dioxide by **permanganate.**

Representative esters of oxalic acid are: Methyl oxalic acid ($COOH \cdot COOCH_3$), melting point 37° C., boiling point 108° C. at 12 mm. pressure; dimethyl oxalate ($(COOCH_3)_2$), melting point 54° C., boiling point 163° C.; diethyl oxalate ($(COOC_2H_5)_2$), melting point −41° C., boiling point 186° C.

Oxalic acid may be obtained (1) from some natural products, e.g., wood sorrel, and other members of the oxalis family, as **potassium** hydrogen oxalate, the bark of certain species of **eucalyptus** (sometimes containing 20% calcium oxalate in the cells and cell walls), (2) by reaction of acid with an oxalate, e.g., calcium oxalate plus sulfuric acid as above. Sodium oxalate is made (1) by heating **sodium** formate at 300° C. in vacuum, with the evolution of **hydrogen gas**, (2) by reaction of **carbon dioxide** plus metallic **sodium** at 360° C., (3) by heating wood powder ("sawdust"), particularly of **coniferous** woods, with **sodium** hydroxide (addition of potassium hydroxide enables one to use a moderate temperature, say 220° C.), (4) by oxidation of sucrose or starch with nitric acid. Oxalic acid is a dibasic acid, that is, two series of salts are known, a third series is also known, thus, sodium oxalate ($Na_2C_2O_4$), sodium binoxalate ($NaHC_2O_4$), sodium tetroxalate ($NaH_3(C_2O_4)_2$).

Oxalic acid is used (1) in the preparation of oxalates, e.g., **titanium** potassium oxalate, and esters, (2) in the purification of certain chemicals, e.g., **glycerol,** stearates, (3) in bleaching straw, (4) in ink and rust remover, (5) in the leather and textile industries, (6) in the manufacture of dyes, (7) in the preparation of glyoxalic and glycollic acids by regulated reduction.

A common test for oxalic acid is as follows: Heat solution with resorcinol (see **Phenol**) in a test tube and on cooling add carefully a layer of sulfuric acid. A blue ring at the junction of the two layers indicates oxalic acid. (R.K.S.)

OXAZOLE. Pyrrole and Related Compounds.

OXIDATION. Reactions Involving Oxidation-Reduction.

OXIDES. Oxygen; and individual elements.

OXIMES. Hydroxylamines and Oximes.

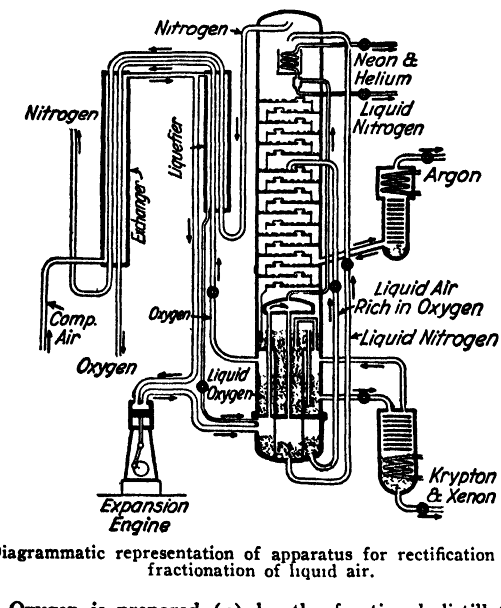
OX-PECKER. Aves, Passeriformes. African birds, (**Aves**) of a group related to the starlings. The common name refers to their habit of climbing about the bodies of domestic cattle in search of ticks and other external parasites. They also visit wild animals for the same purpose. (A.W.L.)

OXYACETYLENE WELDING. Welding.

OXYGEN. Symbol: O. Atomic number: 8. Atomic weight: 16.0000. Density: 1.42904 grams per liter, 0° C., 760 mm., or 1.105 when air equals 1.000. Formula of oxygen gas: O_2 (formula of ozone: O_3). Melting point of oxygen: −218.8° C. Boiling point: −183° C. Critical temperature: −118.8° C. Critical pressure: 49.7 atmospheres. Isotopes: 16 (99.76%), 17 (0.04%), 18 (0.20%).

Oxygen is a colorless, odorless, tasteless, non-toxic gas, found free in the atmosphere (23.15% by weight of oxygen in dry air, 20.98% by volume) mixed with **nitrogen, argon,** the rare gases, **carbon dioxide,** and water vapor. Liquid oxygen is strongly magnetic. Molten **silver** dissolves about ten volumes of oxygen, giving it up upon cooling, with an effect known as "spitting." Oxygen was discovered by Priestley in 1774 by heating **mercuric** oxide, and independently in the same year by Scheele. Oxygen is necessary for the burning of substances. The temperature of ignition of each combustible substance is more or less characteristic, for example, **phosphorus** in air is ignited at 34° C., **ether** in air 340° C., **ethyl alcohol** in air 560° C., **kerosene** in air about 300° C., **hydrogen** in air about 600° C.

Oxygen occurs combined with **silicon, aluminum, iron** and other metals in all rocks (average of the solid crust of the earth 46.7% oxygen), as a constituent of practically all plant and animal substances, except **hydrocarbons,** as the most abundant element in the ocean (85.8% oxygen). The process of respiration of animals involves the reaction of free oxygen with the animal organism at the temperature of its surroundings. The burning of fuels when heated to the **ignition** temperature is a process of combination with free oxygen, as also the corrosion of iron, which is an important reaction at ordinary temperature.



Diagrammatic representation of apparatus for rectification and fractionation of liquid air.

Oxygen is prepared (1) by the fractional distillation of liquid air, (2) by the **electrolysis** of water containing an **electrolyte** such as **potassium** hydroxide, (3) by heating **potassium** perchlorate, which is preferable to potassium chlorate on account of the diminished hazard, and by heating **barium** peroxide or **lead** dioxide, (4) by the reaction of sodium peroxide and water, forming also sodium hydroxide.

When oxygen is subjected to the silent electric discharge, activated atomic oxygen is produced. Atomic oxygen displays an afterglow upon cessation of the cur-

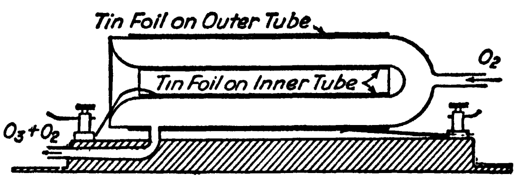
rent, and the oxygen is notably active with **hydrogen bromide** forming water and **bromine**, with **hydrogen sulfide** forming **sulfur, sulfur dioxide, sulfur trioxide**, and **sulfuric acid**, with **carbon disulfide** forming **carbon monoxide, carbon dioxide**, and **sulfur dioxide** and, strangely, reduces **molybdenum** trioxide to a white oxide not reducible with **hydrogen.** The concentration of atomic oxygen obtainable by the silent electric discharge through oxygen is estimated at 20%.

Ozone (O_3) is a blue gas, of characteristic odor, formed when ordinary oxygen is subjected to electrostatic discharge. Density: 1.5 times that of oxygen gas. Melting



Ozonizer

point: −251.4° C. Boiling point: −111.5° C. Explosive by percussion, or under variations of pressure. Ozone reacts (1) with **potassium** iodide, to liberate **iodine**, (2) with colored organic materials, e.g., litmus, indigo, to destroy the color, (3) with **mercury**, to form a thin skin of mercurous oxide causing the mercury to cling to the containing vessel, (4) with **silver** film, to form silver peroxide (Ag_2O_2) black, produced most readily at about 250° C., (5) with tetramethyldiaminodiphenylmethane $(CH_3)_2N \cdot C_6H_4 \cdot CH_2 \cdot C_6H_4 \cdot N(CH_3)_2$ in alcohol solution with trace of **acetic acid** to form violet color (**hydrogen peroxide**, colorless; **chlorine** or **bromine**, blue; **nitrogen tetroxide**, yellow). In contrast to **hydrogen peroxide** ozone does not react with **dichromate, permanganate**, or **titanic** salt solutions. Ozone reacts with olefin compounds to form ozonide addition compounds. Ozonides are readily split at the olefin-ozone position upon warming alone, or upon warming their solutions in glacial acetic acid, with the formation of **aldehyde** and **acid** compounds which can be readily identified, thus serving to locate the olefin position in oleic acid ($C_{17}H_{33} \cdot COOH$) as midway in the chain $CH_3(CH_2)_7CH{:}CH(CH_2)_7COOH$. Ozone is used (1) as a bleaching agent, e.g., for fatty oils, (2) as a disinfectant for air and water, (3) as an oxidizing agent.

Oxides are known of many elements. Metallic oxides are (1) reactive with water, e.g., **calcium, strontium, barium** oxides (CaO, SrO, BaO), (2) insoluble, e.g., ferric oxide (Fe_2O_3), **ferrous** oxide (FeO), ferroferric oxide (Fe_3O_4), **cupric** oxide (CuO), **cuprous** oxide (Cu_2O); and may be otherwise subdivided, (a) reactive with **hydrochloric acid** to yield **chlorine**, e g., **lead** dioxide (PbO_2), plumboplumbic oxide (Pb_3O_4), **manganese** dioxide (MnO_2), (b) reactive with water or dilute acid to yield **hydrogen peroxide**, e.g., **sodium** peroxide (Na_2O_2), **barium** peroxide (BaO_2). Non-metallic oxides are (1) reactive with water, e.g., **carbon dioxide** (CO_2), **sulfur** dioxide (SO_2), **sulfur** trioxide (SO_3), **phosphorous** trioxide (P_2O_3), **phosphorus** pentoxide (P_2O_5), boron oxide (B_2O_3) forming the corresponding acids (H_2CO_3, H_2SO_3, H_2SO_4, H_3PO_3, H_3PO_4, H_3BO_3); reactive with water to form two acids, e.g., nitrogen tetroxide (N_2O_4), yielding **nitrous** plus **nitric acids** (HNO_2 and HNO_3), **phosphorus** tetroxide (P_2O_4) yielding **phosphorus** plus **phosphoric acids** (H_3PO_3 and H_3PO_4), (2) insoluble or non-reactive with water, e.g., **carbon monoxide** (CO), nitric oxide (NO), nitrous oxide (N_2O), **silicon** oxide (SiO_2). Amphoteric oxides are reactive both with acids and with bases to form salts, e.g., **aluminum** oxide (Al_2O_3) with **sulfuric acid** yielding aluminum sulfate ($Al_2(SO_4)_3$), with **sodium** hydroxide yielding sodium aluminate ($NaAlO_2$), **lead** monoxide (PbO) with **nitric acid** yielding lead nitrate ($Pb(NO_3)_2$) with sodium hydroxide yielding sodium plumbite (Na_2PbO_2), zinc oxide (ZnO) with hydrochloric acid yielding zinc chloride ($ZnCl_2$), with sodium hydroxide yielding sodium zincate (Na_2ZnO_2).

Organic compounds of carbon, hydrogen, oxygen only are discussed as follows:

Acetals. (See **Aldehydes and Related Compounds.**)
Acids. (See **Acids, Carboxylic, and Related Compounds.**)
Acid anhydrides. (See **Acids, Carboxylic, and Related Compounds.**)

OXYPYROLINE. **Aminoacids, Polypeptides, and Proteins.**

OYSTER. Mollusca, Lamellibranchiata. Bivalve **mollusks** of the family Ostreidae. Pearl oysters are species of different families found only in warmer oceans, while the edible oysters include a European species, *Ostrea edulis,* a species of the Atlantic coast of North America, *O. virginica,* and the Pacific coast oyster, *O. lurida.* The common oyster of commerce has been transplanted successfully to the Pacific coast. All are marine.

Oysters are the most important of the edible invertebrates. They have been cultivated since the days of the Roman Empire and are now gathered from the oyster beds of the United States alone at an estimated rate of 25,000,000 bushels per year. Fortunately they are extremely prolific, a single oyster of the common American species producing as many as 20–60 million eggs in a breeding season. The young oysters develop in the gills of the parent into ciliated (**cilia**) **larvae** called spat which swim freely for a few days and then settle to the bottom and become attached. From that time they are permanently fixed. In cultivated beds they may be moved to favorable places after once attaching themselves, and after 3–5 years they attain market size. The beds require protection against starfishes and other natural enemies, and for the consumer's sake they must be guarded against pollution by human wastes. Oysters that have lain near sewage outlets are dangerous as possible carrier of typhoid germs, although when they are cooked before eating they are likely to be sterilized. (A.W.L.)

OYSTER PLANT, SALSIFY. *Tragopogon porrifolius.* **Composite Family.**

OYSTER-CATCHER. Aves, Charadriiformes. Birds (**Aves**) of few species but worldwide distribution. They are related to the avocets, from which they differ in being more stoutly built. They frequent the coasts and eat bivalve mollusks, among a much greater variety of food. The American species is *Haematopus palliatus.* (A.W.L.)

OZALID. **Drawing Reproduction.**

OZARKIAN. **Ordovician.**

OZOKERITE. A mineral wax which occurs as a natural, solid **hydrocarbon,** yellowish-brown to green in color and usually translucent with a waxy luster. (E.S.C.S.)

OZONE. **Oxygen.**

OZONIDES. **Oxygen.**

P

P SERIES. **X-Ray Spectra.**

PA. **Public Address.**

PACA. Mammalia, Rodentia. A stoutly built **rodent,** *Agouti paca,* about 2′ long, marked with rows of light spots on a fawn to blackish ground color. It occurs through most of South America east of the Andes. Related to the agoutis. (A.W.L.)

PACHYDERMATA. An obsolete name for a group of mammals, including the **elephants.** It is reflected in the name pachyderm sometimes applied to these animals. The word means thick-skinned. (A.W.L.)

PACIFIC SUITE. A term proposed by A. Harker, in 1896, for the chemically, structurally, and geographically related **igneous rocks** of the Pacific coast line. Chemically the rocks of this suite are described as calc-alkali, and are represented by such types as **andesites, granodiorites** and their relatives, as compared with the alkali igneous rocks of the **Atlantic Suite.** (R.M.F.)

PAD. **Attenuator.**

PADDLE FISH. Pisces, Chondrostei. Large fishes (**Pisces**) related to the sturgeons. The snout is prolonged into a spatulate protuberance. Only two species are known, one in the large rivers of China and the other in the Mississippi and its larger tributaries. The latter, *Polyodon spathula,* is also called the spoon-bill, spoon-beaked sturgeon, and spoon-billed catfish. (A.W.L.)

PADDY BIRD. Aves, Passeriformes. The Java sparrow, *Ardeola grayii,* a **munia.** (A.W.L.)

PAEDOGAMY. **Autogamy.**

PAEDOGENESIS. The attainment of sexual maturity by animals during an immature stage of development. Closely related to **neoteny.** (A.W.L.)

PAGET'S DISEASE. *Osteitis deformans.* A chronic disorder of the bones of unknown origin characterized by enlargement and deformity of the skull, spine and long bones.

The disease develops after 60, the first sign being an increase in the diameter of the head and a bowing of the legs, causing shortness of height. Some cases are marked by severe pain over the involved bones.

Treatment is unsatisfactory. **Calcium, vitamin D, ultra-violet** light, and **x-ray** are used. (R.S.M.)

PAHOEHOE. An Hawaiian term introduced to geological nomenclature by C. E. Dutton, in 1883, and signifying a lava flow with a smooth, ropy surface. Contrast with **aa.** (R.M.F.)

PAINT. **Pigments, Paints, Varnishes; Protective Coatings; Resins.**

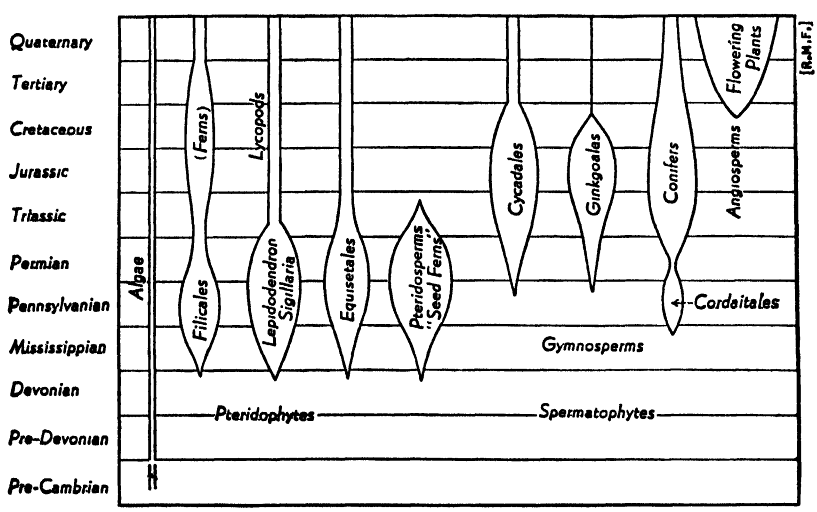
PAINTER. **Puma.**

PALA. **Impala.**

PALATE. The partition between the oral cavity and the nasal passages. The anterior portion contains flat bones and is called the hard palate, while the posterior soft palate is made up entirely of soft tissues. (A.W.L.)

PALEA. A small, usually thin **bract** or scale borne on the **axis** of a grass flower, just above the **lemma.** (R.M.W.)

PALEOBOTANY. This is the study of ancient plants which are known today only through **fossil** remains. These are of two general types: prints and petrifactions. Most of our knowledge of fossil plants has been derived from the study of petrifactions in which the original structure of the plant has been replaced by mineral material.



Geologic range of plants. (*Field, Geology Manual, Part II, Princeton University Press.*)

Originally the study of fossil material was a laborious process, for sections of the material were necessary and sections of such fossils were not easily made. At first these sections were obtained by cutting the fossil in two, grinding the cut surface smooth and examining it, or fastening it firmly to a glass slide and making a

second cut close to the slide, thus getting a thin section which was then ground as thin as possible. Naturally the preparation of fossil material was not only a tedious process, but also one that wasted much of the material.

In recent years an entirely different and much more satisfactory method has been developed. One surface of the fossil is first ground flat. This flat surface is then etched with **hydrochloric acid** or **hydrofluoric acid** according to the material composing the fossil. When the acid has etched deeply enough, it is washed off with water and the surface dried. The dried surface is flooded with a celloidin solution and the latter allowed to dry. The dried celloidin film is then carefully peeled from the surface of the fossil, removing with it a thin film of fossil material. The peeled surface is reground and the process repeated as long as desired, or until the fossil is completely "sectioned." The thin peels may be either mounted on glass slides, like sections of living material, or they may be dried under pressure, so that they remain flat. The advantages of fossil peels for scientific investigations are many. They are so thin that they can easily be examined with high magnifications; they can be rapidly made; they permit serial sections of the material. In this process little of the material is wasted. Finally, fossil peels permit examination of material which can be sectioned only with the greatest difficulty by any other method. This method of preparation has greatly advanced the study of fossil life.

Paleobotany yields much interesting information about the plants of prehistoric times, notably of the **Carboniferous** and **Devonian** periods. Probably the best known fossil plants are those which grew during the Carboniferous period of the **Palaeozoic** era. The many types of coal are geochemical compounds and mixtures of plants including their spore cases, oxidized cellulose (mother of coal), lignite and bacterial by-products The nature of the processes by which coal has been formed is such that coal is often not the best material to study to get a picture of the fossil plants composing it. But found associated with the coal are mineral masses called coal balls. Within these, plant remains are often preserved with beautiful detail. Microscopic studies of peels and thin sections of coal balls have made it possible for the paleobotanist to reconstruct many of the Carboniferous plants.

Plants growing in the Carboniferous period differed strikingly from those of today. Many were trees of large size but rather weird in appearance; today their relatives are small and inconspicuous, if indeed they have not entirely disappeared. *Lepidodendron* was then a common genus with many species. These plants had radiating roots which forked **dichotomously** and spread out near the surface of the ground; the stem was columnar and covered with a rough bark which in the younger parts was composed of spirally arranged cushions of various shapes. Compared with the large size of these stems the **vascular** tissues were very small, giving little support to the stem. Stems having a diameter of 10″ or more would have a stele less than 3″ across. Characteristically branching was dichotomous, forming an open crown of branches covered with needle-shaped leaves, and bearing cones having an outward appearance somewhat like those of several living **conifers**, but structually quite different. Another genus whose members often attained large size was *Sigillaria*, which became increasingly common as the Carboniferous period continued. These plants also had tall thick stems each bearing at its top a crown of branches covered with needle-like leaves. Giant **horse-tails**, known as *Calamites*, were also abundant.

All these plants and many others have a structure which suggests that they grew in a very uniform climate. From the Proterazoic to the late **Silurian** or **Devonian**, the only fossil plants are calcareous **algae**, usually marine.

In the Devonian have been found the first terrestrial fossil plants, which are the progenitors of the Carboniferous flora. The plants were without roots or leaves, but had a prostrate **rhizome** from which arose erect sparingly branched stems, many of which bore **sporangia** at their tips. These stems had a well developed vascular system. Other Devonian plants were larger, some being 10–12′ high, and much branched. As the Devonian period continued, the plants became larger and more like those in the Carboniferous.

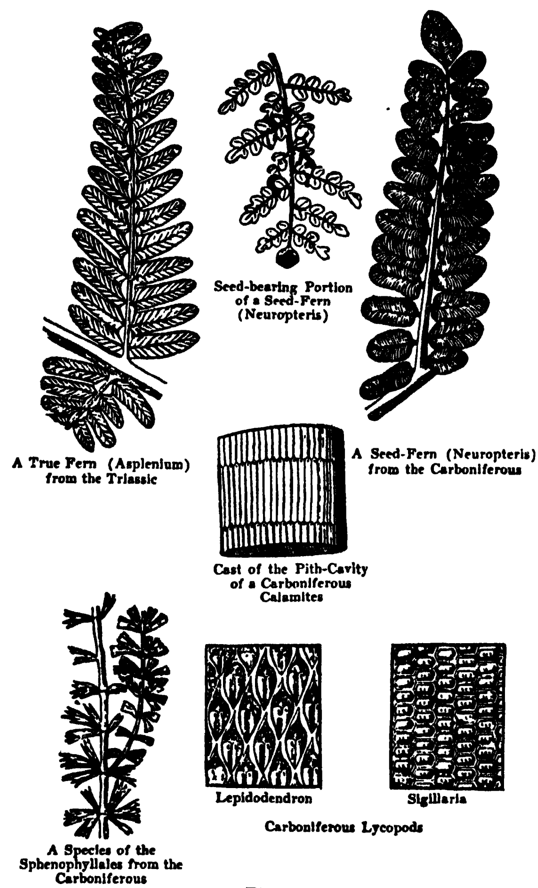


Fig. 1.
(*Field, Laboratory Manual, Princeton University Press.*)

The following brief classification of plants includes the principal types of fossil plants from the **pre-Cambrian** to the **Pleistocene**, together with the paleontological record of their **evolution**.

I. Thallophytes. Lowest and simplest plants. They range from microscopic bacteria to enormous sea-weeds. They are found from pre-Cambrian to the present.

(I-a) **Algae** (marine sea-weeds and fresh-water plants). Some of the algae secrete calcium carbonate. These calcareous algae are an abundant constituent of modern coral reefs. Algal (**cryptozoan**) reefs occur as early as the late **Proterozoic**.

(I-b) **Fungi.** These plants depend upon other living plants or organic debris for food. Include familiar forms such as mildew, yeast, wheat rust, and mushrooms. Not important as fossils.

II. **Bryophytes** (moss plants). These plants possess organs which resemble true stems and leaves, though no true roots or woody tissue. Small and delicate

forms, living largely in moist habits. Occur from **Carboniferous** to present. Not important as fossils.

Fig. 2.
A Cycad (*Plagiozamites*) from the Carboniferous. (*Field, Laboratory Manual, Princeton University Press.*)

III. **Pteridophytes** (fern plants). These plants have acquired roots and woody tissue in stems, and larger and more complex plant body. **Devonian** to present.

(III-a) **Filicales (true ferns).** A dominant Carboniferous type, illustrated on page 1032. 4000 living species, ranging from small temperate ferns to large tropical tree-ferns.

(III-b) **Lycopodiales** (club mosses). Large tree forms in Carboniferous. 500 living species, all small and herbaceous. *Lepidodendron* and *Sigillaria* are best known Paleozoic types, illustrated on page 1032.

(III-c) Equisetales (**Horsetails**). Tall tree types (*Calamites*) in Carboniferous. 25 species now living, all small and herbaceous, illustrated on page 1032.

(III-d) Sphenophyllales. Small, thin-stemmed plants (illustrated on page 1032) of late Paleozoic. Now extinct. Closely related to Equisetales.

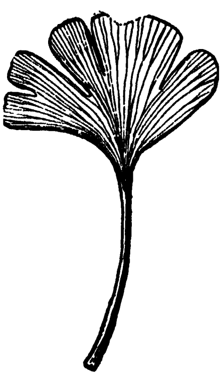

Fig. 3.
A Jurassic Ginkgo. (*Field, Laboratory Manual, Princeton University Press.*)

IV. **Spermatophytes** (seed plants). Dominant terrestrial forms of modern flora. Most highly evolved plants. Not dependent upon moisture for fertilization. Three important groups:

(IV-a) Cycadolfilicales or Pteridosperms (seed-ferns). Important Paleozoic group; now extinct, illustrated on page 1032. Possessed fern-like foliage but also true though simple seeds. Perhaps represent transitional form between ferns and modern seed-plants. An important fossil genus is *Glossopteris* which is found in the **Permian** formations of both South America and Africa.

(IV-b) **Gymnosperms** (naked seeds). Seeds not protected by a covering, but borne on scales, usually in cones. Trees mainly evergreen, with scales or needle-shaped foliage. Five groups:

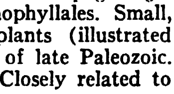

Fig. 4.
A Common Tertiary Conifer (*Sequoia*). (*Field, Laboratory Manual, Princeton University Press.*)

(IV-b-1) Cycadales. Tropical **cycads** or sago-palms. Dominant in **Mesozoic** in 3 families, only one of which has survived. (Figure 2 above.)

(IV-b-2) Cordaitales. Tall Paleozoic tree form. Now extinct. Supposed ancestor of modern conifers.

(IV-b-3) Ginkgoales (Figure 3 above). Peculiar tree, dominant in Mesozoic. Only 1 species in Western China now living.

(IV-b-4) Coniferales. Modern evergreen **conifers.** Mesozoic to present (Figure 4). 350 species now living, mostly temperate forms, such as the pines, spruces, hemlocks and cedars.

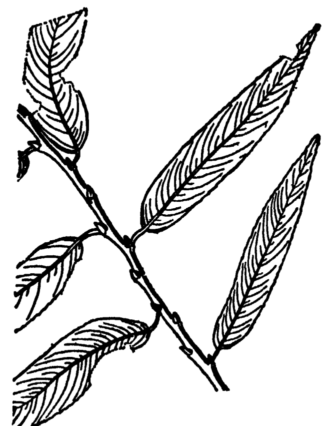

Fig. 5.
A Tertiary Willow (*Salix*). A common Dicotyledon. (*Field, Laboratory Manual, Princeton University Press.*)

(IV-b-5) Gnetales. Desert type. Peculiar and unimportant group.

(IV-c) **Angiosperms** (enclosed seed). Seed protected by seed coats and enclosed in a ripe ovary, the fruit. Only group which produces real "flowers." Leaves usually broad and **deciduous.** Represent highest type and most numerous of modern plants. Upper **Cretaceous** to present. Two groups:

(IV-c-1) **Monocotyledons.** Plant begins growth with single seed leaf or **cotyledon.** Leaves parallel-veined. No growth rings in the stem. Parts of the flowers arranged in threes or multiples of three. Mostly herbaceous. Supposedly derived from primitive dicotyledons. 30,000 species now living; grasses, sedges, etc.

(IV-c-2) **Dicotyledons.** Plant begins growth with two cotyledons. Leaves net-veined. Annual growth rings present in the stem. Floral parts arranged in multiples of four or five. 100,000 species now living; oaks, willows, maples, chestnuts. (Figure 5.) R.M.F., R.M.W.)

PALEOCENE. The earliest period in the **Cenozoic** Era of the geologic time-scale. (See **Historical Geology.**) It is also spoken of as basal **Tertiary.** The term was first proposed by Schimper in 1874. The greatest thickness of the formations of this system occur in Wyoming. The Paleocene began approximately 60 million years ago and lasted for about 10 million years. In the United States the sediments are mainly of terrestrial origin, occurring as intermontane deposits of sands, gravels, and clays. The Paleocene is chiefly remarkable in that the **dinosaurs** have been replaced by the archaic or earliest types of mammals, including survivors of the **Mesozoic** Multituberculates. Principal types are creodonts (archaic flesh-eaters), amblypods and **condylarths** (primitive hoofed animals). Also several species of primitive **insectivores,** lemuroids (ancestral monkeys) and **carnivores.** (R.M.F.)

PALEOCHRONOLOGY. Stratigraphy, Paleontology, Evolution, Historical Geology.

PALEOCLIMATOLOGY. The study of ancient climates which obtained during the previous periods of

the earth's history, as determined by the criteria derived from **sedimentary rocks** and the included **fossils**. Certain types of fossils such as **corals** are assumed to have lived in tropical seas. **Limestones** are assumed to have been formed only in warm seas. **Aeolian** sandstones, red sediments, **playa** deposits, salt, **gypsum**, and desiccation products in general, are usually evidence of aridity. **Tillites** are evidence of glacial climates. Fossil plants are particularly good evidence as to the climatic conditions under which they lived. (See **Paleobotany.**) (R.M.F.)

PALEOLITHIC. Paleontology of Man.

PALEOMASTODON. Fossil Mammals.

PALEONEMERTEA. Nemertea.

PALEONTOLOGY. The study of fossils. A fossil is the evidence of the former existence of an organism, either animal or plant. Fossils may be classified according to their method of fossilization as follows: 1. Actual remains, sharks teeth, ear bones of whales, **chitin**, etc. 2. Petrifactions. Minute replacements in which the original organic matter has been completely or partially replaced by mineral matter. The principal replacing minerals are calcite, quartz, chert and pyrite. 3. Molds and casts of interiors and exteriors. 4. Prints of leaves, jellyfish, etc., sometimes showing carbonized traces of organic matter, as in the case of some fossil plants. 5. Coprolites, fossil excrement. 6. Tracks, trails and burrows. The geologist is principally interested in fossils, not from the point of view of paleobiology, but rather as valuable aids to **stratigraphy** in helping to determine the relative ages of the **sedimentary rocks** in which the fossils occur. Unfortunately the fossil record is so incomplete that the general principle of evolution is of little or no value for determining the age of the smaller divisions of the geological time scale. Because of the complexity of the fossil record and the host of fossil types, including whole classes of organisms, which are now extinct, Paleontology has been subdivided into the following natural divisions: 1. Micropaleontology, or the study of microscopic fossils, especially the **foraminifera.** 2. Invertebrate Paleontology. 3. Vertebrate Paleontology. 4. Paleobotany. 5. Stratigraphic Paleontology. (R.M.F.)

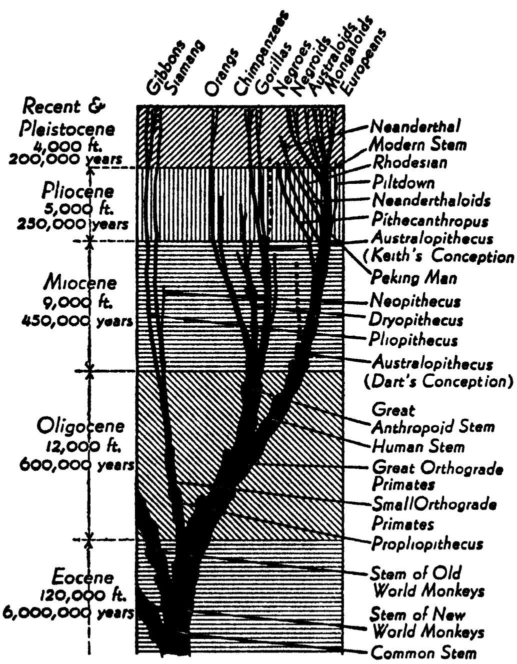
PALEONTOLOGY OF MAN. Since the time of Charles Darwin's publication "On the Origin of Species" (1859), certain formations from the **Pleistocene** have been found to contain fossil remains which are anatomically different from any existing race of men, but which are also more "human" than any other existing type of anthropoid. Within the last few years the study of fossil man, including the study of his increasing mentality, as disclosed by his creative art (artifacts), has led to a special branch of geological history called the Paleontology of Man. The accompanying diagrammatic presentation of the fossil and stratigraphic record of man is in the form of a family tree, buried in the stratigraphic record of successive **sedimentary** formations containing numerous fossil animals and plants, which help to date, or correlate, the ancestral stock and divergent branches of *Homo Sapiens.* The generic and specific names represent specific types, certain of which are supposed to be "milestones" in man's total evolutionary journey from a lower form of anthropoid to his present state. The geological proofs of the evolution of man depend upon the following studies, both in the field and in the laboratory:

1. Paleontology. The comparative anatomy of the fossil bones, principally the bones of the skull, teeth, and, to a certain extent, the limbs. The comparison of analogous bones of different fossil types. The comparison of the analogous bones of fossil types with those of living anthropoids, including man.

2. Artifacts. Comparative studies of the cultures of extinct races of men, including instruments, sculpture, and painting.

3. Archeology. Including both the vertical (stratigraphic) and lateral (paleogeographic) distribution of anthropoid bones and artifacts. The correlation (relative age) of each "find" which may have a bearing on the evolution of man may not be determined primarily by the apparent evolutionary stage of the object because: *a.* The known total vertical (stratigraphic) range of a fossil species or artifact may be increased by further discoveries. *b.* Concepts as to the evolutionary stage of a fossil species may be still further strengthened or radically changed by new discoveries of fossil bones and artifacts which either do or do not fit into the previously postulated evolutionary series.

The accompanying chart illustrates, in stratigraphic sequence, the cultural history of prehistoric man from



Diagrammatic synopsis of human evolution. (Keith.) (*Field, Outline, Barnes & Noble.*)

some 350,000 years ago to the present day. A few of the most significant progenitors, or prehistoric relatives of the genus *Homo* are:

1. Peking Man (*Sinanthropus*). This type, and *Pithecanthropus*, are the oldest known primitive progenitors of man. While *Sinanthropus* may occur stratigraphically lower than *Pithecanthropus*, it appears to be fairly closely related to *Pithecanthropus*, and possibly a slightly higher type (see chart of cultural ages). The bone beds in which the Peking Man was discovered are dated as early Pleistocene, and it is estimated that he lived some 250,000 years ago. The discoveries were made in a limestone cave near Peking. The undisturbed cave deposits contain 110′ of richly fossiliferous deposits which date the "human" remains.

2. Java Man (*Pithecanthropus*). Has been thought, and still may be, the nearest known approach to the "missing link." Total evidence intimates an animal having a brain of 900.94 cc., or approximately that of the lowest limit amongst the primitive living races of mankind (aboriginal Australian woman). The discovery was made in the same stratigraphic horizon as a

number of **fossil mammals** of **Pliocene** age, near Trinil, Java, in 1891. The restoration of the type depends upon a skull cap, some teeth and a femur which may or may not have belonged to the same individual, or to the same species.

3. Piltdown Man (*Eoanthropus*). The most ancient fossil man so far discovered in England. Cranial capacity some 300–400 cc. greater than that of the Peking Man. While not in the direct evolutionary line of the existing races of man, it probably represents a higher western race which was probably contemporaneous with a lower eastern type. The skull was found at Piltdown, Sussex, England, in river gravels. The associated artifacts have been determined as probably Pre-Chellean in age, and may be older than the skull. The exact age of the formation is still under dispute, but it appears to be Pliocene or early **Pleistocene**.

4. Neanderthal (*Homo neanderthalensis*). A well-established race with progenitors probably well down in the Pliocene, and probably contemporaneous with the earlier races previously cited. Cranial capacity on the order of 1600 cc. meters, or possibly somewhat larger than that of modern man. This race appears to have died out during the late Pleistocene and is not directly ancestral to the living races of man. The Neanderthal race had a wide geographic distribution, including eastern and western Europe and Africa. The first discovery was the Gibraltar skull in 1848, but the type locality is a cave in the Neanderthal gorge of the valley of the Düssel, a German tributary of the Rhine. Numerous complete skeletons are known. The jaw, flatness of the cranium, pronounced eyebrow (supra-orbital) ridges and thickness of bone in the skull are decidedly simian. The development of retouch, and the flake for special types of flint instruments have tended to supersede the more primitive general utility tool called a hand stone or coup de poing of the earlier Chellean and Acheulian cultures.

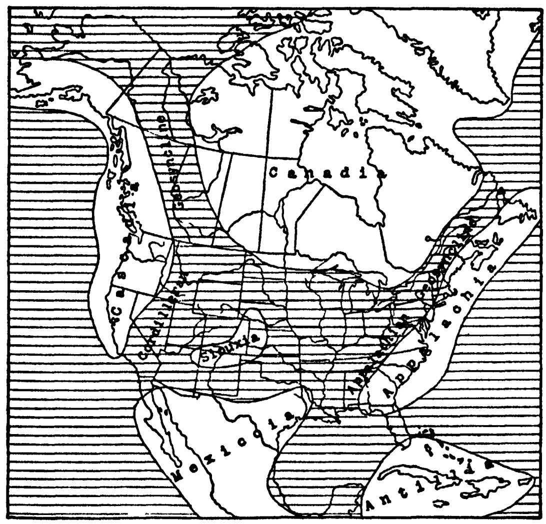
5. Crô-Magnon (*Homo Sapiens*). The highest type of the extinct races of men, both anatomically and mentally. Not directly ancestral to the modern races

Sketches of stone implements of various cultural ages used by Paleolithic man. Upper left, Chellean; upper right, Mousterian; and lower, Solutrian. (*The Nature of the World and Man, University of Chicago Press.*)

of men, because of distinct differences in the skull. Abundant fossil skeletons have been found, including children and adults of both sexes. Skull large, and brain size exceeding that of the average modern man. On the other hand the skull retains primitive characters. It is long and narrow (dolichocephalic) with relatively broad face, large eye sockets and pronounced supra-orbital ridges. Complete skeletons show that the males were broad-chested and fairly erect, with an average stature of 6′ 1½″. The culture ranges from Aurignacian to the close of the Paleolithic (Azilian). The Aurignacian culture includes flint, bone and horn instruments, including the burin, or engraving tool. Also the first evidence of prehistoric art in the form of sculptures, tinted engravings on the walls of limestone caverns, and art moblier, or figurines. During the Solutrian occurred the culmination of the retouch in the making of flint instruments, as exemplified in the pointes en feuille de laurier, or laurel-leaf points. The following Magdalenian period represents the culmination of the Paleolithic or prehistoric culture. With the decadence of flint, and the increasing use of bone instruments also occurs the climax of Paleolithic art, including engraving, sculpture and painting. The Azilian shows a complete revolution in culture with a degeneration of the retouch in making flint instruments and the foreshadowing of the polished stone instruments of the Neolithic. (R.M.F.)

PALEOSTRACA. **Xiphosura.**

PALEOZOIC. The **Era** of "ancient" life or the age of invertebrates. Subdivided from the base up, into the following **Periods: Cambrian, Ozarkian, Canadian, Ordovician** (lower Paleozoic), **Silurian, Devonian** (middle Paleozoic), **Mississippian, Pennsylvanian, Permian** (upper Paleozoic). The lower Paleozoic was characterized by: the first known marine faunas; domi-



A highly generalized map of North America showing a rather typical arrangement of the principal Paleozoic positive and negative areas, and also the Appalachian and Cordilleran geosynclines, from Middle Cambrian to Middle Pennsylvanian time.

nance of **trilobites**; rise of animals with hard shells (Cambrian); rise of **nautiloids**, armored **fishes** and **corals**; also first evidence of colonial life (Ordovician). The middle Paleozoic was characterized by: the rise of **lung-fishes** and **scorpions** (Silurian); first known land floras (Devonian) not very different from those of the Pennsylvanian; earliest evidence of a terrestrial vertebrate in the form of a single footprint from the Devonian of Pennsylvania. The upper Paleozoic was characterized by ancient sharks, and **echinoderms** (Mississippian); primitive reptiles and insects (Pennsylvanian); periodic glaciation and extinction of many Paleozoic groups during and after the Permian. Rise of modern insects, land vertebrates and **ammonites**. (Permian.) The Paleozoic Era began 500 million years ago and lasted for 300 million years. (R.M.F.)

PALINGENESIS. A term proposed by Sederholm in 1907 for the reversal of **petrological** processes, such as the melting of **batholithic** and **metamorphic rocks** *in situ*. Theoretically the completion of a cycle of rock genesis. (R.M.F.)

PALISADES DISTURBANCE. **Triassic.**

PALLADIUM. Symbol: Pd. Atomic number: 46. Atomic weight: 106.7. Density: 12.16. Hardness: 4.8 Melting point: 1553° C. (**Isotopes**: page 290.)

Compact palladium is a white metal, and due to its property of softening at temperatures below the melting point can be easily welded. Heated in air to redness palladium becomes coated with oxide. The molten metal absorbs **oxygen,** and on cooling "spits" like **silver.** Finely divided palladium adsorbs 1000 to 3000 times its volume of hydrogen gas, and retains most of this gas when heated to 100° C. **Acetylene** is adsorbed similarly. Palladium is slowly dissolved by boiling **hydrochloric** or **sulfuric acid** and by cold **nitric acid;** is readily dissolved by **aqua regia;** upon heating reacts with **chlorine** and with **sulfur;** upon fusion with **potassium** hydrogen sulfate forms palladous sulfate, soluble in water; reacts with fused **sodium** hydroxide. Discovered by Wollaston in 1803.

Palladium metal is used in dentistry, in non-magnetic springs for watches and clocks, as a permanent mirror when deposited on glass, in jewelry as white gold when alloyed with **gold,** being superior in whitening power to **platinum** in this respect.

Palladium occurs native in platinum ores, sometimes to the extent of 2%, and in sufficient amount in the nickel ores of Canada to be recovered in the process of their manufacture. When **osmium** and **ruthenium** are present, they are removed as volatile oxides; when platinum and **iridium,** by precipitation of the **ammonium** chloro-compounds, insoluble in alcohol, upon addition of **ammonium** chloride; and precipitation of palladium as the ammonium chloro-compound with ammonium chloride and **chlorine** leaves rhodium in the solution. The ammonium chloropalladate is ignited and reduced by heating with hydrogen to yield palladium metal.

Chlorides: Palladous chloride ($PdCl_2$), absorbs **carbon monoxide** gas, a reaction which is used for estimating this gas in mixtures; palladium tetrachloride ($PdCl_4$), more commonly as chloropalladic acid (H_2PdCl_6).

Chloropalladate: Ammonium chloropalladate ($(NH_4)_2PdCl_6$), slightly soluble in water, and insoluble in alcohol.

Oxides: Palladium monoxide (PdO), black; palladium dioxide (PdO_2), black. (R.K.S.)

PALLET, PALETTE. A structure formed of horny and calcareous materials, associated with the siphons of **shipworms.** A pair of pallets lie near the end of the siphons and serve as a plug for the burrow in which the worm lives. (A.W.L.)

PALLIAL GILL. Folds of the **mantle** which serve as respiratory organs in some of the **bivalve mollusks.** (A.W.L.)

PALLIAL LINE. The scar on the inner surface of the shell of a **bivalve mollusk** which marks the marginal attachment of the **mantle** folds. (A.W.L.)

PALLIUM. A mantle-like structure. 1. The cortex of the cerebrum (**brain**) with its underlying white substance. 2. The **mantle** of mollusks. (A.W.L.)

PALM FAMILY. Palmaceae. This family of plants contains some 1100 species, most of which are tropical. Many are of large size. A tall woody stem bearing at its top a crown of large compound leaves characterizes most of them, although some are short and bushy, while a few are vine-like. Only rarely does branching occur, although many do develop numerous basal offshoots. The leaves are either **pinnately** or **palmately** compound. The **inflorescence** is either a simple or a compound **spike,** surrounded by a **spathe** which may become extremely large. The flowers are regular, with their parts in threes or multiples of three. Wind **pollination** generally occurs in palms. The fruit is a berry, a drupe, or a nut which in many species has a fibrous mesocarp.

Many species of palms are planted extensively, because of their ornamental habit, in tropical and subtropical countries. Large numbers are also grown as greenhouse or conservatory plants. A few species are of great economic value. Chief among these is the **Coconut** palm. Somewhat less valuable than the Coconut is the Date Palm. This plant, *Phoenix dactylifera,* is a tree whose mature trunk often attains a height of 75–100′. From the base of this trunk numerous **adventitious roots** extend into the soil to a depth of 20′ or more. From the base of the stem many basal offshoots develop. The pinnate leaves are from 10–20′ long, with the individual pinnae sharp-pointed, linear and from 1–3′ long. These leaves remain attached for an indefinite time to the trunk, giving it a very ragged appearance. In cultivation the old leaves are removed. The inflorescence is a large branched spike enclosed in a large tough spathe. In a mature tree a single flower cluster may be composed of several thousands of flowers. The flowers are of two different sexes, borne on different plants, and are small, wax-white and of firm texture. The pistillate (see **Pistil**) flowers have three **carpels,** each with a short curved **stigma.** The carpels are almost surrounded by the **perianth,** composed of three united **sepals** and three **petals.** The staminate (see **Stamen**) flowers, bearing six stamens, are of larger size than the pistillate and more showy. The fruit is a drupe. After fertilization only one of the three carpels develops, the other two being suppressed. At first the carpel is wax-white, but some time after fertilization it becomes green and remains so during growth. As the drupe becomes mature, the color changes to yellow or red or a blending of these colors, according to the variety of date. When ripe the color of the fruit varies from pale straw color through deep amber to a deep purple. The seed of the date contains an abundance of **endosperm** and a rather small **embryo.**

Many varieties of dates are grown in cultivation. Since cross-pollination is usually necessary to produce seeds, propagation by seeds cannot be used to increase the number of plants. For such plants would not remain true to the seed-bearing parent in type but would be affected by the pollen from the staminate plant; such crossing would cause the formation of new varieties with the possibility that less desirable forms might arise. Furthermore, about half the seedlings would be staminate, producing no fruit. To perpetuate desirable varieties propagation is largely by means of the basal offshoots. These shoots are cut from the parent and planted, ensuring new plants identical with the parent.

Cultivation of the date has been carried on in Arabia and adjoining countries since prehistoric times. It is probable that the plant is native to this region, even though it is unknown in the wild state. Today the date palm is grown widely in regions having a sufficiently hot climate. The Mesopotamian valley is the chief producing region of the world. In the United States the date can be grown successfully only in a very limited region in the southern parts of California, Nevada and Arizona.

The principal product of the plant is the edible fruit. In the Orient the fruit is often fermented, yielding a very potent alcoholic drink, and also vinegar. Various materials used in building houses, and making baskets, ropes, and household articles are also obtained from the tree in regions where other sources of such materials may be lacking. (See **Esters.**)

Another useful palm is the Oil Palm, *Elaeis guineensis,* a native plant occurring in large numbers in the forests of the west coast of Africa. The plant is also extensively cultivated elsewhere in Africa and in the East Indies, particularly in Sumatra. From the fruit of this palm two valuable oils are obtained. The

orange-yellow **pericarp** yields palm oil, much used in the making of soaps. The **endosperm** yields a white pleasantly flavored oil known as palm-kernel oil, also used in making soaps. In Africa the fruits are eaten by the natives.

In India, *Phoenix sylvestris* is widely cultivated as a plant from which sugar is obtained. Many other palms are used as sources for sugar in regions where they grow. (R.M.W.)

PALMATE. **Leaf.**

PALMITIC ACID AND PALMITATES. Palmitic acid ($H \cdot C_{16}H_{31}O_2$ or $C_{15}H_{31} \cdot COOH$ or $CH_3(CH_2)_{14} \cdot COOH$) is a white solid, melting point 64° C., boiling point 272° C. at 100 mm. pressure, insoluble in water, moderately soluble in alcohol, soluble in ether. Palmitic acid is present as cetyl ester in spermaceti from which, by **hydrolysis,** the acid may be obtained; it is present in bee's wax as the melissic ester; and in most vegetable and animal oils and fats, in greater or less amounts, as glyceryl tripalmitate or as mixed **esters,** along with **stearic** and **oleic acids.** Palmitic acid is separated from stearic and oleic acids by fractional vacuum **distillation,** and by fractional **crystallization.** With **sodium** hydroxide, palmitic acid forms sodium palmitate, a soap. Most soaps are mixtures of sodium stearate, palmitate and oleate.

Representative esters of palmitic acid are: methyl palmitate ($C_{15}H_{31}COOCH_3$) melting point 30° C., boiling point 195° C. at 15 mm. pressure; ethyl palmitate ($C_{15}H_{31}COOC_2H_5$), melting point 24° C., boiling point 185° C. at 10 mm. pressure; cetyl palmitate ($C_{15}H_{31}COOC_{16}H_{33}$), melting point 54° C.; glyceryl tripalmitate (tripalmitin) ($C_3H_5(COOC_{15}H_{31})_3$), melting point 65° C., boiling point 310° C., approximately.

As the glyceryl ester, palmitic acid is one of the constituents of many vegetable and animal oils and fats. (See **Esters.**) (R.K.S.)

PALOLO WORM. Annelida, Polychaeta. Marine worms of the genus *Leodice* which live in burrows in coral rock. They have two body regions. In the posterior part the reproductive organs develop, and when they are mature this part breaks away from the anterior region and swims to the surface of the sea. The attainment of sexual maturity occurs at a specific time, and during this period the water swarms with the reproductive portions of the worms. The anterior part remains in the burrow and during the succeeding year produces another reproductive region. One species lives in the southern Pacific Ocean and another in the West Indies. (A.W.L.)

PALP, PALPUS. An appendage of sensory functions. 1. In some of the segmented worms thick fleshy protuberances on the head are called palpi. 2. **Bivalve mollusks** bear two pairs of flap-like appendages near the anterior end of the body which are called palps. 3. The **maxillae** and **labium** of insects each bear a pair of segmented appendages called palpi. (A.W.L.)

PALPIFER. **Maxilla.**

PALPIGER. **Labium.**

PALPITATION. The consciousness of temporarily abnormal action of the **heart,** characterized by increased force, rate or irregularity of the beat. Palpitation is a symptom present in many conditions; it is not a disease in itself. It is commonly seen in emotional, nervous or excitable subjects, in acute fevers, following the drinking of tea, coffee or alcohol in certain individuals, and often as a symptom of organic heart disease. (R.S.M.)

PALSY. **Paralysis agitans.**

PAMPEAN FAUNA. **Pleistocene.**

PANAMA HAT PALM. *Carludovica palmata.* Cyclanthaceae. This plant is very abundant in tropical forests of America, where it forms large clumps of **long-petioled** leaves. In contrast to true palms, the Panama hat palm is stemless. It is frequently planted as an ornamental plant. For making Panama hats, the young leaves are gathered, cut into narrow strips, bleached, and woven into the hats. These hats are actually manufactured only in a section of Equador, and not in Panama. (R.M.W.)

PANCREAS. A large digestive gland whose duct empties into the alimentary tract (**Digestive System**). The name is sometimes applied to a mass of tissue surrounding the duct of the principal digestive gland of the **squid** but it belongs characteristically to the **vertebrates.** The vertebrate pancreas develops as a group of outgrowths from the embryonic (**embryo**) gut just behind the stomach. In the higher vertebrates one outgrowth is dorsal and one or two ventral, but all normally unite to form one mass which usually discharges by one of the original ducts, although in some species both persist. The ventral duct often joins the duct of the **liver.** In man this duct becomes the pancreatic duct, joining the hepatic duct to discharge into the intestine by the common bile duct. The pancreas is a compound acinous gland. (See **Glands.**) The human pancreas is a large, elongated gland situated on the posterial abdominal wall behind the stomach above the level of the navel, lying between the spleen on the left and the duodenum on the right. The pancreas has both an external and an internal secretion.

The external secretion of the pancreas empties into the duodenum. This digestive fluid contains at least three important **enzymes:** 1. Trypsin, which interacts with an enzyme secreted by certain cells of the small intestine. It causes **protein** food substances to be broken down into simpler forms so that they may be absorbed and utilized by the body. 2. Amylase, which assists in the digestion of **starch.** 3. Lipase, which breaks down **fatty** foods into glycerine and fatty acids.

The internal secretion of the pancreas is formed by small cell groups scattered throughout the gland substance. They are called Islands of Langerhans and their function is to secrete **insulin** into the blood stream. Insulin is necessary for the oxidation of **sugar** by the body. When insufficient insulin is manufactured by the gland **diabetes** occurs. When too much insulin is discharged into the blood stream hyperinsulinism develops and is characterized by a low blood sugar accompanied by weakness and fainting spells.

The pancreas is stimulated and pours out its secretion due to the action of secretin, a **hormone** originating in the walls of the duodenum. This hormone is activated by the passage of acid food from the stomach into the duodenum. The hormone is then absorbed in the blood stream where it acts upon the pancreas.

The pancreas is subject to acute and chronic **infections** and **tumor** and **cyst** formation. (A.W.L., R.S.M.)

PANDA. Mammalia, Carnivora. A peculiar animal, *Aelurus fulgens,* of the southeastern Himalayas. Its body is about 2′ long, exclusive of the long furry tail, and the legs are strong and only moderately long. The head is shaped much like that of the raccoons, which seem to be fairly closely related. Also called the red cat-bear from its slight resemblance to both forms. (A.W.L.)

PANEL POINT. **Bridge; Truss.**

PANGOLIN. Mammalia, Edentata. The scaly anteaters, a group of peculiar Old World animals which are covered with overlapping horny scales of large size. They are slender animals with a long tail and short legs bearing powerful claws. Like other anteaters they have a sharp snout and long sticky tongue and live chiefly on termites.

The several species are confined to Africa and the southeastern part of Asia, where the most common one is *Manis pentadactyla.* (A.W.L.)

PANICLE. Flower.

PAN-IDIOMORPHIC. A term proposed by Rosenbusch signifying an **igneous rock** whose texture is **idiomorphic.** (R.M.F.)

PANTHER. Puma.

PANTOGRAPH. Parallel Mechanism.

PANTOGRAPH TROLLEY. This is a type trolley often used on electric locomotives to connect with the overhead trolley wire. It is so named because of its resemblance to the drafting instrument of the same name. (L.R.Q.)

PANTOPODA. Synonym of **Pycnogonida.**

PANTOSTOMATIDA. Mastigophora.

PAPAL MITRE. Mollusca, Gasteropoda. A marine shell of the Indian Ocean. It is white with red spots. The name is a translation of the scientific name *Mitra papalis.* (A.W.L.)

PAPAVERINE. Alkaloids.

PAPAYA. Papaw. *Carica Papaya.* Caricaceae. This is a tropical American tree with a straight rarely branching trunk from 6–25′ tall. On the upper portion of the stem is borne a crown of large compound, long-**petioled** leaves. The pale yellow, fragrant flowers are of two kinds, pistillate (see **Pistil**) and staminate (see **Stamen**), borne on different plants. Papayas are therefore **dioecious plants.** The smooth-skinned fruits vary considerably in shape and size, those of wild plants being not much larger than eggs, while cultivated fruits are much larger. The orange-colored flesh is sweet and juicy, and surrounds a central cavity which contains the numerous seeds. Usually the fruit is eaten raw, but may be used in salads or cooked. It is not a good shipping fruit, so rarely appears in United States markets.

From the fruit and sap of the plant is obtained an **enzyme,** papain, which is used as a digestive aid, its action being much like that of pepsin. The leaves, cooked with meat, are said to tenderize meat.

The plant is widely introduced in many tropical lands. It is extensively grown in the Hawaiian Islands and to some extent in Florida and California. Propagation is mainly by seed.

The name papaw, sometimes given to this fruit, is also applied to a North American tree, *Asimina triloba,* with which it should not be confused. (R.M.W.)

PAPER. One of the most important factors in the progress of civilization has been paper, a thin flat tissue composed of closely matted fibers obtained almost entirely from plant sources. In modern life paper finds a variety of uses, for writing, for containers, wrappers, wall covering, and—perhaps most important—in all the forms of printing: newspapers, magazines, books.

The art of making paper seems to have been discovered first by the Chinese, who were making paper as early as the beginning of the Christian era. From China the process was carried to Arabia and thence to Europe. Paper was not an important article at first and, since it is not a very durable substance under ordinary conditions, could not compete with parchment or vellum as a medium for the written word. In the fifteenth century writing became more general and the demand for a cheaper material increased. Paper became an important product. At this time paper was made largely from vegetable fibers reclaimed from cloth (especially linen), as had been done since the invention of paper in China. This paper was made entirely by hand, as is done even today in the manufacture of certain expensive types of paper. In making hand-made paper, a pulp is formed by soaking the vegetable fibers in water in a vat. From this vat the pulp is dipped out in a mold, the bottom of which is a fine screen. By a deft motion of this mold the soft pulp is spread over the screen in a thin layer of matted fibers. The water in the pulp drains off, leaving a rather firm mass which is turned out on a piece of felt. More pieces of half-dried pulp spread on felt are added. The whole pile is then pressed to squeeze out more of the water, press the fibers closer together and form a firm sheet. These are then removed from between the felts, pressed again, and dried. During the final treatment surface sizing is added to render a surface more suitable to receive ink. Sheets of hand-made paper are naturally of limited size and expensive.

To meet the great demand for paper, machine methods were developed. This increased demand for paper also led to the utilization of material which could be obtained in quantities much greater than rags. Out of this developed the vast pulp industry which today converts vegetable material, mostly soft woods such as spruce and fir, as well as poplar, into a white felt-like mass of fibrous substance, known as pulp. Several methods are in use to obtain the fibers from the wood. In one, the logs are barked and then ground by pushing against large grindstones. By this process the separate fibers of the wood are dissociated, their ends being more or less frayed in the process. Water flowing over the grinding surfaces keeps the temperature resulting from friction from rising unduly, and also removes the fibers. These are then washed and drained, undesirable substances such as bits of bark and other materials removed, and then pressed into sheets. These sheets of pulp are folded into bundles, which are then shipped to the paper mills. Pulp mills are commonly located near the source of wood supplies. Ground pulp is largely made from spruce wood and is principally used in making newsprint paper. Usually it is mixed with some chemically prepared pulp so that the paper may have greater strength to resist tearing in handling.

Chemical pulp is prepared by several processes. In these the wood is first barked, and then further cleaned by hand or other mechanical equipment to remove bark, pitch, and other foreign material as completely as possible. It is then cut up into chips which are screened to remove the fine sawdust and dirt. The chips are cooked or digested in very large vertical tanks or digesters. Digestion is accomplished by means of various chemicals. In the sulfite process, **sulfur dioxide** dissolved in **calcium** bisulfite or **magnesium** bisulfite is used. In the soda pulp process, a solution of **sodium** hydroxide in water is used.

In the sulfate or "kraft" process sodium sulfate (Na_2SO_4) is reduced by heating with carbonaceous matter in a furnace—usually a rotary kiln—to form sodium sulfide (Na_2S), which is then used in water solution with sodium hydroxide ($NaOH$) as the cooking liquor. Digesting is done under pressure and at high temperatures. The sulfite process is used with coniferous woods such a spruce, fir and hemlock; the soda process with poplar and other deciduous woods, and the sulfate process for coniferous woods. After digesting, the fiber

mass is washed to free it of chemicals and pressed into sheets of pulp.

To convert the pulp into paper, it is first put into large tub-like containers with water. There it is thoroughly beaten by constantly passing between a roll and stationary plate, the surfaces of both being made up of narrow, closely spaced steel bars. During the beating a certain amount of blue dye is added to neutralize the yellow tint otherwise present. Later alum, sizing and bleaching materials are added. In the case of rag pulps the bleaching is done in the washer beaters, but in the case of wood pulps it must be carried out in large tanks designed specifically for the purpose. The chief bleaching agents are chlorine and calcium hypochlorite. When the mass is thoroughly beaten and mixed, it is poured on a very fine copper screen which is in the form of an endless belt several feet wide. Vibration of the screen spreads the material in a thin uniform layer. As it is carried along much water in the soft mass drains out. To prevent the material from running over the edge thick rubber belts are placed on either side. Mechanical suction removes much of the water left after draining, after which the felted mat passes between rollers on a thick woolen felt which is carried between a series of heavy rollers. Passing between these the paper is pressed into a firm thin sheet, which then has sufficient strength to pass without support of screen or felt through a long series of heated rolls. From these it may go directly to the calender machines, stacks of heavy rolls which give to it a smooth firm surface. If a better surface is required, paper then goes to the coating machines, where it receives a coating of a clay or other mineral pigments and casein, which imparts a very smooth glossy surface suitable for fine reproduction of photographs. Many variations are found in the details of the various processes leading to the production of finished paper.

The principal woods used in the making of paper are spruce, hemlock, southern pine, poplar and fir, with smaller quantities of several other woods. Attempts have been made at various times to use other plant materials, such as cotton and corn stalks, and various straws. So far these have given only slight promise because of the difficulty and expense of obtaining the fibers. Large quantities of cereal straw, namely, oat, wheat, rye, and barley, are used in making brown, coarse straw pulp which is principally used for making paper boards for corrugated paper. From waste paper, pasteboard and cheap grades of paper are made. Large quantities of the better quality waste paper are deinked and used in the manufacture of various grades of printing paper. Unbleached waste papers and lower grade waste which may be badly soiled are disintegrated without deinking and used for the manufacture of container board, boxboard, and some of the low quality grades of paper. (See **Carbohydrates.**) (R.M.W., R.K.S.)

PAPER LOCATION. Surveying.

PAPER WASP. Insecta, Hymenoptera. The hornets and yellow-jackets. **Wasps** which build their nests of coarse paper made by chewing fragments from weathered or partially decayed wood. Some build subterranean nests and others suspend the nest from the eaves of buildings or from the boughs of trees. (A.W.L.)

PAPPUS. Composite Family.

PAPPUS' THEOREMS. These are two mathematical results obtained by Pappus (c. 300 A.D.) concerning areas and volumes of solids generated by rotation of a plane figure about an axis.

If an arc of a curve in a plane is rotated about an axis not cutting it, the area generated by the arc equals the length of the arc times the perimeter of the circle described by its centroid.

If a closed region in a plane is rotated about an axis in the plane not cutting it, the volume generated by the region equals the area of the region times the perimeter of the circle described by the centroid of the region. (L.L.S.)

PAPULA. Thin-walled projections from the surface of starfishes. They increase the surface available for respiratory and excretory interchange. (A.W.L.)

PAPYRUS. *Cyperus Papyrus.* Cyperaceae. In early times writing was done on sheets of material known as papyri. These were prepared from the stems of a huge species of reed growing on river banks and in marshes in Egypt and other eastern countries. This plant, *Cyperus Papyrus,* has a thick **rhizome** which often grows several feet in length. The pith of the rhizome is edible, and frequently is used as food in eastern countries. From the rhizomes arise the erect stems of the plant, which are from 3–12′ tall and bear at the top a radiating mass of **flower** spikes. In making papyri, the stems were first cut into thin strips. These were placed side by side until the desired width, varying from 4–12″, or more, was obtained. Across this layer another was placed, with the strips at right angles to the first. It is possible that the strips were interwoven. This material so arranged was then immersed in water and left to soak for some time. After soaking the layer was beaten flat and into a coherent sheet which was then dried in the sun. Separate sheets of papyrus were pasted together so that rolls of considerable length were obtained. So prepared, papyrus forms a thin flexible sheet of great durability, though some of the larger sheets tended to tear and break apart with use. Papyrus making was principally carried on in Egypt, but the plant was introduced into other eastern countries in early times, and attempts at papyrus making undertaken. The product was often inferior to the Egyptian papyri. (R.M.W.)

PARABASAL BODY. A structure associated with the **nucleus** of some of the flagellate protozoans (**Mastigophora**). Its functions are unknown. (A.W.L.)

PARABOLA. The parabola is one of the conic sections, and may be obtained by cutting a right circular cone by a plane which is parallel to an element of the cone.

A parabola is the **locus** of a point which moves so that its distances from a fixed line and a fixed point are equal. (Fig. 1.) The fixed line is called the directrix,

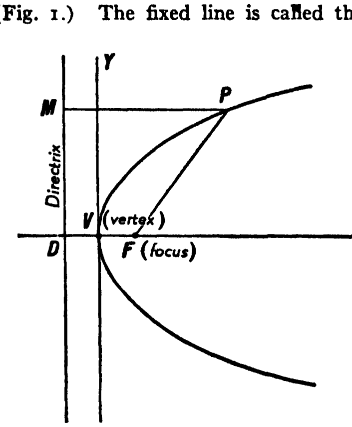


Fig. 1. Parabola.

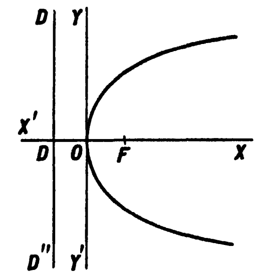
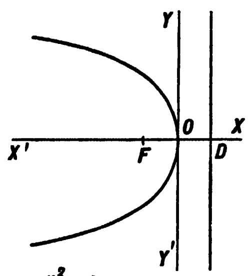
and the fixed point the focus. The line through the focus perpendicular to the directrix is called the axis of the parabola; it is an axis of symmetry of the curve. The point midway between the focus and the directrix, which is the intersection of the curve and the axis,

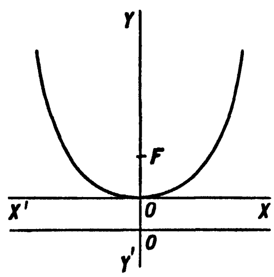
is called the vertex of the curve. The chord of the curve through the focus and perpendicular to the axis is called the latus rectum (or focal width) of the parabola. The line joining any point of the curve to the focus is called a focal radius.



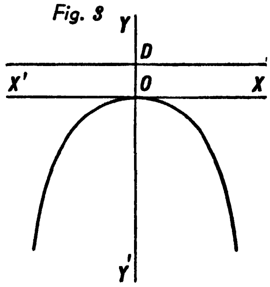
$y^2 = 2px$
Fig. 2



$y^2 = -2px$
Fig. 3



$x^2 = 2py$
Fig. 4



$x^2 = -2py$
Fig. 5

Parabola.

If the origin is taken at the vertex and the X-axis along the axis of the parabola, and if p is the distance of the focus from the directrix, then the equation of the parabola is

$$y^2 = 2px, \text{ (Fig. 2)},$$

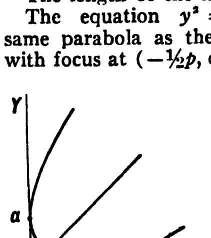
if **rectangular coordinates** are used, and if the curve is open to the right. The focus is at $(\frac{1}{2}p, 0)$ and the equation of the directrix is $x = -\frac{1}{2}p$.

The length of the latus rectum is $2p$.

The equation $y^2 = -2px$ $(p > 0)$ represents the same parabola as the preceding, but open to the left, with focus at $(-\frac{1}{2}p, 0)$ and directrix $x = \frac{1}{2}p$. (Fig. 3.)

The equation $x^2 = 2py$ $(p > 0)$ represents a parabola with vertex at the origin and axis on the Y-axis, open above, with focus at $(0, \frac{1}{2}p)$ and directrix $y = -\frac{1}{2}p$. (Fig. 4.)

The equation $x^2 = -2py$ $(p > 0)$ represents the same parabola open below. (Fig. 5.)



Parabola $x^{1/2} + y^{1/2} = a^{1/2}$
Fig. 6.

The equation $(y - k)^2 = 2p(x - h)$ represents a parabola with vertex at (h, k) and $y = k$ as axis of symmetry.

The equation $(x - h)^2 = 2p(y - k)$ represents a parabola with vertex at (h, k) and $x = h$ as axis of symmetry.

The equation $x^{1/2} + y^{1/2} = a^{1/2}$ represents a parabola tangent to the coordinate axes and having its principal axis bisecting the first (and third) quadrants. (Fig. 6.)

The parabola may be constructed geometrically in several different ways.

Given the focus and directrix of a parabola, it may be constructed point by point as follows: (Fig. 7.) Draw the axis MX, construct the vertex V as the mid-point of MF. Through any point A on the axis to the right of V draw a line AB parallel to the directrix. From F as center with radius MA strike arcs to intersect AB at P and Q. Then P and Q are points on the curve. By changing the position of A we may construct as many points on the curve as desired.

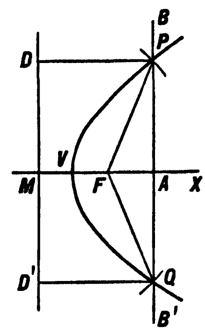


Fig. 7. Construction of parabola.

A construction by continuous motion is the following: (Fig. 8.) An arc of a parabola can readily be drawn in the following way: At the vertex A of a draughtsman's triangle fasten one end of a string of length AB. Fasten the other end at the focus F of the required parabola and place the other leg BC of the triangle along the directrix. Hold the string taut by pressing it against the side of the triangle with the point of a pencil at P. If the side BC of the triangle is now made to slide along the directrix, the point P will describe an arc of a parabola.

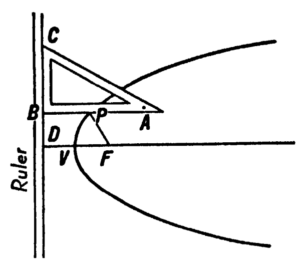

Fig. 8. Construction of parabola.

When the span AB and height OH of a parabolic arch are given, points on the arch may be constructed as follows: (Fig. 9.) Draw the rectangle $ABCD$. Divide

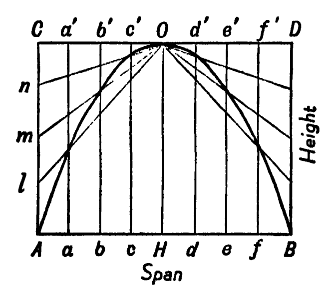

Fig. 9. Construction of parabolic arch.

AH and AC into the same number of equal parts. Starting from A, let the successive points of division be: on AH: a, b, c and on AC: l, m, n. Draw aa' perpendicular to AB and draw Ol, mark point of intersection of aa' and Ol, and do likewise for the points b and m, and c and n. The points of intersection are points on the parabola required.

The equation of the tangent to the parabola $y^2 = 2px$ at the point (x_1, y_1) is $y_1 y = p(x + x_1)$.

The equation of the tangent with slope m to the parabola $y^2 = 2px$ is $y = mx + \frac{p}{2m}$.

Some applications of the parabola are:

The path of a projectile near the surface of the earth (air resistance being neglected) is a parabola.

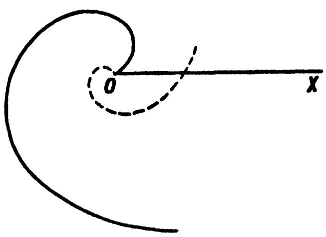
A cable of a suspension bridge, if the load is uniformly distributed along the bridge, assumes a parabolic form.

A parabolic mirror is one whose reflecting surface may be generated by revolving a parabola about its

axis. (Searchlights, locomotive headlight, reflecting telescope.)

If a pan of water is rotated about a vertical axis, the surface of the water assumes a parabolic shape. (L.L.S.)

PARABOLIC SPIRAL. The parabolic spiral is a geometric curve of spiral form. It is the graph of the equation in polar coordinates $r^2 = a^2\theta$. (L.L.S.)



Parabolic spiral.

PARABOLOID OF REVOLUTION. Paraboloids.

PARABOLOIDS. The paraboloids are geometrical surfaces belonging to the class known as **quadric surfaces.**

The **surface** represented in **rectangular coordinates** by the equation

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 2cz$$

is called an elliptic paraboloid, since its sections parallel to the coordinate planes are one elliptic set and two **parabolic** sets. (Fig. 1.)

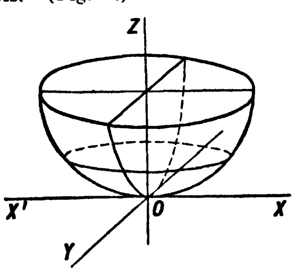


Fig. 1. Elliptic paraboloid.

If $a = b$, the elliptic set of sections becomes **circular**, and the equation represents a paraboloid of revolution, which may be obtained by revolving a **parabola** about its axis of symmetry.

The surface represented in rectangular coordinates by the equation

$$\frac{x^2}{a^2} - \frac{y^2}{b^2} = 2cz$$

is called a hyperbolic paraboloid (Fig. 2) since its sections parallel to the coordinate planes are: one set of **hyperbolas** and two sets of parabolas. (L.L.S.)

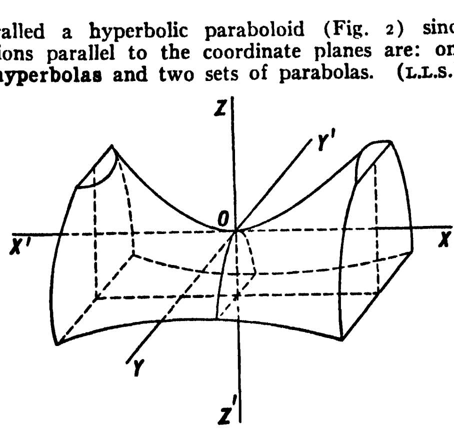

Fig. 2. Hyperbolic paraboloid.

PARACHUTE. The parachute is an aerial life-saving device, and is worn by pilots and passengers of aircraft as a safety measure. The safety parachute is not used except in emergencies, when its wearer is faced with the necessity of quitting the aircraft in midair. This discussion omits consideration of the parachute combination employed in exhibition jumps. The parachute is made up of a circular silk (pongee in cheaper grades) or nylon canopy about 24′ in diameter. At intervals around the edge of this canopy are attached shroud lines which lead to risers. These are straps of webbing joining the ring, to which are gathered the shroud lines, with the harness, which is worn by the user, and in which he is suspended when the parachute is in use. At the center of the canopy is a circular vent edged with rubber bands which tend to keep the vent closed, but which will stretch and allow it to expand to ease the shock when the canopy is opened. The parachute is worn as a back pack, a seat pack, or lap pack. The seat pack is the most convenient type for the average person since the back may rest comfortably against the seat and the pack will act as a cushion to sit on. The lap pack is used chiefly for quick detachable chutes and for exhibition jumps. A parachute is packed into a canvas cover, shroud lines and all. The pack is held closed by a flexible wire which passes through eyelets in the pack cover. Two things cause the mainsail to be thrown out of the pack when the flexible wire, which is called the rip cord, is pulled to release the parachute. Rubber bands attached to the canvas cover pull it away from the parachute itself and spring ribs throw a small pilot parachute into the airstream, where it forms an anchor which drags out the mainsail.

The recommended practice when leaving an airplane is to dive headlong, pulling the rip cord when clear of the aircraft so that there may be no danger of the aircraft fouling some part of the chute. A variation of this method of releasing the canopy is employed by paratroopers (air-borne troops landing by parachute). Requirements of rapidly timed jumps of a squad from a troop carrier, often at low altitude for tactical reasons, are better met by automatic than by individual release. The release wire is pulled by a strap attached to the airplane, this strap being long enough to allow the jumper to clear the airplane before the slack is absorbed and the release pulled. A "Jumpmaster" times the jumping intervals and the system allows all the paratroopers in a troop transport to be landed in a small area without danger of fouling parachutes. Its success depends on straight, level flight of the airplane. Emergency jumps from aircraft in distress are more safely made if the jumper has control over the moment of release of the canopy. About three-fifths of a second after the rip cord is pulled, the mainsail is inflated and the velocity of descent is checked. While successful parachute landings are made from jumps below 500′, any casual parachute jump from below that altitude may be considered extremely hazardous. The standard rate of descent of a 24-ft. parachute is 17 ft. per sec., which is said to be equivalent to a jump from a 10-ft. wall.

In addition to the parachuting of humans, the parachute has been used to drop circulars, food, supplies, and consigned cargo to points inaccessible to any other transportation, and to points not possessing a landing field. So important is the requirement of correct and careful packing of the parachute that the Civil Aeronautics Administration undertakes to license parachute-packing ability. A parachute which has been correctly packed within three months of the time of use and which is in good physical condition, is certain to open when released. (F.T.M.)

PARACONIINE. Alkaloids.

PARADOXURE. Mammalia, Carnivora. An anglicized form of the generic name *Paradoxurus,* applying to the civets. (A.W.L.)

PARAESOPHAGEAL OR PERIESOPHAGEAL CONNECTIVES. The slender nerve cords that connect the dorsal brain of invertebrates with the ventral nerve cord. (A.W.L.)

PARAFFIN. **Petroleum; Petroleum Products.**

PARAFORMALDEHYDE. **Formaldehyde.**

PARAGASTER. The large central cavity of **sponges,** also called the gastral, paragastral, or paragastric cavity. It is superficially like the enteric cavity of the gastrula of higher animals but it is formed by an involution of the layer of cells which cover the external surface of the **larval** sponge. Water passes into it through the canal system of the body wall and flows out through the **osculum.** It is not a digestive cavity. (A.W.L.)

PARAGASTRIC CAVITY. **Paragaster.**

PARAGENESIS. The term applied by **petrographers** to the succession, or order of development, of the minerals in an **igneous** or **metamorphic** rock. More particularly applied to the order of crystallization of related minerals in a vein or ore-body, including processes of alteration. (R.M.F.)

PARAGLOSSA. **Paragnatha.**

PARAGNATHA. 1. The lobes into which the lower lip or metastoma of the **crustacean** mouth is sometimes divided. 2. Lobes or appendages borne by the **hypopharynx** of the insect mouth. They lie between the mandibles and **maxillae** and have also been called paraglossae, superlinguae and maxillulae. They are homologous with the paragnatha of crustaceans. (A.W.L.)

PARAGNEISS. **Gneiss.**

PARAGUAY TEA. **Maté.**

PARALDEHYDE. A powerful sleep-producing drug which may be given by mouth, by vein, or by rectum. It is a volatile liquid with a penetrating burning taste. It is rapidly absorbed and produces sleep very quickly. After paraldehyde is given, the disagreeable odor of the drug is very noticeable as it is excreted in the breath. (See **Acetaldehyde.**) (D.M.H.)

PARALLAX. As an observer moves about, the relative positions of distant objects seem to change. This apparent change of position of distant objects, due to the actual change of position of the observer, is technically known as parallax; and the amount of apparent shift is known as the parallactic shift. The amount of parallactic shift is inversely proportional to the distance of the object.

In taking readings of instruments employing scales and pointers, care must be taken that the eye of the observer and the pointer are both in a line perpendicular to the plane of the scale. To facilitate this, many instruments have a mirror in the plane of the scale so that the observer may eliminate parallax errors by bringing the reflected image of his eye coincident with the pointer and its reflected image.

In astronomy parallax effects play a very important part. In transferring from one system of coordinates to another parallax effects must always be applied when the location of the origin changes. For example, observations are taken from the surface of the earth and **geocentric parallax** must be applied when transferring the observations to the center of the earth. Distances of many celestial objects are expressed in terms of parallactic angles. The angle subtended by an equatorial radius of the earth at the distance of the sun is known as **solar parallax,** while the angle subtended by the radius of the earth at the distance of any other member of the solar system is known as the horizontal parallax of that object. In measuring the distances of the stars the parallactic shift due to the revolution of the earth about the sun is employed; the angle subtended by one **astronomical unit** at the distance of the star being known as the **stellar parallax** of the object. As the characteristics of **solar motion** become more completely known, parallactic shifts due to this motion will undoubtedly be used for the determination of distances. (W.K.G.)

PARALLEL FEED. **Shunt Feed.**

PARALLEL MECHANISM. Parallel mechanisms are those in which the links which compose the mechanism are pinned together in a **parallelogram.** The parallel rulers (Fig. 2) are simply two straight edges joined with pin joints by two connecting links having points of connection so spaced that the rulers and the connecting links form a parallelogram. In this mechanism the straight edges are always parallel, but the perpendicular distance between them may be varied from zero up to the length of the connecting links. An interesting application of the parallel linkage is shown in Fig. 3. In this device the line AB is movable over the plane of the mechanism, within limits. In all positions, however, the line will be parallel to the position shown in the illustration. This linkage is the basis of the universal drafting machine, which is composed of two parallelograms connected through the intermediary of a rigid ring.

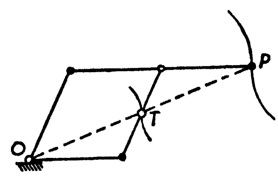

Fig. 1. Pantograph.

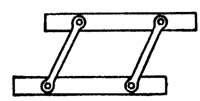

Fig. 2. Parallel rulers.

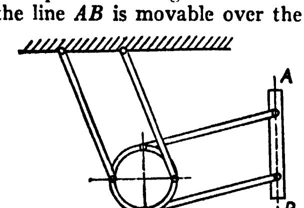

Fig. 3. Drafting machine.

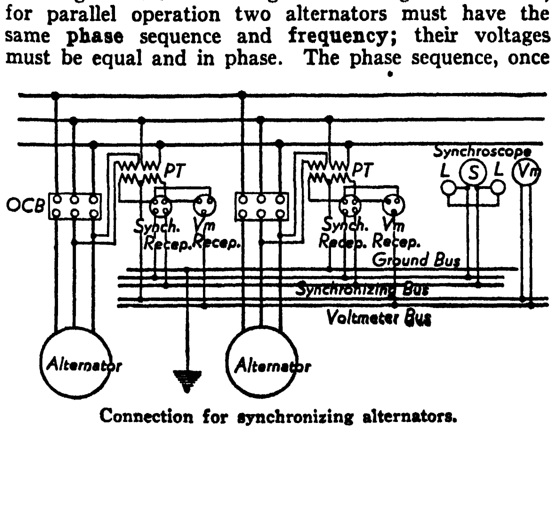
The pantograph has incorporated in it a parallel mechanism. It increases or decreases the scale of the line which is being paralleled (Fig. 1). The point O must be fixed, but the points P and T may be, interchangeably, the tracer point or pencil point, depending on whether the scale is to be reduced or increased. It is necessary, however, for point T to be such that O, T, P are all on the same straight line. The pantograph is used to copy drawings to the same or different scale, and to reduce or increase a motion in exact proportion to the original. (F.T.M.)

PARALLEL OPERATION. The parallel operation of equipment is taken in contrast to series or "booster"

connections. Parallel operation, of course, implies at least two units, although the individuals do not necessarily have to be of the same capacity. Generally speaking, in the parallel operation the quantities of output of the units are additive, whereas in series operation certain characteristics, such as pressure, voltage, and the like are additive, and the quantity output is the same as for each machine. Machines operated in parallel discharge to a common collective device such as a **header** or a **bus** or a **conveyor**. Among the more common instances of parallel operation are found the operation of two or more power plants feeding electrical energy into the same distribution network, the parallel operation of electric generating equipment within a plant, the parallel operation of prime movers such as **steam** or **hydroturbines**, and the parallel operation of **transformers**. Industry offers numerous examples of parallel operation of production machines, the output of which is collected by some mechanical conveyor system.

On account of the interesting technical problems associated with the parallel operation of power equipment, particularly electric generating equipment, this field will be described in some detail. D-c **generators** can be paralleled on a bus, and the load divided between them at will by adjustment of their shunt fields. Shunt-wound generators of like voltage may be operated in parallel merely by being connected to the buses of the same polarity. In the case of compound-wound generators, and most d-c machines are of this type, an equalizer bus must be connected between the series fields of the two **armatures**. Should the machines be paralleled without the equalizer, they might run satisfactorily until some slight unbalance caused one of them to supply a little more terminal voltage. This would lead to a cumulative action due to the presence of series coils, and there would be a heavy surge of load to that machine, which would cause the other to operate as a motor accompanied by excessive circulation of current. By using an equalizer bus, there is a stabilizing action due to the series field currents being determined by the total load current and the series field resistances of the different machines. Any tendency to increase the armature current of one machine will have the effect of strengthening the field of the other, and increasing the load carried by the other. As stated before, shifts of load between d-c generators in parallel are accomplished by altering the shunt-field strength, and no manipulation need be given to the prime mover governors.

When a-c generators are connected in parallel, no such simple method of dividing load is possible, since variation of excitation only causes more wattless current to circulate between the machines. A division of load in this field is accomplished by prime mover governor action, and the principles involved are explained under **governor**. As pointed out there, division of load is accomplished by adjustment of the prime mover governor. Reverting to the a-c generator itself, for parallel operation two alternators must have the same **phase** sequence and **frequency**; their voltages must be equal and in phase. The phase sequence, once correctly established, need not be considered upon subsequent paralleling operations unless the generator or its leads has been altered in the meantime. Visual indication that these electrical quantities are correct is obtained in routine operation by the voltmeter and synchroscope. A diagram of typical synchronizing connections is shown herewith.



Connection for synchronizing alternators.

When transformers are to be connected in parallel, they should have the following similar characteristics stated in order of importance: (1) equal voltage ratings, (2) the same ratios of transformation, (3) equivalent **impedances** which are inversely proportional to their current ratings, (4) equal ratios of equivalent resistance to equivalent **reactance**. (F.T.M., L.R.Q.)

PARALLEL PERSPECTIVE. Perspective.

PARALLEL SAILING. The term parallel sailing is frequently used to designate the problem of converting the distance traversed by a ship along a parallel of **latitude** into difference of **longitude**. This problem is solved under the subject of **departure**. (W.K.G.)

PARALLELS. Steel bars of rectangular section generally used in pairs for supporting work parts and for measurement. They are finished to a tolerance of one-half thousandth of their nominal size, and the surfaces are parallel or perpendicular within this limit. In addition to solid parallels, large hollow bars, known as box parallels, and adjustable parallels with a range of heights, are used by machinists and toolmakers. (H.C.H.)

PARALYSIS. Loss of motor activity in some part of the body. Paralysis occurs when the nerve impulse has met with interference. This may occur in the brain centers, the spinal-cord centers or pathways, nerve trunks or individual nerves, or the nerve endings in the muscles. It may be temporary or permanent, depending on the cause. The cause may be due to a specific disease, to chemical or bacterial poisons, toxins or injury to nervous tissue. (R.S.M.)

PARALYSIS AGITANS (Shaking Palsy, Parkinson's Disease). A chronic organic disorder of the central nervous system characterized by a spontaneous tremor, weakness and rigidity of muscles.

The cause is unknown. Degenerative changes take place in cells and blood vessels in the basal ganglia of the **brain**. One form of paralysis agitans occurs after epidemic **encephalitis**.

The onset of the disease is gradual and the symptoms progress slowly. The small muscles are most frequently involved; the "pill-rolling" tremor of the fingers is characteristic. Eventually weakness and rigidity appear. Rigidity of the face muscles gives a mask-like appearance to the face which does not change with any emotion.

Patients with this disorder may live for years. Death is usually not due directly to the disease, but to complications or intercurrent infections. (D.M.H.)

PARAMAGNETISM. Magnetism.

PARAMETRIC EQUATIONS. A plane curve is usually represented by a single equation in two variables representing **rectangular coordinates** or **polar coordinates**. Sometimes it is preferable to represent the curve by two equations expressing the coordinates separately in terms of a third variable called a parameter; these equations are then called parametric equations.

We may also have parametric equations of surfaces and of curves in space. (L.L.S.)

PARAMORPHISM. A term used by mineralogists and petrologists to denote the passage of one mineral into

another without any fundamental change of chemical elements. A specific example is **uralite**, secondary **hornblende**, paramorphic after **augite**. Paramorphism has also been used to describe the process of **metamorphism** by which a rock is completely changed. (R.M.F.)

PARAPODIUM. A lobed appendage formed as a protuberance of the lateral body wall in some of the segmented worms (chiefly **Polychaeta**). The typical parapodium consists of two principal divisions, a dorsal notopodium and a ventral neuropodium. Each may be divided into subordinate lobes. A slender basal process, the dorsal cirrus, extends upward and outward from the edge of the notopodium and a similar ventral cirrus is borne by the lower edge of the neuropodium. Each of these main divisions also bears a cluster of **setae** and contains a strong supporting rod, the **aciculum.**

In various species of marine **annelids** the parapodia are modified in many ways to serve as respiratory organs, protective structures, and organs for the creation of water currents through the tubes occupied by the worms.

It is possible that parapodia were the forerunners of the **biramous appendages** of **arthropods.** (A.W.L.)

PARAQUE. Aves, Caprimulgiformes. A large bird of Mexico and Texas which resembles the poor-will. One of the goatsuckers or **nightjars.** (A.W.L.)

PARASITE AREA, EQUIVALENT. Flat-Plate Area; Equivalent.

PARASITE DRAG. Aerodynamic drag which is unaccompanied by useful lift is parasitic. In everyday parlance this interpretation is not always followed. The drag of airplane tail surfaces, although accompanied by useful reactions of a balancing or maneuvering nature, is usually included in the parasite drag. Some writers have wished also to refer to profile drag of wings as parasitic, leaving only induced drag nonparasitic. However, in the generally practiced nomenclature of airplanes, no part of wing drag is parasitic, and all other drag is parasitic.

All true parasitic drag may be subdivided into (1) skin friction, (2) turbulence. The smoother the surface in contact with the air, the lower the surface frictional drag, but parasitic drag is apt to consist largely of the effects of a turbulent wake formed by the "bluffness" of the body. To reduce turbulence by streamlining or "fairing" a body so as to avoid all turbulence in the wake may not be desirable since it may unduly increase skin friction because of the larger surface area. Also the boundary layer may reach the separation point farther forward on the drag body. Experience with total drags of shapes with varying degrees of streamlining bears out these conclusions. If by "fineness ratio" (equal to length/breadth ratio) one describes degree of streamlining, a ratio of approximately 3.5:1 is found to have less drag than any other. This is the shape assumed by a freely falling drop of water, and is the shape striven for in faired airplane parasitic bodies such as struts and braces. Often other considerations render it impractical to build the optimum fineness ratio into parasitic components of aircraft. The fuselage must usually have a much greater fineness ratio in order to fulfill its other requirements. Streamline wire must be shaped so its drag is as low as possible in either 0° or 180° position of its longitudinal axis; thus it is made oval instead of teardrop in section.

The usual methods of expression for this type of drag are:

1. Coefficient of drag, C_D, in the basic drag equation. S is some significant surface or projected area of the object, while ρ and V have the usual meaning in **drag.**
2. **Equivalent flat plate area.**
3. **Disk** ratio. Ratio of the area of a disk of equal drag to the maximum area of the object, projected on a plane normal to the air stream. This is sometimes used to compare drags of fuselages, a streamlined fuselage having a disk ratio of 1/6 as against a possible 1/3 for a poor shape.
4. Actual drag of a unit length of the object at 100 m.p.h. This is sometimes employed in the case of struts, wires, and the like, normal to the air stream. Thus if a certain wire had a drag of 0.15 lb. per ft., the drag of a 12-ft. wire at 150 m.p.h. would be $12 \times .15 \times \left(\frac{100}{150}\right)^2$ (+ an allowance for drag of the two terminal fittings).

The principal parasitic components of an airplane are listed here, with some mention of devices or methods employed to reduce said drag to the minimum in the effort to improve speed.

1. *Fuselage.* Reduction or streamlining of protuberances such as cabin enclosures, cockpit covers, etc. Adoption of streamline shapes of optimum fineness ratio. Maximum smoothness of external surface, attained with flush riveting, waxing, etc.

2. *Engine and Cowling, Nacelles, etc.* Engine-fuselage combination for single-engine airplane, engine-nacelle combinations for multi-engine airplanes. Parasitic drag, in this case, is involved with the **cowling and cooling** of the engine and as improved cooling is perfected, parasitic drag is decreased.

3. *Landing Gear, Consisting of Wheels, Struts, Floats, etc.* Fixed undercarriages are partially streamlined by fairing the struts, employing streamline-shaped tires, and partially covering wheels with streamline "pants." But drag can be completely eliminated by mechanically retracting the landing gear, wheels and all, into fuselage, wings, or nacelles. The additional expense, complexity, and vulnerability to mechanism defects are considered to be justified by the increase of speed if the cruising speed is over 150 m.p.h., but is questionable in the case of cruising speeds of 100 m.p.h. or less.

4. *Bracing Struts and Wires.* Streamline strut and wire sections, replacing round types, reduce drag materially. High-speed airplanes are constructed with internally braced wings and empennage for the elimination of this form of drag.

5. *Empennage.* The drag of stabilizer, elevator, fin, rudder may be diminished by employing smooth, low-drag profiles having as small an area and large an aspect ratiô as other conditions permit. (See also **Airfoil, Drag, Induced Drag.**) (F.T.M.)

PARASITIC ANIMALS. In general, parasitism is an association of living things in which one lives on or in the body of the other and consumes materials available in that body without rendering any service in return. The organism which provides maintenance is the host and the one that lives at its expense is a parasite.

Parasites are classified in various ways. Those which remain on the surface of the body, such as **lice** and **ticks**, are called ectoparasites, and those which live in the alimentary tract or in tissues of the host are endoparasites. One-celled animals, **flukes**, roundworms, the larvae of **bot flies**, and other forms belong to the latter category.

Animals like **mosquitoes**, which visit others occasionally to secure food, are known as temporary parasites. Species like some of the **leeches**, which may suck blood or catch invertebrates as prey, are facultative, and those which can live only in association with a host are obligate.

Parasites which carry out their entire reproductive cycle in one host are known as autoxenous or autoecious, in contrast with those which must pass different stages in different hosts. The latter are heteroecious or metoecious. They include the malarial parasite which develops in man and the mosquito, and the flukes, some of which develop in a snail and a vertebrate.

None of these categories is rigidly distinct. In each are included species which normally behave in one way but may adjust their mode of life to meet unusual cir-

cumstances, or species whose normal habits are not limited to one or the other type.

No phylum of animals is made up entirely of parasitic species, but many members of the phyla **Protozoa, Platyhelminthes, Nemathelminthes,** and **Arthropoda** are parasites, and entire orders of these phyla are composed of parasitic species. In many other groups a few parasitic species are known.

The habit of depositing eggs in the nests of other animals, practiced by the European **cuckoo** and the **cowbird,** and by some of the **wasps** and **bees,** is also referred to as parasitism. (A.W.L.)

PARASITIC ANTENNA. **Directional Antenna.**

PARASITIC OSCILLATION. This is an undesirable oscillation occurring in radio-frequency **amplifiers** or **oscillators** usually caused by circuit elements becoming ineffective at frequencies very remote from their normal operating frequencies. Thus very high frequency parasitic oscillations may occur because the normal tuning condensers act essentially as short-circuits and the normal tuning inductances are effectively open-circuits while the interelectrode and wiring capacitances and lead inductances become the **tank circuits.** Low-frequency parasitics may occur because the normal tuning inductances are ineffective and the radio-frequency **chokes** become parasitic tank elements. Parallel-operated vacuum **tubes** are especially susceptible to parasitic oscillations, becoming push-pull oscillators at the parasitic frequencies. Adjustment of leads, insertion of chokes or resistors, etc., are expedients for eliminating these oscillations. (L.R.Q.)

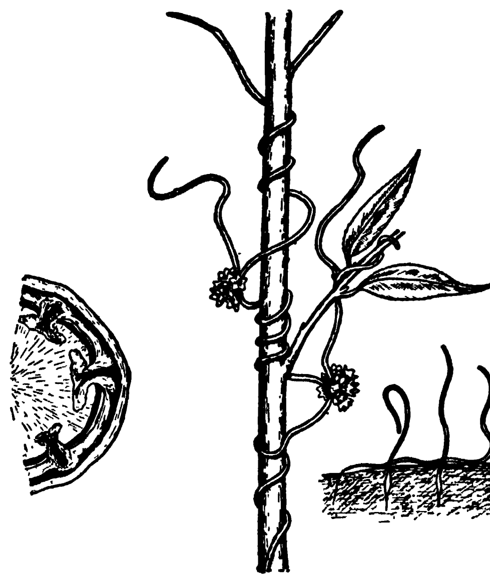
PARASITIC PLANTS. Parasitic plants obtain part or all of their food from other living organisms, called hosts. Except for the lowest groups of plants, the host of a parasitic plant is another plant. The greatest number of parasites are numbered among the **bacteria** and **fungi,** many of which cause diseases of great economic consequence.

Among flowering plants there are relatively few parasites. Of these there are two different types, differing very greatly in appearance. One type contains those plants which are only partially parasitic, the other those which are total parasites, depending on the host entirely for their nourishment.

In the first group the parasites are green and appear very much like ordinary plants. Indeed, some of them, such as the eyebright, a species of *Euphrasia* of the **Figwort Family,** can live independently, but usually attach their roots to those of other plants and obtain a part of their food requirements from the host. Another member of the same family, the common cow wheat, *Melampyrum americanum,* of open woods is less independent. Without a host, its growth is stunted. To come to maturity and fruit it must find a host. Since, like all the other members of this family, it grows where host plants (commonly grasses) are abundant, little difficulty in meeting a host occurs. The roots of the parasite fasten to those of the host and send sucking organs, called haustoria, into the host roots. From these the parasite draws the water and mineral salts it needs. It seems to affect the host plant very little. Some members of this family do cause certain changes in the host plant, whose roots are stimulated by the parasite haustoria to become much enlarged, producing knob-like growths. In this group of parasites, the principal difference from ordinary non-parasitic plants is a deficiency of roots.

Another type of partial parasites, including the various mistletoes, do not grow on the ground, but attach themselves to the branches of trees. In these parasites the seeds are usually very sticky and attractive to birds. The latter carry them from one tree to another. On germinating, the seed forms a structure called an adpressorium, which attaches itself firmly to the branch. Then a hard, penetrating, root-like growth pushes into the wood of the host until it reaches the water-conducting cells. There it may form numerous peg-like growths or branches, which greatly increase the absorbing surface. Meanwhile the seed has sent out a normal stem which bears green leaves, and which branches abundantly. This plant carries on **photosynthesis** *normally,* but gains all its water supply and mineral salts from a host plant. Often such parasites are mistaken for branches of the host, and again for **epiphytes.** In these plants, no normal root system ever develops.

Complete or total parasites are strikingly different. They are usually entirely lacking in **chlorophyll,** and so cannot carry on photosynthesis. They must obtain from the host plant their food supply, in the form of **carbohydrates,** fats, and proteins already synthesized by the host. Parasites of this group have the leaves reduced to minute scales or frequently entirely lacking. Roots also are missing, being replaced by haustoria, the structures which enter the host and absorb nutrients from it.



Dodder, a parasite. Middle, habit sketch; right, seedlings of dodder; left, section through stem of host and parasite showing haustoria of dodder reaching the fibro-vascular bundles of host. (*After Strasburger, Noll, Schenck and Schimper, Lehrbuch der Botanik, Gustav Fischer, Jena.*)

A common parasite, and one widely distributed and often very destructive, is the dodder (species of the genus *Cuscuta*), which parasitizes many crop plants, as well as wild hosts. Dodders are twining vines in the same family as the morning glory, to which they are closely related. The seed of the dodder germinates and forms a short root which attaches itself firmly to the soil, but does nothing more. Then a long slender stem is formed. This swings about in a wide arc until it makes contact with some green plant. Around this the stem of the dodder winds tightly. Soon that part between the host and the ground withers and dries, leaving the parasite to grow entirely at the expense of the host. This it does very rapidly, pushing a series of haustoria into the stem of the host and absorbing from it all necessary food. The mature dodder is a long, slender, much-branched vine. The stem is regularly divided into nodes, at which are borne small scale leaves and, when mature, compact clusters of waxy white flowers. The entire plant is yellowish or pinkish and has very little chlorophyll. Under favorable conditions a dodder plant will cover an area of many sq. ft. with a tangle of slender branching stems which pass from one host

plant to another. Common species will attach to many different species of plants as hosts.

The broomrapes (species of *Orobanche*) form another group of parasites. These attach themselves to the roots of various host plants. The parasite is a low-growing plant, lacking chlorophyll, with greatly reduced leaves and small but attractive flowers. It is of little importance.

In the tropics many species of parasitic flowering plants are found, some of them very striking. In many South American parasitic species the reduction of the plant body has continued until there remains but a short thick stem rising from the host plant's roots, and a mass of flowers, the latter often brilliantly colored. (See **Orchid Family.**)

The extreme of reduction of parts occurs in certain parasites of the East Indies and Malayan jungles. One species, *Rafflesia Arnoldii,* is worthy of note. It grows attached to the spreading roots of species of *Cissus,* forming in them tumorous enlargements. From these the flower of the parasite bursts out directly, there being practically no stem and no leaves. Reduction of parts has left only the absorbing organs and the reproductive organ. The flower is remarkable, being a dark mottled red structure nearly a yard across and possessing a powerful stench of carrion. **Pollination** is accomplished by flies, which are attracted by this foul odor. Other species of this genus are known, all conspicuous, if not as large, and all showing this same reduction of parts and the marked parasitic habit. These parasites are not widely distributed, being necessarily confined to regions where the host plant grows. The element of chance in pollination further restricts the range of the plants. Parasites of this sort are extremely interesting to study, because of their unusual morphological features. (R.M.W.)

PARASPHENOID. A dermal bone supporting the roof of the mouth in fishes and amphibians. Also found in the reptiles and birds, while in the mammals it is represented by the vomer. (A.W.L.)

PARASYMPATHETIC NERVOUS SYSTEM. Autonomic Nervous System.

PARATHYROID GLANDS. The parathyroid glands, usually four in number, are found on the posterior side of the lobes of the **thyroid gland,** two on either side. Accessory glands may be present.

These glands of internal secretion control the calcium and phosphorus **metabolism** of the body. Complete removal results in death with painful spasms, twitching, and convulsions. The symptoms are due to overexcitability of the nervous system due to the low concentration of **calcium** in the blood. Without proper function of the parathyroids calcium cannot be utilized by the body. **Vitamin D** enters into this process, acting in some manner with parathyroid **hormone.** Collip has described and prepared an extract of these glands which relieves symptoms from hypofunction.

Overactivity of the parathyroids causes a condition known as **Osteitis fibrosa cystica** (Von Recklinghausen's bone disease). In this condition there is often a tumor of the parathyroid with overproduction of its hormone and withdrawal of calcium from the bones into the blood. This produces cystic areas in the bones. Often **kidney** stones are formed from the excess of calcium excreted in the **urine.** Surgical removal of the involved gland results in clinical cure.

Deficiency of the parathyroid hormone results in the condition known as tetany, characterized by painful spasm of the muscles due to deficiency of calcium in the blood. (D.M.H.)

PARATYPE. Any specimen of animal or plant, living or **fossil,** considered by the describer to be similar to the type or **holotype.** (R.M.F.)

PARATYPHOID FEVER. Paratyphoid and **typhoid** fevers are distinct and separate diseases. Paratyphoid fever is an acute general infection caused by the paratyphoid bacillus A or B, having the same clinical signs and symptoms and pathological changes as are seen in typhoid fever except in milder degree. The organism is in an intermediate position between *Bacillus typhosus* and *Bacillus Coli.*

An attack of, or immunization against, typhoid fever does not give immunity to paratyphoid fever. Until World War I, paratyphoid was considered a rare disease. It was found at that time that not only did the inoculations against typhoid fail to give protection against paratyphoid, but that the disease was far more prevalent than previously believed. At present inoculations are given using a triple vaccine which protects against typhoid and paratyphoid A and B.

The sources of infection are the same as of typhoid, as is the manner of contagion. The incubation period varies from 3 to 15 days. Paratyphoid cannot be distinguished from typhoid by clinical signs or symptoms, but only by means of laboratory tests. It is a milder infection than typhoid as a rule, of shorter duration, and with a lower mortality.

The complications of paratyphoid are similar to those of typhoid, and the chief causes of death are pneumonia, hemorrhage, and perforation of the intestines. (R.S.M.)

PARAZOA. A major division of the animal kingdom containing only the **sponges** (Porifera). In contrast with the 1-celled Protozoa on the one hand and the many-celled Metazoa on the other, these animals are made up of many cells, but the cells are organized in tissues only to a limited extent and are not closely coordinated by a nervous system. (A.W.L.)

PARENCHYMA. In zoology, this term is commonly used in two ways. 1. It designates the essential or functional elements of an organ in contrast to the connective elements or framework. 2. Parenchyma also designates a loosely compacted tissue of **mesodermal** origin which fills the space between the viscera and the body wall in flatworms and some roundworms.

In botany, parenchyma tissue is the fundamental tissue found in all parts of the plant. From parenchyma cells all other kinds of cells are formed. A typical parenchyma **cell** is thin-walled and more or less rounded in shape. Mutual pressure of many parenchyma cells against one another causes them to become angular. They are generally isodiametric.

Parenchyma cells contain living **cytoplasm** and are potentially capable of dividing to form new cells at any time. In certain parts of the plant parenchyma cells have definite functions. For instance, in the growing tips of both stems and roots there are groups of cells which divide rapidly, adding to the length of the stem or root. These groups of actively dividing cells make up the meristematic region. Many of the parenchyma cells, especially in the outer cortical tissues of stems and in leaves, contain **chloroplastids** and are green. Cells of this kind are called chlorenchyma cells. In them **photosynthesis** is carried on. In other parenchyma cells food reserves are stored. **Carbohydrates** may move through the plant in the parenchyma cells. Pith, rays, most of the cortex, and leaves (excepting the veins) are composed of parenchyma cells. (A.W.L., R.M.W.)

PARENTHESES. In **algebraic expressions** it is sometimes desirable to group several parts together to indicate that they are to form a single unit of investigation. For this purpose, parentheses, ( ), brackets, [ ], braces, { } and occasionally a vinculum, —, are used.

Rules for the removal of parentheses in algebraic expressions are: If a parenthesis is preceded by a **plus** sign, the parentheses may be removed without any

change in the terms within it; if a parenthesis is preceded by a minus sign, the parentheses may be removed if all the signs of the terms within it are changed.

By reversal of these rules, parentheses may be insorted in expressions. (L.L.S.)

PARESIS, GENERAL (Paretic Neurosyphilis, General Paralysis, General Paralysis of the Insane, Dementia Paralytica). General paresis is a chronic infection and inflammation of the brain and its coverings occurring as a manifestation of late or tertiary **syphilis.** It is characterized by progressive dementia and a generalized paralysis which eventually terminates fatally.

About 3% of syphilitics develop paresis.

Pathologically, the changes in the brain are characterized by degeneration of the brain cells, especially in the frontal lobes which control the higher mental processes. Cerebral atrophy is usually marked, and the brain coverings are thick and adherent.

The symptoms may assume any form. Since the onset may be sudden or insidious, paresis may resemble and be mistaken for any kind of mental disease. The diagnosis is easily established by finding a positive spinal fluid Wassermann test.

In the early stages, changes in personality, lack of judgment, carelessness, may lead to financial and moral difficulties. These early symptoms may last weeks, months, or years. Visual, auditory, and speech defects are common.

During the fully developed stage of the disease, characteristic symptoms are euphoria with grandiose ideas, delusions of wealth and power. In others, depression may be marked, with anxiety and fear. There is also a form characterized by delusions of persecution. Convulsive seizures followed by temporary paralysis are common. Progressive dementia is present with all the above syndromes.

In the late stages the paralysis is marked, involving all muscles, and the patient is bedridden until death occurs either by intercurrent infection or by respiratory paralysis.

The prognosis is more hopeful at present since more cases receive early treatment. Remission of the disease for varying periods has been obtained by means of fever therapy together with tryparsamide, which has more effect on neurosyphilis than the common arsenical compounds.

Juvenile paresis is much more common than juvenile tabes and is a form of congenital syphilis. It is characterized by a rapidly progressing dementia or feeblemindedness.

Often central nervous system syphilis appears as a combination of paresis and **tabes dorsalis,** known as tabo-paresis. (D.M.H.)

PARESTHESIA. Any abnormal sensation on the surface of the body. It may be described by the patient as burning, tickling, itching, pricking, etc. Paresthesias occur in nervous-system diseases involving the spinal cord, in pernicious **anemia,** and polyneuritis. (R.S.M., D.M.H.)

PARIETAL. One of the large bones of a pair which form the sides and roof of the human skull, and the smaller bones of similar relations in the skulls of other vertebrates. The word is used in a similar descriptive sense to refer to the walls of various organs. (A.W.L.)

PARKERIZING. A protective iron phosphate coating applied by immersing iron or steel in a hot solution of manganese dihydrogen phosphate for 30–60 minutes. Bonderized coatings are much thinner iron phosphate coatings applied by spraying or dipping in hot phosphate solutions containing accelerators. Similar processes use nitrate salts, oxalic acid, and chromic acid as the reactive agents. Bonderizing and similar processes are often applied to galvanized steel to provide a suitable base for painting. (R.H.H.)

PARKINSON'S DISEASE. Paralysis Agitans.

PARONYCHIA. Infection of the tissues surrounding the finger nail. Paronychia commonly follows injury, especially from a "hang nail." Treatment is surgical. (R.S.M.)

PAROTID GLAND. Salivary Glands.

PAROTITIS. Infection of the **parotid glands.** Parotitis may occur as a complication of any prolonged illness, especially after operations or illnesses in the aged and debilitated. **Mumps** is a form of parotitis. (D.M.H.)

PARRAQUET. Parrot. Also spelled parakeet, parrakeet, and in various other ways. (A.W.L.)

PARROT. Aves, Psittaciformes. Birds (**Aves**) with a strong hooked beak and with two toes of the foot directed forward and two back. They are represented on all continents except Europe but are confined chiefly to tropical and subtropical areas. They eat nuts and other fruits and seeds, although the kea parrot, *Nestor notabilis,* of New Zealand is said to have acquired a taste for mutton.

The brilliant colors of many parrots and their ready imitation of human speech have led to their being kept as cage birds for many centuries, hence they are familiar even beyond their natural range.

There are many subsidiary forms of parrots. The nestor parrots of New Zealand and the neighboring islands are dark-colored birds, including the kea and the kaka. The bad reputation of the former for destroying sheep has recently been denied, hence it is impossible to give accurate information on this point. It is a mountain bird. Cockatoos are crested species with the hook of the beak transversely ridged below; an Australian species is called the cockatiel. The lories and loriquets are small species of the Australian region. Macaws are large brilliantly colored birds of the American tropics with a very large beak and long tail. They are sometimes seen in captivity. Conures are small species, including the only North American representative of the order, commonly called the Carolina paraquet, *Conuropsis carolinensis.* The term paraquet, spelled in various ways, designates many small species of typical parrot of the Oriental and Australian regions. Among them are the broadtail, turquoisine, and budgerigar, as well as other species with less striking names. They are closely related to the small parrots so often seen in cages under the name love-birds.

A curious member of the order is the owl-parrot or kakapo of New Zealand, which constitutes a distinct family. It is a flightless bird of owl-like appearance, barring its more brilliant colors, and is largely nocturnal in habits. (A.W.L.)

PARROT-FISH, PARROT-WRASSE. Pisces, Teleostei. Brightly colored marine fishes (**Pisces**) with a prominent beak formed by the partial coalescence of the teeth. They occur in tropical waters, chiefly about coral reefs. (A.W.L.)

PARSEC. The parsec is a unit of distance used for expressing distances between stars and other members of the **sidereal universe.** Technically an object is at a distance of one parsec when it has a **stellar parallax** of 1″ (one second of arc) or, in other words, one **astronomical unit** would subtend an angle of one second at the distance of one parsec.

Expressed in other units of distance:

1 parsec = 3.26 **light years.**
= 206265 astronomical units.
= 1.02×10^{13} miles or about 20 millions of millions of miles.
= 3.08×10^{13} kilometers.

Within recent years in the discussion of distances between **extra-galactic** objects the parsec is not large enough to be convenient and the terms kiloparsec (1000 parsecs) and even megaparsec (1,000,000 parsecs) have been proposed. (W.K.G.)

PARSLEY. **Carrot Family.**

PARSNIP. **Carrot Family.**

PARTHENOCARPY. The development of a fruit without fertile seeds. In most flowering plants fruit production depends upon **pollination,** fertilization, and the subsequent growth of embryos in the seeds. The size and shape of fruits are largely determined by the number and location of the fertile seeds. Cucumbers, for instance, sometimes are pollinated in such a way that seeds develop only in the stem end, resulting in an undesirable, constricted blossom end.

Certain fruits, such as the banana and the "seedless" or navel orange, are normally parthenocarpic. It is now possible to induce parthenocarpy in plants which normally fail to produce any fruits at all without pollination by spraying the open flowers with auxin. "Seedless" tomatoes, apples, and possibly other fruits may be produced commercially in this manner. The dilute auxin solutions produce parthenocarpic fruits whether applied to the stigma or to the surface of the ovary from which the style and stigma have been removed. (P.A.W.)

PARTHENOGENESIS. The development of eggs without **fertilization.** In some groups of animals eggs normally develop in this way, either for a series of generations interrupted occasionally by a normal fertilization or as a special part of the reproductive process associated with the development of some young from fertilized eggs. The **rotifers** are extensively parthenogenetic. In some cases males are not known and it is possible that parthenogenesis has entirely superseded normal sexual reproduction. Among the insects plant lice reproduce parthenogenetically for many generations, but in the temperate zones the onset of cold weather is accompanied by the appearance of a sexual generation. The honey-bee and other related species carry on parthenogenesis to a limited extent. Male or drone honey-bees are produced from unfertilized eggs and females, both queens and workers, from eggs which have been fertilized.

Artificial parthenogenesis has been induced experimentally by subjecting eggs to varied chemical and mechanical stimuli. The eggs of marine invertebrates, such as **sea** urchins, have been especially favorable subjects, but Loeb, in one of the most famous experiments, produced several frogs from unfertilized eggs by the mechanical stimulus of pricking the egg with a needle. (A.W.L.)

PARTIAL CORRELATION. We often desire to find the dependence of two variables x_1 and x_2 when other variables x_3, x_4, $\cdots$, xN are kept constant. This is readily accomplished by partial linear correlation and we refer to the **coefficient of partial correlation** for a complete discussion. The more general theorem of partial curvilinear correlation is in very many respects similar but somewhat more complicated. (L.A.A.)

PARTIAL DERIVATIVES. Let $u = f(x, y, z, \cdots)$ be a **function** of two or more variables. If all the variables except one, say x, are held **constant** and x is given an increment Δx, and if Δu is the corresponding increment of u, and if we form the ratio $\Delta u/\Delta x$ and take the limit when $\Delta x \to 0$, then the limit $\lim\limits_{\Delta \to 0} \left(\frac{\Delta u}{\Delta x}\right)$ is called the partial derivative of u with respect to x, and is denoted by $\frac{\partial u}{\partial x}$ or u_x. Similarly, we define the partial derivatives $\frac{\partial u}{\partial y}$, $\frac{\partial u}{\partial z}$, etc.

Partial derivatives of a function of two variables may be given a geometric interpretation as follows: If $z = f(x, y)$ represents a **surface**, then $\frac{\partial z}{\partial x}$ represents the **slope** of the curve of intersection of the surface and a plane perpendicular to the Y-axis; and similarly for $\frac{\partial z}{\partial y}$.

A change of variable in partial derivatives may be effected as follows: Let u be a function of a first set of independent variables $x, y, z, \cdots$; let us introduce a second set of variables $r, s, t, \cdots$, related to the first set of variables $x, y, z, \cdots$ by explicit or implicit functional relations. Then

$$\begin{cases} \dfrac{\partial u}{\partial r} = \dfrac{\partial u}{\partial x}\dfrac{\partial x}{\partial r} + \dfrac{\partial u}{\partial y}\dfrac{\partial y}{\partial r} + \dfrac{\partial u}{\partial z}\dfrac{\partial z}{\partial r} + \cdots, \\ \dfrac{\partial u}{\partial s} = \dfrac{\partial u}{\partial x}\dfrac{\partial x}{\partial s} + \dfrac{\partial u}{\partial y}\dfrac{\partial y}{\partial s} + \dfrac{\partial u}{\partial z}\dfrac{\partial z}{\partial s} + \cdots, \\ \dfrac{\partial u}{\partial t} = \dfrac{\partial u}{\partial x}\dfrac{\partial x}{\partial t} + \dfrac{\partial u}{\partial y}\dfrac{\partial y}{\partial t} + \dfrac{\partial u}{\partial z}\dfrac{\partial z}{\partial t} + \cdots, \\ \cdots\cdots\cdots\cdots\cdots \end{cases}$$

the number of equations being the same as the number of variables in the second set and the number of terms on the right in each equation being the same as the number of variables in the first set. Also

$$\begin{cases} \dfrac{\partial u}{\partial x} = \dfrac{\partial u}{\partial r}\dfrac{\partial r}{\partial x} + \dfrac{\partial u}{\partial s}\dfrac{\partial s}{\partial x} + \dfrac{\partial u}{\partial t}\dfrac{\partial t}{\partial x} + \cdots, \\ \dfrac{\partial u}{\partial y} = \dfrac{\partial u}{\partial r}\dfrac{\partial r}{\partial y} + \dfrac{\partial u}{\partial s}\dfrac{\partial s}{\partial y} + \dfrac{\partial u}{\partial t}\dfrac{\partial t}{\partial y} + \cdots, \\ \cdots\cdots\cdots\cdots\cdots \end{cases}$$

Let $u = f(x, y, z, \cdots)$ be a function of two or more variables, and let $x, y, z, \cdots$ be functions of a single independent variable t. Then

$$\frac{du}{dt} = \frac{\partial u}{\partial x}\frac{dx}{dt} + \frac{\partial u}{\partial y}\frac{dy}{dt} + \frac{\partial u}{\partial z}\frac{dz}{dt} + \cdots$$

is called the total derivative of u with respect to t.

Partial derivatives of higher order are defined thus: In general, the partial derivatives $\frac{\partial u}{\partial x}$, $\frac{\partial u}{\partial y}$ of a function $u = f(x, y)$ are themselves functions either of x or of y or of both x and y. They may then be differentiated partially with respect to x or y. Thus, we get

$$\frac{\partial^2 u}{\partial x^2} = \frac{\partial}{\partial x}\left(\frac{\partial u}{\partial x}\right), \qquad \frac{\partial^2 u}{\partial y^2} = \frac{\partial}{\partial y}\left(\frac{\partial u}{\partial y}\right),$$

$$\frac{\partial^2 u}{\partial x \partial y} = \frac{\partial}{\partial x}\left(\frac{\partial u}{\partial y}\right), \qquad \frac{\partial^2 u}{\partial y \partial x} = \frac{\partial}{\partial y}\left(\frac{\partial u}{\partial x}\right),$$

$$\frac{\partial^3 u}{\partial x^3} = \frac{\partial}{\partial x}\left(\frac{\partial^2 u}{\partial x^2}\right), \qquad \frac{\partial^3 u}{\partial x \partial y^2} = \frac{\partial}{\partial x}\left(\frac{\partial^2 u}{\partial y^2}\right), \text{ etc.}$$

Frequently the notation u_{xx} is used for $\frac{\partial^2 u}{\partial x^2}$, u_{xy} for $\frac{\partial^2 u}{\partial x \partial y}$, etc.

For functions having continuous first partial derivatives,

$$\frac{\partial^2 u}{\partial x \partial y} = \frac{\partial^2 u}{\partial y \partial x} \quad \text{or} \quad u_{xy} = u_{yx}.$$

(L.L.S.)

PARTIAL DIFFERENTIAL EQUATIONS. A partial differential equation is an **equation** which involves **partial derivatives**; it therefore involves an unknown function of two or more independent variables. A solution of such an equation is a relation among the variables, dependent and independent, that satisfies the equation.

In general the solution of a partial differential equation involves arbitrary functions, just as the solution of an ordinary differential equation involves arbitrary constants.

The problem of solving partial differential equations is inherently more difficult than that of solving ordinary differential equations, so no further indication of methods of solution can be given here. (L.L.S.)

PARTIAL DIFFERENTIATION. **Partial Derivatives.**

PARTIAL FRACTIONS. When a given rational **fraction** is resolved into a sum of simpler fractions, usually with linear and quadratic denominators, the resulting fractions are often called partial fractions.

The following fundamental theorem lies at the basis of the method of partial fractions:

Any rational proper fraction with real coefficients may be resolved into a set of partial fractions, of the following types:

1. To any linear factor, as $ax + b$, occurring once in the denominator of the given fraction, there corresponds a single partial fraction of the form $\frac{A}{ax + b}$, where A is a constant;

2. To any linear factor, as $ax + b$, occurring r times in the denominator, there corresponds a set of r partial fractions of the form

$$\frac{A_1}{ax + b} + \frac{A_2}{(ax + b)^2} + \cdots + \frac{A_r}{(ax + b)^r},$$

where $A_1, \cdots, A_r$ are constants;

3. To any quadratic factor, as $ax^2 + bx + c$, occurring once in the denominator, there corresponds a single partial fraction of the form $\frac{Ax + B}{ax^2 + bx + c}$, where A and B are constants;

4. To any quadratic factor, as $ax^2 + bx + c$, occurring r times in the denominator, there corresponds a set of r partial fractions of the form

$$\frac{A_1x + B_1}{ax^2 + bx + c} + \frac{A_2x + B_2}{(ax^2 + bx + c)^2} + \cdots + \frac{A_rx + B_r}{(ax^2 + bx + c)^r},$$

where $A_1, B_1, \cdots, A_r, B_r$ are constants.

The undetermined coefficients in these assumed forms of partial fractions may be found by clearing of fractions and equating coefficients of like powers of x on both sides of the equality, which is an **identity** in x; or by other special devices, such as substituting special values of x. (L.L.S.)

PARTICULAR SOLUTIONS OF A DIFFERENTIAL EQUATION. **Ordinary Differential Equations.**

PARTING. In **geology**, a small joint in a sedimentary rock, especially coal. In **mineralogy**, the tendency of crystals to separate along certain planes that are not true cleavage planes. (R.M.F.)

PARTRIDGE. Aves, Galliformes. Game birds (**Aves**) of numerous species, related to the pheasants and turkeys. The francolins of Asia and Africa are included here. True partridges are similar to the **quails**. The latter, although more generally known in North America by the name quail, are members of the group. They are found over Europe, Asia, Africa, and North America. Aside from the common quail or bob-white of North America, the names quail and partridge are both applied to the several western species, and in the southern states even the bob-white becomes the partridge. To confuse the term still further the ruffed **grouse** is often called a partridge in the northern states. (A.W.L.)

PARTURITION. The process of **labor**, or the act of giving birth to a child. (R.S.M.)

PASCAL'S LAW. **Hydrostatics.**

PASCAL'S TRIANGLE. **Binomial Formula.**

PASCHEN-BACK EFFECT. **Zeeman Effect.**

PASSERES, PASSERIFORMES. The largest order of birds (**Aves**), containing many families and several thousand species. All of the common songbirds belong here, including such familiar forms as **sparrows, warblers, wrens, thrushes,** and similar forms. (A.W.L.)

PASSION FLOWERS. *Passiflora* sp. Passiforaceae. The passion flowers are mostly tropical American plants which climb by means of axillary **tendrils**. The leaves are of various shapes, sometimes varying greatly on a single plant. The flowers are borne singly or in small cymes in the **axils** of the leaves, and are of a variety of colors, some species having white flowers, others blue, and still others scarlet. The five **sepals** are borne on the margin of a cup-like receptacle, as are the five **petals** and the corona, an outgrowth from the receptacle, which in many species is cut into numerous slender segments colored like petals. Five **stamens** are borne at the base of the ovary; these bend outward over the corona. The fruit is a **berry**, in which the seeds are surrounded by a fleshy **aril**. Many species of passion flower are extensively grown for their curiously beautiful flowers. In tropical America the edible fruits appear on the market. (R.M.W.)

PASSIVITY. When **iron** is immersed in **nitric acid** concentrated, there is no visible reaction (Keir, 1790), although nitric acid dilute results in a marked reaction with iron. Upon removal of the iron from the nitric acid concentrated and immersion in **copper** sulfate solution, the iron is not plated by copper, although this occurs with ordinary iron. Iron in such a condition is described as passive iron and the phenomenon is known as passivity.

Passivity of iron is produced by other means than the use of nitric acid concentrated, for example, (1) by immersion in solutions of **chromic acid, iodic acid, arsenic acid, potassium** permanganate, potassium dichromate, **lead** nitrate, **hydrogen peroxide,** (2) by anodic oxidation in sulfuric acid **electrolyte**. Other metals than iron are subject to passivity by anodic oxidation, e.g., **cobalt, nickel, aluminum.** In sulfuric acid dilute aluminum as **anode** withstands 25 volts, and in ammonium borate solution 500 volts. Reversal of the current permits the current to pass, thus aluminum may serve as a rectifier of a.c. in a suitably constructed cell.

Formation of a thin film of oxide on the surface of the metal was proposed as the explanation for the behavior (Schonbein, 1836). Passivity is readily removed by percussion, by immersion in a non-oxidizing acid such as **hydrochloric acid**, or by heating in an atmosphere of **hydrogen**. Passive iron shows the **photoelectric effect** less than ordinary iron (Allen, 1914), thus indicating a change of surface in the former. (R.K.S.)

PATCHOULI. **Mint Family.**

PATELLA. 1. A short segment of the jointed leg of **spiders** and related forms, between the **femur** and **tibia**.

2. The kneecap of man and the corresponding bone of other vertebrates. (A.W.L.)

PATENT. A United States patent grant gives the inventor the right to exclude all others from making, using, or selling his invention for the term of 17 years, but it does not give the patentee the right to make, use, and sell his own invention if it is an improvement on some unexpired patent whose claims are infringed thereby. The Patent Office in its investigation preceding the issue of a patent does not consider whether the invention infringes prior patents.

A patent is granted only upon a regularly filed application, complete in all respects, upon payment of the fees, and only after a determination of utility and completeness of disclosure of the invention, and a search to determine its novelty.

No patent is granted upon a mere idea or a suggestion.

There must be a complete description of the invention and it must be accompanied by drawings suitably illustrating the same, if it is of a machine or other device that can be illustrated. If the device is not operative and not so clearly set forth as to make it capable of manufacture from the description, no patent can issue.

An application for patent must be made by the inventor *only,* and no person who has not actually created a portion of the invention is entitled to be considered a joint inventor. A patent issued to more than one inventor where only one has actually invented the device is invalid. A person who makes a financial contribution merely is not a joint inventor, but the invention may be assigned to him.

Patents are not granted for useless devices, for printed matter, for methods of doing business, for improvements in devices which are the result of mere mechanical skill, nor for machines that will not operate, particularly for alleged perpetual-motion machines.

A patent is not granted for a new composition of matter unless the component parts thereof, as well as the manner of making and using the same, are fully disclosed in the application when filed.

No protection is afforded by the Patent Law prior to the actual issue of a patent. The terms "Patent applied for" and "Patent pending" have no effect in law but give information that an application has been filed.

Once a patent has been issued it is out of the jurisdiction of the Patent Office, and, therefore, the office is not concerned with questions of infringement, the scope of a patent, or any other questions that arise out of the grant. These matters are within the jurisdiction of United States District Courts.

Protection of the Patent Law extends throughout continental United States, Alaska, Hawaii, and the Canal Zone, and, upon compliance with certain regulations, to Porto Rico, the Philippine Islands, the Virgin Isles, and Guam. (F.T.M.)

PATENT LOG. The term patent log is applied to any one of a large group of instruments for recording the speed of a ship through the water, and also the distance run through the water in a given interval of time.

The screw of the ship itself is, in a sense, a patent log, for the speed of the ship through the water is proportional to the rpm of the screw, and the distance run is proportional to the total number revolutions in a given time. However, the distance that the ship will move for a single revolution depends upon a number of variable factors such as the trim of the vessel, the speed of the vessel, the state of the sea, etc.

The earliest, simplest, and, perhaps, the most reliable of the various types of patent logs is the so-called taffrail log. This instrument consists of a spinner which is towed astern of the ship, well beyond the turbulence produced by the screw. The revolutions of the spinner are transmitted to a recording mechanism which was originally at the stern, or taffrail, of the ship. In modern installations the recording dials may be located on the bridge or wherever they will be of most use to the navigating staff. The dials show the speed of the ship at any instant, and also the distance run since the indicator was set to zero. The instrument must be continually watched to see that it is not fouled by seaweed or debris thrown overboard from the ship. Furthermore, it must be frequently checked by the log chip and line, or some other method, to be certain that the blades have not been bent by striking objects floating in the water.

The spinner in the Forbes type of patent log projects below the keel of the ship, at the turning center of the vessel, and its revolutions operate dials similar to those of the taffrail log.

The principle of the **Pitot tube** is used in another type of patent log. The tube itself is below the ship, at the turning center, and operates dials similar to those with the other instruments. (W.K.G.)

PATENTING. **Heat Treating.**

PATHOGENIC. A term used to describe the agents producing disease. Most commonly, bacteria are so described. (D.M.H.)

PATHOLOGY. That branch of medicine which is concerned with the structural changes caused by disease. Pathologists perform necropsies, examine the organs and tissues grossly, and prepare sections of these for microscopic examination. (D.M.H.)

PATINA. The **geochemically** altered surface of any discrete object such as a mineral, pebble or rock. A film, usually green, formed on copper and bronze after long atmospheric exposure. Particularly used by archeologists to describe the altered surface of **artifacts.** (R.M.F.)

PATTERN. **Sheet Metal Processes; Casting.**

PAUROMETABOLA. A division of the insects characterized by gradual metamorphosis. The insect hatches from the egg in a form resembling the adult and adapted for the same mode of life. It is called a nymph. As growth proceeds the nymphs of winged species acquire rudimentary wings in the form of small external flaps, which increase in size with each moult and become fully formed wings at the last transformation.

The **cicadas** are in an order of this group but they differ from most of the other forms in having nymphs adapted for life underground and consequently less like the adults than is usual.

The group includes the orders **Orthoptera, Isoptera, Corrodentia, Dermaptera, Thysanoptera, Hemiptera,** and **Homoptera.** (A.W.L.)

PAUROPODA. Minute animals related to the centipedes and millipedes. Usually regarded as a distinct class of the phylum **Arthropoda.** They resemble millipedes in having the segments of the body fused in pairs above but the legs are not grouped two pairs together. They have a distinct head and body, branched antennae, and no eyes. The body consists of twelve segments.

Pauropods live in damp places under debris on the surface of the ground. They have been recorded from Europe and the Americas. (A.W.L.)

PAVEMENT. **Highways.**

PAX. Private automatic exchange. This is a small machine switching telephone system used for interphone service within the confines of a privately owned build-

ing or group such as a factory. It may or may not be connected by trunk lines with the public telephone system. (L.R.Q.)

PAXILLA. A modified spine of starfishes. A thick process bearing small spines at the end. (A.W.L.)

PBX. This is a private branch exchange, a small manual telephone system used for interphone service with connecting trunks to the outside or public telephone system. Frequently such branch exchanges are supplied operating current from the main telephone office. (L.R.Q.)

PEA FAMILY. Leguminosae. The Pea Family is second only to the **Composite Family** among the **dicotyledons**, with respect to the number of species it includes. Of its more than 10,000 species in nearly 500 genera, many are trees or shrubs, especially those in tropical regions. Herbaceous species are numerous in temperate regions. Many climbing plants, also, are found in the family. Leguminous plants are found in all sorts of environments and climates.

Nearly all the plants in this family have **pinnately** compound leaves. The **stipules** present in the leaves are sometimes modified to persistent **spines.** The flowers are either regular or irregular. When regular, the flowers have five **sepals,** commonly more or less united, five **petals,** a varying number of **stamens** and a single **pistil.** Irregular flowers are of the type known as papilionaceous, a name given because of the fancied resemblance of the flower to a butterfly. In flowers of this type the **calyx** has five unequal, more or less united sepals, which frequently persist during development of the fruit, five separate petals, showing very constant difference in form. The upper one, called the standard, is large and showy; the two lateral to this, called wings, are smaller in size; and the two lower ones are more or less united into one unit, called the keel or carina. Within this keel are the ten **stamens,** which may be separate but in many genera are united in groups, the nine lower ones having their filaments more or less completely joined, while the tenth stamen remains free. The pistil has a somewhat flattened **ovary,** a long **style,** and a terminal **stigma.** The ovary contains several **ovules.** The mature fruit is called a pod or legume, which when mature often splits open with sufficient force to eject the seeds to considerable distances. The seeds in most cases have large food reserves stored in the thick cotyledons.

There are three subfamilies in the Leguminoseae. The Mimosoideae have regular flowers and valvate **corolla.** The Caesalpinioideae have irregular (zygomorphic) flowers. These two subfamilies are essentially tropical. The Papilionoideae have irregular (papilionaceous) flowers, and include most of the important cultivated forms.

Many members of this family supply man with important foodstuffs, such as **beans,** peas, and **peanuts,** while others are important forage crops for domestic animals. The high **protein** content of the plant is the principal reason for its importance as a food source. Clovers and **alfalfa** are not only valuable as forage plants, but furnish an excellent hay. Legumes are also of immense value because of their association with nodule-forming **bacteria,** resulting in a considerable accumulation of nitrogenous substance, which is later liberated into the soil, greatly enriching it. Other members of the family yield valuable **dyes, gums and resins,** and **oils;** many are sources of timber.

The leaves of many genera of legumes are interesting because of their ability to move. In many of them the leaflets fold together at night, so that the blade of the leaflet is vertical. Of particular interest in this connection is the Sensitive plant, *Mimosa pudica,* the leaves of which respond very quickly to external stimuli. A light blow will cause the many leaflets to fold together, and the whole section of the compound leaf to bend down. A sudden breeze or change of temperature will produce the same result. Recovery from the shock is gradual. When stimulated by a series of successive shocks, the plant recovers more and more slowly each time. (R.M.W.)

PEA WEEVIL. Insecta, Coleoptera. A **beetle** which attacks growing peas in the pod. The most effective control measures are to avoid planting infested seed or to fumigate it with **carbon disulfide** before planting. (A.W.L.)

PEACH. **Rose Family.**

PEACH-TREE BORER. Insecta, Lepidoptera. *Synanthedon.* Any of three species of **moths** whose **larvae** burrow in the sapwood and inner bark of peach trees, sometimes killing younger trees. The moths belong to the family Aegeriidae, characterized by the long body and narrow wings, more or less free from scales. All three species attack other fruits as well as peaches.

The larvae of all species are destroyed by digging them out of their burrows and by burning badly infested boughs or entire trees. The common species is also treated by placing a ring of paradichlorobenzene (see **Chlorine**) on the surface of the ground about two inches from the trunk and covering it with earth. It should be left 4–6 weeks and should be applied on dates ranging from early September in New York to the middle of October in Georgia. The treatment is not recommended for trees younger than 3 years, and for those up to 6 years not more than ¾ of an ounce of the material should be used. (A.W.L.)

PEACH-TWIG BORER. Insecta, Lepidoptera. The **larva** of a small **moth,** *Anarsia lineatella,* which bores in the young twigs and fruit of peaches and other fruit trees. It is an important pest, chiefly in the western states, where various spraying programs have been found effective in controlling it. (A.W.L.)

PEAFOWL, PEACOCK. Aves, Galliformes. *Pavo.* Large birds (**Aves**) of the Oriental region, related to the pheasants and Guinea fowls. They are beautifully colored and the males have gorgeous tail feathers. They are kept to a limited extent as ornamental birds for the garden but are scarcely to be regarded as domesticated. Several species are known. (A.W.L.)

PEAK CURRENT. **Rectifier.**

PEAK VOLTAGE. **Rectifier.**

PEANUT. *Arachis hypogaea.* Leguminosae. A native legume of South America which is now widely cultivated in warm climates throughout the world. The plant is a bushy annual with pinnately compound leaves and rather showy yellow flowers. After fertilization, the flower stalk elongates greatly and bends downward so that the ovary is pushed into the ground. There it develops into the familiar peanut with its two or more seeds. The total peanut crop harvested in the United States in 1932 was over a billion lbs. Much of the crop is roasted in the shell and so marketed. Large quantities are ground for peanut butter, or crushed for peanut oil. (See **Esters.**) (R.M.W.)

PEAR. **Rose Family.**

PEARL. A gem formed by **bivalve mollusks,** particularly by several marine species known as pearl oysters. Pearls are formed as a protection against the irritation caused by foreign objects, either parasites or bits of gravel, which lodge inside the shell. A fold of soft

tissue envelops the foreign particle and deposits layer after layer of nacre on it, similar to the mother-of-pearl lining the shell.

Pearl oysters occur in all of the tropical seas, but the ancient center of pearl fishing is at Ceylon. Pearls of considerable value are also taken from the fresh-water **mussels** caught for the button industry in the Mississippi River system. A large majority of fresh-water pearls, however, are poorly shaped or of undesirable color, and many are too small to be of much value. (A.W.L.)

PEARLITE. Steel.

PEARSON SYSTEM OF PROBABILITY FUNCTIONS. Karl Pearson developed his system of probability and frequency functions from 1895 to 1916. We follow C. C. Craig's simplified exposition. The Pearson system is useful in fitting an actual **frequency distribution** by means of the **sample moments.** The sample moments in conjunction with the criterion, δ, tell which Pearson type will explain the sample results. This Pearson type is then considered as a hypothesis which is tested against the actual frequencies by the **chi-square test of goodness of fit.**

The second use of the system is to approximate a theoretical **probability function** by means of the first 4 moments of the theoretical probability function. This use is regarded as empirical and a convenience until more exact results are obtained.

In fitting an actual frequency distribution either the method of **moments** or the method of maximum **likelihood** is available. While the method of maximum likelihood is preferable on theoretical grounds, it is somewhat arduous in practice. We shall explain the method of moments.

The Pearson system is based on the differential equation,

$$\frac{dy}{ydt} = \frac{a - t}{b_0 + b_1 t + b_2 t^2},$$

where $t = \dfrac{x - \bar{X}}{\sigma_x}$, **standard units.**

This differential equation may be derived from the **hypergeometric probability function** and consequently the Pearson system may be considered as having a basis in **probability.** The system consists of *3* main types, *9* transitional types, and the **normal curve.** The types cover a very wide range of bell-shaped, J-shaped, and U-shaped functions. These will be briefly explained in terms of the criterion,

$$\delta = \frac{2\alpha_4 - 3\alpha_3^2 - 6}{\alpha_4 + 3}.$$

If δ is negative, we have main *Type I;* if δ is positive and the roots of $b_0 + b_1 t + b_2 t^2$ are complex, we have main *Type IV;* if δ is positive and the roots of $b_0 + b_1 t + b_2 t^2$ are real, we have main *Type VI.* The types occurring most frequently are *I, III, IV,* and *VII.* The values of a, b_0, b_1, and b_2 are

$$a = \frac{-\alpha_3}{2(1 + 2\delta)},$$

$$b_0 = \frac{2 + \delta}{2(1 + 2\delta)},$$

$$b_1 = \frac{\alpha_3}{2(1 + 2\delta)},$$

$$b_2 = \frac{\delta}{2(1 + 2\delta)}.$$

We assume hereafter that $\alpha_3 \geqq 0$. If $\alpha_3 < 0$, we can make it positive by changing the signs of all variates.

TYPE I, $\delta < 0,\ y = C(t - r_1)^{m_1}(r_2 - t)^{m_2},\ r_1 \le t \le r_2$

$$r_1 = \frac{-\alpha_3 + \sqrt{D}}{2\delta},\quad r_2 = \frac{-\alpha_3 - \sqrt{D}}{2\delta},$$

$$D = \alpha_3^2 - 4\delta(\delta + 2),\quad m_1 = \frac{1 + \delta}{\delta}\frac{\alpha_3}{\sqrt{D}} - \frac{1 + 2\delta}{\delta},$$

$$m_2 = -\frac{1 + \delta}{\delta}\frac{\alpha_3}{\sqrt{D}} - \frac{1 + 2\delta}{\delta},$$

$$C = \frac{\Gamma(m_1 + m_2 + 2)}{\Gamma(m_1 + 1)\Gamma(m_2 + 1)(r_2 - r_1)^{m_1 + m_2 + 1}}.$$

The *Type I* function may be J-shaped, U-shaped, or bell-shaped.

TYPE IV, $\alpha_3 \neq 0,\ \delta > 0,\ \alpha_3^2 < 4\delta(\delta + 2).$

$$y = Ce^{\frac{v\pi}{2}}[(t + r)^2 + s^2]^{-m}e^{-v\tan^{-1}\frac{t+r}{s}},$$

$$-\infty < t < \infty,\quad \frac{v}{2} = -\frac{1 + \delta}{\delta}\frac{\alpha_3}{\sqrt{-D}},\quad m = \frac{1 + 2\delta}{\delta},$$

$$r = \frac{\alpha_3}{2\delta},\quad s = \frac{\sqrt{-D}}{2\delta},\quad D = \alpha_3^2 - 4\delta(\delta + 2),$$

$$C = \frac{s^{2m-1}}{G(2m - 2, v)},$$

$$G(2m - 2, v) = \int_0^\pi \sin^{2m-2}\varphi e^{v\varphi}\,d\varphi.$$

The *Type IV* function is always bell-shaped.

TYPE VI, $\alpha_3 > 0,\ \delta > 0.$

$$y = Cz^{m_2}(z - \alpha)^{m_1},\quad \alpha \le z < \infty,\quad t - r_2 = z,$$

$$t - r_2 = z,\quad r_1 - r_2 = \alpha,\quad r_1 = \frac{-\alpha_3 + \sqrt{D}}{2\delta},$$

$$r_2 = \frac{-\alpha_3 - \sqrt{D}}{2\delta},\quad D = \alpha_3^2 - 4\delta(\delta + 2),$$

$$m_1 = \frac{1 + \delta}{\delta}\frac{\alpha_3}{\sqrt{D}} - \frac{1 + 2\delta}{\delta},$$

$$m_2 = -\frac{1 + \delta}{\delta}\frac{\alpha_3}{\sqrt{D}} - \frac{1 + 2\delta}{\delta},$$

$$C = \frac{\Gamma(-m_2)}{\alpha^{m_1 + m_2 + 1}\Gamma(m_1 + 1)\Gamma(-m_1 - m_2 - 1)}.$$

The *Type VI* function may be J-shaped or bell-shaped.

TYPE III, $y = Ce^{-\frac{2}{\alpha_3}t}\left(\frac{\alpha_3}{2}t + 1\right)^{\frac{4}{\alpha_3^2} - 1},$

$$-\frac{2}{\alpha_3} \le t < \infty,\quad C = \left(\frac{4}{\alpha_3^2}\right)^{\frac{4}{\alpha_3^2} - \frac{1}{2}} \cdot \frac{1}{\Gamma\left(\frac{4}{\alpha_3^2}\right)}.$$

The *Type III* function may be J-shaped or bell-shaped. It is an excellent approximation to the **Bernoulli probability function**

TYPE II, $\alpha_3 = 0,\ -1 < \delta < 0.$

$$y = C(S^2 - t^2)^M,\quad -S \le t \le S,\quad S = \sqrt{-(1 + 2/\delta)}$$

$$M = -\left(2 + \frac{1}{\delta}\right),\quad C = \frac{\Gamma(2M + 2)}{(2S)^{2M+1}[\Gamma(M + 1)]^2}.$$

Type II may be bell-shaped or U-shaped.

TYPE VII, $\alpha_3 = 0,\ \delta > 0.$

$$y = C(t^2 + s^2)^{-m},\quad -\infty > t > \infty,\quad s = \sqrt{1 + \frac{2}{\delta}},$$

$$m = 2 + \frac{1}{\delta},\quad C = \frac{s^{2m-1}\Gamma(m)}{\sqrt{\pi}\Gamma(m - \frac{1}{2})}.$$

Type VII is always bell-shaped.

TYPE V. $\alpha_3 \neq 0, \quad \delta > 0, \quad \alpha_3^2 = 4\delta(\delta + 2).$

$$y = C(t + r)^{-2m} e^{-\frac{2r(m-1)}{t+r}}, \quad -r \leq t < \infty,$$

$$m = 2 + \frac{1}{\delta}, \quad r = \frac{\alpha_3}{2\delta}, \quad C = \frac{[2r(m-1)]^{2m-1}}{\Gamma(2m-1)}.$$

Type V is always bell-shaped.

The remaining special types *VIII*, *IX*, *X*, *XI*, and *XII* occur infrequently. The normal curve is the special case $\alpha_3 = 0$, $\delta = 0$. (L.A.A.)

PEARSON'S TYPE III FUNCTION. **Pearson System of Probability Functions.**

PEAT. **Coal.**

PEAT MOSS. **Bryophytes; Lignite.**

PEBA. Mammalia, Edentata. The 9-banded **armadillo,** *Dasypus novemcinctus,* found from southern Texas and New Mexico to Argentina. (A.W.L.)

PECCARY. Mammalia, Artiodactyla. Animals of two species related to the Old World swine but differing in the 3-toed hind feet and in other anatomical features. The collared peccary or muskhog, *Dicotyles tajaca,* ranges from the southwestern United States to southern South America, and the white-lipped peccary, *D. labiatus,* is found only from British Honduras to Paraguay. The latter species is gregarious, living in bands of large size. Its vicious nature makes it dangerous to encounter, although a single animal is too small to trouble a human being. The collared peccary lives singly or in small groups and is inoffensive. (A.W.L.)

PECORA. An obsolete term for the group of hoofed animals known as **ruminants.** (A.W.L.)

PECTINE. A comb-like organ of a pair found on the under surface of the second abdominal segment of **scorpions.** They are supposed to be accessory organs of reproduction. (A.W.L.)

PEDIATRICS. That branch of medicine which is concerned with the prevention, diagnosis, and treatment of the diseases and disorders of children. (R.S.M.)

PEDICEL. **Flower.**

PEDICELLARIA. Minute pinchers on the surface of starfishes (**Asteroidea**). Pedicellariae are modified spines formed with two or more apposed jaws. They may be stalked or **sessile** and may have the jaws crossed like the blades of scissors or merely in contact. They vary greatly in form in different species. (A.W.L.)

PEDICULOSIS. **Louse** infestation. There are several varieties: *pediculosis capitis* refers to head lice, *pediculosis corporis,* to body lice, *pediculosis pubis* to pubic lice. Lice live on the skin and deposit their eggs on hair or, in the case of body lice, on the clothing. Their presence produces an itchy **dermatitis.** Treatment varies with the site of infestation, but the hair should be cut short or removed, and insecticides such as crude coal tar in olive oil, or thymol in olive oil applied. Infested clothing should be destroyed. DDT dusted in clothing when exposure is likely, as with soldiers in campaigns, is a highly effective preventive measure. (D.M.H.)

PEDIPALPI. The **whip scorpions,** an order of **Arachnida.** (A.W.L.)

PEDOLOGY. The study of the origin and classification of soils. The investigation of the **regolith** as a fundamental natural resource or the basis of terrestrial plant life. (R.M.F.)

PEDUNCLE. A stalk, either of an organ or of an entire animal. The stalks by which **brachiopods, crinoids,** and similar **sessile** animals are attached to the supporting surface are peduncles. For the use of this term in botany, see **Flower.** (A.W.L.)

PEEWIT. Aves, Charadriiformes. 1. The black-headed **gull,** *Larus ridibundus.* 2. The common European **lapwing,** *Vanellus vanellus,* a bird related to the plovers. (A.W.L.)

PEGMATITE. The term pegmatite, derived from the Greek word meaning joined together, was first applied by Haüy in 1822 to a peculiar interpenetrating growth of **quartz** and **feldspar** sometimes called graphic granite from its resemblance to written characters, particularly those of the Hebrew language. Pegmatite is also used to designate those coarse-grained dikes and sheets, chiefly of **granite** or syenite, that are apophyses of **stocks or batholiths,** or of the residual magma, during their congelation. The individual minerals may often reach great size. Granite pegmatites are chiefly composed of alkali **feldspar** and quartz with some **muscovite** or **biotite,** but may carry such minerals as **tourmaline, topaz, beryl, fluorite, apatite, garnet, lepidolite,** etc.

The general characters of pegmatite **dikes** suggest that they are the solidified products of the residue of the **magma** which is rich in volatile matter and water vapor, and because of the abundance of **mineralizers,** remain liquid at relatively low temperatures. These physical-chemical conditions permit the maximum opportunity for the growth of large crystals. (R.M.F.)

PEKAN. **Marten.**

PEKING MAN. **Paleontology of Man.**

PELAGIC. Living in the water independent of the bottom and shores. The word applies to both the **plankton** and the **nekton.** It is usually applied only to marine animals but is used to some extent for fresh-water forms. (A.W.L.)

PELECANIFORMES. The **pelicans, cormorants, gannets,** and related birds. An order made up of swimming and wading species, many with long necks and legs. (A.W.L.)

PELECYPODA. **Lamellibranchiata.** The name Pelecypoda for the bivalve mollusks is now widely used but according to the rules of nomenclature the older name, Lamellibranchiata, should be retained. (A.W.L.)

PELE'S HAIR. A fibrous, basic, natural glass (**tachyllite**). The congealed liquid lava blown out of volcanoes. Type locality, the Hawaiian Islands. (R.M.F.)

PELICAN. Aves, Pelecaniformes. Widely distributed birds (**Aves**) of few species. They are large with long

Pelican. *(E. R. Sanborn and N. Y. Zoological Society.)*

necks, short legs, and webbed toes. The beak is very long and the lower mandible bears a flexible pouch which can be distended to accommodate a large amount of food. They live principally on fish but also eat other aquatic animals.

The common pelican of North America, *Pelecanus erythrorhynchos,* is chiefly white with orange beak and feet during the breeding season. It frequents inland waters. (A.W.L.)

PELITE. The general term proposed by Naumann for **argillaceous** sediments containing minute fragments of quartz. Principally used as a textural term, especially when applied to fine-grained volcanic ashes, or **tuff.** Compare and contrast with **bentonite.** (R.M.F.)

PELLAGRA. A deficiency disease resulting from lack of **vitamin** B_2 or G. This disease was first described by Gaspar Casal in 1735. It is a common disease in Europe, Egypt, and in Central America, and in the southern portion of the United States. The largest outbreak in this country was between 1907–1915 and resulted in a high mortality. The disease occurs mostly among the poorer classes whose diet is inadequate.

Pellagra is due to a restricted diet and lack of vitamin B_2 (G), which is not a single substance, but is made up of a number of active principles, including nicotinic acid, riboflavin, and pyridoxine. Those afflicted are accustomed to a diet low in **protein** and made up largely of **carbohydrates.** Predisposing causes are food idiosyncrasies, chronic alcoholism, and diseases which interfere with the assimilation of a proper diet.

The symptoms of the disease appear gradually and affect primarily three of the bodily systems, the skin, digestive tract, and nervous system.

The exposed skin on the neck, hands, and feet becomes dark, raw and scaly, and eventually becomes red with a lifeless scarred appearance. The mouth is sore and ulcerated and the tongue is sensitive, red, and smooth. Diarrhea, severe and persistent, is prominent in acute cases. **Hydrochloric acid** is frequently absent from the stomach.

The symptoms referable to the nervous system are tremor, muscular cramps, and, in marked cases, weakness and paralysis. Mental symptoms are common in the severe form of the disease, and consist of confusion, hallucinations, delusions, and even dementia.

The treatment of pellagra is diet and supplementary vitamins, either as brewer's yeast, or nicotinic acid and riboflavin. In acute cases, supportive treatment with fluids and very large doses of vitamin B_2 are necessary. Liver extract intramuscularly is beneficial. (R.S.M., D.M.H.)

PELORUS. The pelorus, or "dumb compass," is an instrument used on board ship for taking **bearings** of external objects. It consists fundamentally of a circular plate, heavily ballasted and mounted in gymbals. This plate has two pairs of indicators, one pair parallel to the keel of the ship and the other perpendicular to the keel. Concentric with the circular plate, and capable of being rotated independently of each other about a vertical axis, are a graduated dial plate and an alidade or arm for reading angles. The dial plate is graduated in a manner similar to the **compass card** and may be clamped to the circular plate in any desired position. The alidade carries sighting vanes and the line through these vanes passes through the axis of rotation of the instrument carrying indicators at each end which may be read on the dial plate.

The instrument may be used to eliminate **compass errors** from bearings by setting the dial circle relative to the keel indicators on the circular plate so that they give the **true heading.** The external object is then lined up through the sighting vanes on the alidade and the indicator on the alidade will give the true bearing as read on the dial plate. (W.K.G.)

PELUDO. Mammalia, Edentata. The hairy armadillo of Argentina, *Tatu pilosa.* (A.W.L.)

PELVIS. Literally, a basin. Commonly applied to the bony pelvis of man, which is a compact pelvic girdle comparable to that of vertebrates generally (**skeletal system**). The human pelvis is properly the basin-like abdominal cavity containing the **viscera,** supported by the bony pelvis, which is composed of the hip bones on either side, and in front, and the **sacrum and coccyx.** The pelvis rests upon the lower extremities, and supports the spinal column. Within the pelvis are found the rectum, bladder, and generative organs. There are certain sexual differences in the pelvis. The female pelvis is lighter, more slender, with a cavity that is larger, less funnel-shaped, and shorter. When the female pelvis resembles the male type or is deformed by bony disease such as rickets, childbirth is interfered with and either made difficult or impossible by the vaginal route.

The pelvis of the **kidney** is the principal cavity, which receives the urine from all subordinate divisions and discharges it to the **ureter.** (A.W.L., R.S.M.)

PEN. An internal horny plate found in the **squids.** It is a vestige of a portion of the shell, which was well developed in related **cephalopod** mollusks that are now extinct. (A.W.L.)

PENCIL STONE. Pyrophyllite.

PENDULUMS. We shall here consider only gravity pendulums, leaving **torsion pendulums** and **magnetic pendulums** to be discussed separately. Let a rigid body of mass M swing on an axis which is located at distance r above its center of mass, and with respect to which axis the **moment of inertia** of the body is I. This motion is mathematically not simple, but if the amplitude of swing is small, certain terms in the differential equation of motion may be disregarded and the remaining equation readily solved. The solution gives as the period of the complete oscillation

$$T = 2\pi\sqrt{\frac{I}{Mgr}},$$

in which g is the acceleration of a freely falling body. Huygens found experimentally, what may be proved theoretically, that for any given period of oscillation greater than a certain minimum there are two different distances r for which I/r, and hence T, has the same value. If these two distances are laid off on opposite sides of the center of mass, the two points resulting are "conjugate points" (center of suspension and center of oscillation). Denoting the whole distance between these points by l, the period of swing when the pendulum is suspended at either of them is

$$T = 2\pi\sqrt{\frac{l}{g}}.$$

This is the same as the period for an "ideal simple pendulum," i.e., a single particle of mass m suspended by a weightless thread of length l, for which $r = l$, and $I = ml^2$. Kater utilized this principle in his well-known reversible pendulum (see **Kater's Pendulum**). It was Huygens who first adapted the pendulum to regulate a mechanism for keeping time and thereby gave us the common clock. (L.D.W.)

PENEPLAIN. Meaning nearly a plain. A physiographic term implying a broad flat erosional surface which has been finally developed regardless of the structure, relative hardness, and solubility of the rocks of

the region. In the case of widespread **unconformities** the plain of **erosion** which truncates the subjacent de-

Block diagram showing a peneplain surmounted by a monadnock of more resistant rock. (*After W. M. Davis.*)

formed rocks and underlies the superjacent formations is an ancient peneplain. Local topographic features which rise above the peneplain are called monadnocks, after the type, Mt. Monadnock, in New England. (R.M.F.)

PENGUIN. Aves, Sphenisciformes. Flightless marine birds (**Aves**) of the south temperate zone and the Antarctic. They have short legs, webbed toes, and paddle-

Galapagos penguin. (*N. Y. Zool. Soc.*)

like wings which are used in swimming. The beak is strong. On land the penguins walk in an erect position with a curiously human air. They swim and dive with exceptional skill and eat fish almost exclusively. The King Penguin is *Aptenodytes longirostris.* (A.W.L.)

PENICILLIN. (Pronounced pĕn-ĭ-sĭl'ĭn.) An antibacterial substance produced by micro-organisms of the *penicillium chrysogenum* group, principally *penicillium notatum NRRL 832* for deep or submerged fermentation and *NRRL 1249.B21* for surface culture. Penicillin is antibacterial towards a large number of gram-positive and some gram-negative bacteria, and is used in the treatment of a variety of infections. (See below.)

Penicillin was discovered by Alexander Fleming, professor of bacteriology, St. Mary's Hospital, London, in 1929, when he observed that the mold colony—later identified as *penicillium notatum*—inhibited the growth of the pathogenic organism *staphylococcus aureus.* The development of penicillin dates from 1939 when Professor H. W. Florey and associates, working at Oxford University, prepared sufficient material to make chemical tests. In 1941, the Rockefeller Foundation invited Florey and Heatley to visit the United States, with the result that the U. S. Northern Regional Research Laboratory, Peoria, Illinois, undertook the problem of producing sufficient penicillin for clinical testing. A. J. Moyer, microbiologist in the Fermentation Division of the laboratory, found that the addition of corn steeping liquor to the medium on which the mold grows increased the yield of penicillin ten times. This was later improved so that instead of the original 2 Oxford units per milligram a commercial yield of 80 to 100 was obtainable in 4 to 5 days.

The "Oxford unit" is that amount of penicillin which, when dissolved in 50 milliliters of meat-extract broth, just completely inhibits the growth of the test strain of *staphylococcus aureus.* Penicillin is recovered as a mixture of the sodium or calcium salt of most of the organic acids in the original broth, in the form of a pale yellow to dark brown powder, stable at temperatures below 10° C., and generally containing 100 to 500 Oxford units per milligram (8 to 30% sodium penicillin). The finished material is scrupulously tested for potency, sterility, toxicity (by injecting into the tail of white mice, four of five mice must survive), and pyrogens (by injecting into the ear of a white rabbit, less than 1° C. rise in temperature must ensue) according to the requirements of the U. S. Food and Drug Administration.

The production of penicillin presents many difficulties which are both new and baffling. How these have been overcome can be comprehended by examining in outline the process of manufacture. During the fermentation there must be complete sterility, a continuous supply of air, controlled agitation, and the maintenance of a temperature of 24° C. The fermentation broth is filtered, and then the liquid is treated with activated carbon to adsorb the active principle, following which the material is again filtered. This time the solid moist residue is recovered and extracted by a solvent, such as acetone 80%, water 20%, and again filtered with the recovery of the liquid. Repeated alternate treatments with activated carbon and solvent may be required to obtain the penicillin in sufficiently concentrated form. In an acid medium the destruction of penicillin is rapid, and it is in an acid medium that the solvent extraction functions best, so the materials must be handled rapidly. This is immediately followed by extraction with an alkaline (sodium bicarbonate) water treatment whereupon the penicillin forms the sodium penicillin salt in water solution. This is the form in which the remaining process of concentrating is performed. The concentration is conducted in an air-conditioned (10% relative humidity), sterile (using ultra-violet lamps) atmosphere by operators wearing surgical caps, gowns, gloves, masks, and foot coverings, all frequently changed. Sterile bottles are charged with say 100,000 units of sodium penicillum solution, and immediately frozen. The final drying is conducted in a high vacuum (pressure of the order of 200 microns of mercury) at a low temperature (−70° C. on the condenser) to obtain sublimation of water below the freezing point of the solution. The final moisture content is less than 1%. The manufacturing process is concluded by stoppering, capping, and labeling the bottles, all in a sterile atmosphere.

The mode of action of penicillin is not completely understood. Apparently it is both bactericidal and bacteriostatic—i.e., it acts by killing organisms and by inhibiting their growth. The bacteriocidal effect does not occur on organisms in the resting phase, but only on those undergoing active multiplication and growth. It is thought that the drug interferes with bacterial metabolism in the early stages of growth.

Penicillin's toxicity is remarkably low even when enormous doses are given. In this respect it has a great advantage over the sulfonamides. The toxic reactions reported have been rare and of mild nature. They include fever, allergic reactions such as urticaria (hives), **dermatitis,** and **conjunctivitis** when the drug is used locally on the eye.

The purified drug is administered in a variety of ways. Since it is excreted very rapidly by the kidneys, it is necessary to give repeated doses every few hours in order to maintain an effective blood level. For severe infections the drug is given intravenously or intramuscularly. Oral administration requires 5 times the dosage necessary parenterally and is therefore used only in treating infections with organisms highly susceptible to penicillin action, or where the treatment need not be prolonged. Inhalation therapy with penicillin aerosol is of benefit in certain types of upper respiratory and lung infections, although it is often necessary to combine such

treatment with intramuscular injection of the drug. In superficial acute infections penicillin is given locally, sometimes in ointment or powder form, for infections of the skin; it is also used locally for infection of the eye (**conjunctivitis**). In suppurative conditions, such as **empyema** and infected joint cavities, it is introduced directly into the affected area.

Not all organisms are susceptible to the action of penicillin. The more common ones against which the drug is effective are staphylococci, streptococci, pneumococci, gonococci, meningococci, Cl. tetani and the other gas-forming bacilli, and the spirochete of syphilis. The penicillin resistant organisms include B. coli, B. typhosus, the dysentery bacilli, Mycobacterium tuberculosis, viruses, yeasts, molds, and the organisms causing undulant fever, plague, cholera, tularemia, and malaria. The degree of susceptibility of each organism is different, and some strains of the same organism are more resistant than others. Occasionally susceptible strains become resistant during therapy, but this has not been common.

The diseases in which penicillin has been used successfully are numerous. The principal ones are severe staphylococcal and streptococcal infections, especially those with **septicemia; osteomyelitis, puerperal sepsis, scarlet fever, pneumonia, gonorrhea, syphilis,** pneumococcal **meningitis.** and **Vincent's angina** (Trench mouth). One of the outstanding successes has been with subacute bacterial **endocarditis**, which until the advent of penicillin was almost uniformly fatal. Penicillin has also been used extensively in the treatment of war wounds, infected compound fractures, and gas bacillus infections. In many instances penicillin is preferable to the sulfonamides, although in meningococcus meningitis sulfadiazine is still the drug of choice. In some severe infections both sulfonamides and penicillin are used. (R.K.S., D.M.H.)

PENICILLIUM. **Ascomycetes.**

PENIS. A projecting, protrusible, or erectile organ of the male animal, used in the act of **copulation** to introduce the seminal fluid into the genital passages of the female.

In the insects the organ is a fleshy duct enclosed in a chitinous sheath called the aedeagus. In the vertebrates it develops as a fold in the wall of the cloaca and may be no more than a grooved protuberance of this simple origin. The penis of mammals, however, is a complex organ formed by the union of two external folds of tissue. The space between is enclosed as a continuation of the **urethra** and serves as a common duct for the **excretory** and **reproductive systems.** The organ is composed of soft tissue, including some erectile tissue, in three cylindrical bodies. This tissue becomes engorged with blood under certain stimuli and makes the entire organ rigid. When relaxed the terminal portion of the penis is retracted into an enveloping fold of skin called the prepuce, or foreskin.

Special intromittent organs of all animals are known by this name but they are not at all uniform in origin in the different phyla. (A.W.L.)

PENNSYLVANIAN PERIOD. A **period** of the **Paleozoic** era. A systemic term first proposed by H. S. Williams in 1891. Type locality, Pennsylvania. The period began about 250,000,000 years ago. The term Pennsylvanian is roughly equivalent to the more general term Upper **Carboniferous.** In Britain this system is referred to as the Coal Measures. During this period there were many oscillations of sea level with relatively rapid alternations of marine and terrestrial sediments and fresh-water swamp deposits in which were formed important **coal** beds. The principal occurrence of the formations of this system are in the Allegheny Plateau region of the eastern United States, westward to the Ohio River. There is an abundance of plant fossils, including the non-flowering plants *Calamites, Equisetum* ("horse tails"), and the progenitors of the modern **ferns.** These earliest known "forests" harbored the earliest known **insects** and **spiders.** The oldest known **amphibians** inhabited the swamps and lowlands. Among the marine life, the highest order appears to be the ancestors of the modern **sharks.** As in the case of the **Mississippian** formations, the essentially terrestrial, **clastic** sediments of eastern North America grade westward into marine **limestone** deposits, which in turn grade upward into sediments of **Permian** Age. The principal marine invertebrate fossils are **brachiopods** (especially the genus *Productus*), **pelecypods,** and **cephalopods** (including **nautiloids, goniatites, ceratites,** and **ammonites**). **Foraminifera,** especially the genus *Fusilina*, were also common. Mountain building began in Europe in early Pennsylvanian time, accompanied with great volcanic activity. In eastern North America these deformative movements culminated, in the late Pennsylvanian and early Permian time, in the folding and uplift of the Paleozoic formations of the **Appalachian Geosyncline.** (R.M.F.)

PENNYROYAL. **Mint Family.**

PENSTOCK. Some considerable surface distance usually separates the intake works and turbines in a medium- or high-head hydroelectric project. Even where an open **canal** is employed to carry the water from the forebay of a diversion **dam** to intake works located near the plant, there is still a considerable span to be bridged by a closed water conduit of the pressure type. This water conduit is called the penstock, and is always circular in form because that shape is best adapted to withstand internal pressure. There are many engineering problems, both hydraulic and mechanical, to be met and solved in connection with these penstocks. The hydraulic problems of water hammer and surging are chiefly the result of the inherent momentum of large, rapidly moving masses of water; the mechanical problems are the result of large sizes and weights of pipes used for penstocks, the rugged profiles over which they are laid, and the necessity of making many joints which will be water-tight under high pressure. Penstocks are constructed from wood stave pipe, reinforced concrete, welded and riveted steel pipe, and banded steel pipe, the latter used only for the lower sections of very high-head developments. The penstock may be either buried, partially exposed, or completely exposed. If completely exposed, it rests on concrete or timber saddles. The trend of present practice is toward the use of exposed penstocks because of their greater accessibility and longer life. Exposed pipe is more liable to have ice form in it in the winter, and it also is subjected to larger temperature variation, making it absolutely necessary to provide expansion joints.

It is common practice in this country to proportion the penstock so that the sum of the value of energy lost annually in penstock friction and the annual fixed and operating costs of the pipe line is a minimum. When all the required data are obtainable this does not prove to be a difficult problem.

Penstocks are commonly designed to meet the stress put upon them by designing for the static head, allowing for dynamic conditions by using a factor of safety of two on the elastic limit of the steel used. In other cases it has been the static head plus water hammer introduced by rapid closing of the turbine gates.

Valves to stop the flow of water are always installed in a penstock at its upper end. High-head plants have a valve at the lower end also so that water can be shut off from the turbine in less time than it would take to close the upper valve and drain the penstock. Vacuum relief valves must be provided to avoid subjecting the penstock to full vacuum inside, full air pressure outside, and hence possibility of collapse. The penstock valve will stop the flow of water if a failure is expe-

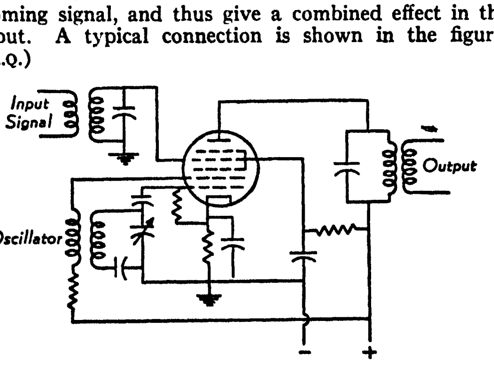
rienced by either the penstock or the turbine, and it also serves to unwater the turbine for inspection and repair. (F.T.M.)

PENTADACTYL APPENDAGE. The form of **vertebrate** appendage which is regarded as the fundamental terrestrial limb from which all of the specialized appendages of animals above the fishes have been derived.

The two pairs of vertebrate limbs, pectoral and pelvic, are similar in structure and both are attached to the girdles of corresponding name (**Skeletal System**). Each girdle consists, in the primitive state, of three pairs of bones meeting at the articulation of the limbs. On each side of the body one bone extends toward the back and two toward the middle of the body below. The skeletal structure of the limbs includes a single bone in the segment next to the body, followed by two bones. Then follows a group of small bones, and last five divergent series of moderately long bones which extend into the digits. Of the more constant bones in the pectoral girdle of vertebrates with limbs, the dorsal bone is the scapula and the two ventral are an anterior clavicle (of dermal origin) and a posterior coracoid. This girdle may contain a procoracoid between the last two bones. The bones of the pectoral appendage are, in the order described above, the humerus, the ulna and radius, the carpals, the five metacarpals of the hand and the five series of phalanges in the digits. In the pelvic girdle of vertebrates with limbs, the dorsal bone is the ilium and the two ventral are an anterior pubis and a posterior ischium. The bones of the appendage are the femur, the tibia and fibula, the tarsals, the metatarsals and the phalanges.

Specialized appendages such as the wings of birds, flippers of marine mammals, and the legs of the hoofed species, show either a simplification or a slight increase in complexity of the skeletal system and in some cases a consolidation by webbing of the digits or a still more compact fleshy union between them. In all of these cases, however, the basic pentadactyl structure is still present. (A.W.L.)

PENTAGRID CONVERTER. This is a **vacuum tube** containing 5 **grids** in addition to the usual **anode** and **cathode** and is used primarily as a combined **oscillator** and mixer or first **detector** in a superheterodyne **receiver.** In operation the cathode and the first two grids form the cathode, grid and anode of a conventional oscillator circuit. The electrons which would all contribute to the plate current of a conventional oscillator tube largely pass through the openings in the gridlike anode and are then acted upon by the incoming signal which is applied to one of the other grids. Upon finally reaching the real anode of the tube the electrons have both the effect of the oscillator and the incoming signal, and thus give a combined effect in the output. A typical connection is shown in the figure. (L.R.Q.)



PENTASTOMIDA. Worm-like **arthropods** of a few parasitic species, sometimes regarded as an order of the class **Arachnida** but more often as a distinct class. The known species live in the **respiratory system** or body cavity of reptiles and mammals. Also called Linguatulida.

The adult has an unsegmented anterior region bearing two pairs of claws and a segmented body whose subdivisions are not metameric. The **larvae** resemble certain **mites.** They are shorter than the adults and their claws are borne at the ends of leglike prominences. (A.W.L.)

PENTLANDITE. The mineral **sulfide** of **iron** and **nickel** corresponding to the formula (Fe,Ni)S. It is **isometric,** appears in granular masses; hardness, 3.5–4; specific gravity, 5.0; color, bronze-yellow; opaque. Occurs with **pyrrhotite, millerite, niccolite,** etc. The best known deposit of **pentlandite** is at Sudbury, Ontario, Canada, where it is associated with a nickel-bearing **pyrrhotite.** (E.S.C.S.)

PENTODE. Tube, Electronic.

PENTOSANS. Carbohydrates.

PENTOSES. Carbohydrates.

PENTRAMITES. Invertebrate Paleontology.

PEONY. Buttercup Family.

PEPO. Fruit.

PEPPER. *Piper nigrum.* Piperaceae. The pepper plant, *Piper nigrum,* is a woody climbing shrub, which is indigenous in India. It is aided in climbing by the **adventitious roots** which are formed at the nodes. The ovate leaves are evergreen. The flowers are minute, without petals, and borne in slender **spikes.** The **fruit** is a bright red berry less than ¼″ in diameter. Each berry contains a single seed. On drying the **pericarp** becomes black and wrinkled.

The berries are gathered before they are ripe and dried, usually by the sun. The dried berries are separated from the stem and ground, producing black pepper. If the pericarp is removed from the berry, leaving the seed and **endocarp,** the ground product is known as white pepper. The pericarp may be removed by using mature berries and soaking them to soften the pericarp. Or machines may rub off the dried pericarp, a method used in western countries. Pepper is one of the most extensively used of all spices. White pepper is less pungent than black, and hence not so conspicuous when used in cooking. Pepper is grown mostly in British India and in the Malaysian regions. Propagation is usually by cuttings, which begin to fruit within four or five years, after which they bear continuously but somewhat irregularly for many years.

Related to *Piper nigrum* is *Piper Betle,* a perennial creeping vine native to Java, but widely grown in tropical Asia. From its leaves is prepared a chew with the nut of the **Areca** palm. *Piper Cubeba* is another species, also native of Java and the Molucca Islands, which yields a volatile oil which is used medicinally.

See also Capsicum in the **Potato Family.** (R.M.W.)

PEPPERMINT, OIL OF. Volatile Oils.

PEPSIN. Enzymes.

PEPTIC ULCER. A common chronic disease of the gastro-intestinal tract characterized by recurrent abdominal pain and indigestion. The symptoms are due to the presence of an **ulcer,** either in the wall of the **stomach,** or in the wall of the **duodenum** just beyond the stomach. Peptic ulcer occurs in all races, in all countries, and at all ages. It is far more common in men than in women, and the peak incidence is between 30 and 50 years. Although it occurs in all constitutional

types, it is seen most often in people of asthenic body build—tall, lean, "nervous," hard-driving individuals. It is estimated that 10% of the population suffer from the disease at some time.

The cause of peptic ulcer is unknown, although many predisposing factors are recognized. Among these are constitutional elements and an inherent failure of the cells of the mucosa to resist acid digestion by the gastric secretions. Neurogenic and psychogenic factors play a large role; it is well known that emotional tensions precipitate and accentuate the disease.

The pain of peptic ulcer is characteristic. It is a gnawing discomfort, felt high in the mid **abdomen**, in the epigastrium. It is associated with hypermotility and a high content of hydrochloric acid in the stomach, and therefore comes on when the stomach is empty, i.e., just before meals. Food dilutes and neutralizes the hydrochloric acid and relieves the pain. Sodium bicarbonate neutralizes the acid and similarly relieves the pain. Other symptoms such as nausea, vomiting, weight loss are not common in uncomplicated ulcer. The outstanding feature, pain, is chronic, but is also periodic. It tends to disappear after a few months, only to reappear again in months or years.

The treatment of simple peptic ulcer consists of rest, diet, and drugs. The latter are used to neutralize the excessive amounts of hydrochloric acid and to reduce the hypermotility of the gastro-intestinal tract. Psychotherapy, especially in individuals suffering from definite psychoneurotic disturbances, is an important phase of treatment (see **psychoneurosis**).

Complications of serious nature are not uncommon. These include perforation of the ulcer into the abdominal cavity with the development of **peritonitis**; **hematemesis** due to massive **hemorrhage** from eroded vessels in the ulcer bed; and chronic obstruction resulting from fibrosis and scarring. Perforation is a surgical emergency which requires prompt treatment. Hemorrhage is treated medically with **transfusions** and iron therapy. Chronic obstruction requires surgical measures usually. (D.M.H.)

PEPTIDES. **Aldehydes, Ketones, and Related Compounds.**

PEPTONES. **Aminoacids, Polypeptides, and Proteins.**

PERCENTILE. The percentiles P_1, P_2, $\cdots$ P_{99} are the 99 points dividing a distribution into 100 equal parts. They are determined by this definition in the case of a **serial distribution** and by interpolation in the **cumulative frequency distribution** if a **frequency distribution** has been formed. Sometimes the term first percentile refers to all variates below P_1. (L.A.A.)

PERCH. Pisces, Teleostei. 1. The yellow perch, ringed perch, or common perch, *Perca flavescens*, a fresh-water food fish (**Pisces**) which lives in lakes and streams from Iowa to South Carolina and northward into Canada. Introduced on the Pacific Coast. 2. The pike-perch, *Stizostedion vitreum*, a related species also known as the wall-eye, glass-eye, wall-eyed pike, and jack salmon. It is a valuable food fish of the Great Lakes basin, the Mississippi valley, and the northeastern states to Virginia. 3. Several marine fishes, some of large size, found in the seas of the Oriental and Australian regions and the Mediterranean. Some ascend rivers. They are related to the sea basses. (A.W.L.)

PERCHED. Used by hydrologists to describe the **ground water** table when it is separated from an underlying layer of ground water by an unsaturated layer of rock. Used by **glaciologists** to describe a glacial boulder, **erratic**, resting on a prominent topographic position. Used by **physiographers** and **hydrologists** to describe a stream whose bed is separated from the top of the ground water table by a dry, unsaturated zone. (R.M.F.)

PERCHLORIC ACID AND PERCHLORATES. Perchloric acid ($HClO_4$) is a colorless, fuming, oily liquid, miscible with water, volatile under diminished pressure with safety (at 18 mm., volatilization temperature 16° C.) or by distillation of the dilute solution (70% $HClO_4$ or less) at atmospheric pressure. There is a maximum constant boiling point 203° C. (760 mm.) at 73% $HClO_4$ (distillate) for mixtures of perchloric acid and water. Cold dilute perchloric acid reacts with such metals as **zinc** and **iron**, yielding **hydrogen** gas and the corresponding perchlorate in solution; is stable from the point of view of oxidation and reduction (except that **iodine** is oxidized to **periodic acid**, with liberation of **chlorine**, **ferrous** salt solutions to **ferric**, **titanous** salt solutions to **titanic**). Concentrated hot perchloric acid, on the other hand, is a powerful oxidizing agent, exploding violently in contact with charcoal, paper, alcohol; causes serious wounds in contact with the skin.

Prepared by distilling **ammonium** perchlorate with **nitric** and **hydrochloric** acids.

Metallic perchlorates are soluble in water, except that **potassium** perchlorate is slightly soluble. Potassium perchlorate is, however, insoluble in alcohol containing perchloric acid, a property made use of in the qualitative recognition and quantitative estimation of potassium in salt solutions. Perchlorates, when heated, evolve oxygen and leave the chloride as a residue—potassium perchlorate decomposes at 400° C. (R.K.S.)

PERCUSSION. **Kinetics.**

PERENNIAL. As distinguished from **annuals** and **biennials**, perennials are plants in which at least a part of the vegetative body remains alive for a number of years. Perennial herbs are usually perennial only by underground organs such as roots or rhizomes, the aerial parts dying at the end of each growing season. Some of the species falling in this category have "winter rosettes" of leaves which survive above the ground through the winter months. Examples of such species are the evening primrose and some kinds of asters. Woody perennials include all species of trees and shrubs. In deciduous trees and shrubs the stems are the only aerial parts to remain alive from year to year. In many kinds of evergreen woody plants the leaves are also perennial in the sense that a given crop of leaves may remain on the plant continuously for several years before abscising. (B.S.M.)

PERFORMANCE PARAMETERS, AIRPLANE. The classic method of determining various items of airplane performance from horsepower vs. speed curves at various altitudes is paralleled by short-cut methods based upon special parameters which have been found to be the main influence in various phases of performance such as rate of climb, ceiling, maximum level speed, etc. The more common of these parameters are:

Wing loading, $s = W/S$

Power loading, $p = W/P$

Parasite loading, $l_p = W/f$

Span loading, $l_s = W/b_e^2$

Thrust loading, $l_t = W/\eta P$

Ceiling parameter, $\Lambda = l_s l_t^{4/3}/l_p^{1/3}$.

In the above, W = total weight of airplane and contents, P = rated horsepower, η = propeller efficiency, f = **equivalent parasite area**, b_e = effective monoplane span. (F.T.M.)

PERFUMES. Odorous constituents of plants usually occur as an essential or volatile oil, which upon separation is a highly aromatic liquid, and almost always a very complex mixture of substances. Some of these substances are easily destroyed by heating. **Alcohols and phenols, aldehyde and ketones, phenolethers and esters**—especially esters—are represented among the known constituents. Information of scientific character in the field of odorous chemicals seems to be more specific than general. Very slight differences in constitution often change notably the odorous character of substances, e.g., the contrasting odors of acetic and butyric acids (CH_3COOH, C_3H_7COOH, respectively), and of acetaldehyde and propionaldehyde ($CH_3 \cdot CHO$, $C_2H_5 \cdot CHO$, respectively). Whereas the odors of the paraffin aldehydes from C_3 to C_6 are disagreeable, the paraffin aldehydes from C_7 to C_{14}, inclusive, and the corresponding alcohols are used in traces as desirable odorous additions to a number of perfumes.

The naturally occurring odorous constituents are found distributed in various parts of various plants, as illustrated below:

Part of the Plant	Plant Supplying Odorous Material
Flowers	Cassia, carnation, clove, hawthorn, hyacinth, heliotrope, jasmin, jonquil, lilac, orange, rose
Flowers and leaves	Lavender, rosemary, violet
Leaves	Bay, cinnamon, eucalyptus, geranium, peppermint, wintergreen
Barks	Cassia, cinnamon
Woods	Camphor, cedar, sandalwood, pine
Roots	Angelica, sassafras
Rhizomes	Ginger, orris, citronella, lemongrass
Fruits	Bergamot, grapefruit, lemon, lime, orange
Seeds	Almond, anise, clove, juniper, nutmeg
Gums, oleoresins	Myrrh, Peru balsam, storax, tolu.

Musk is obtained from the dried secretion of the preputial follicles of the male musk deer, now found only at high elevations in the Himalaya Mountains, and ambergris from the diseased intestines of the whale.

Since most of the odorous substances are volatile and easily vaporized at 100° C., the simplest procedure for their separation from the plant material is distillation with steam in cases where the odorous material is not thereby injuriously affected. Rose, orange blossom, lavender, peppermint and other odorous principles are obtained in this way—but not those of the citrus fruits.

The citrus oils are obtained by expression or squeezing the rinds, thus rupturing the oil cells of the fruits, and collecting the oil. These oils are spoiled by heating.

To obtain the odorous substances of roses and many other flowers, there is a method of absorption by beef and pork fats, called enfleurage when conducted with thin layers of fat at ordinary temperatures, and maceration when fat is melted at about 65° C. The product, called pomade, is treated with alcohol to extract the odoriferous material.

Finally, extraction by the use of a volatile solvent, especially for flowers and leaves, is practiced. After evaporation of the solvent, the residue is known as a concrete. When this concrete is further treated with alcohol, in which solvent the odorless and colored materials are insoluble, and the resulting solution separated from the solvent alcohol, the residue is known as an absolute.

Various substances are used as fixatives, which have little or no odor value themselves, but serve to make odors with which they are mixed less volatile, accordingly available over a longer period of time, and in some cases sweeten the odor.

Some of the individual odorous chemicals that have been identified, and material in which each is contained are as follows:

Odorous Chemical	Material in Which Contained
Benzaldehyde	Bitter almond
Phenylethyl alcohol	Rose
Vanillin	Vanilla
Eugenol	Clove
Citral (geraniol aldehyde)	70% in lemongrass oil 8% in lemon oil
Methyl salicylate	Wintegreen
Ethyl salicylate	Wintergreen, superior
Amyl salicylate	Clover blossom
Benzyl alcohol, formate, propionate	Synthesized
Benzyl acetate	Jasmin
Geraniol esters	Rose
Citronellol esters	Rose
Methylphenyl acetate	Gardenia
Ethyl-, amyl-, benzylphenyl acetates	Synthesized
Linalyl alcohol	Lavender
Linalyl acetate	Bergamot
Phenylacetic aldehyde	Hyacinth
Terpineol	Lilac
Methyl anthranilate	Grapes
Isobutyl-, isoamylsalicylate	Synthesized
Cinnamic aldehyde	Synthesized
Cinnamic alcohol	Storax
Methyl, ethyl, amyl, cinnamyl cinnamate	Synthesized
Anisic aldehyde	Mayblossom
Ionone	Violet
Phenol-, diphenyl oxide	Geranium
Beta-naphthol ethyl ether	Orange blossom
Acetophenone	Synthesized
Para-methylacetophenone	Synthesized
Benzylideneacetone	Sweet pea
Coumarin	Tonka, new mown hay
Isoeugenol	Carnation
Heliotropin	Heliotrope
Hydroxycitronellal	Lily, lilac
Ethyl protocatechnic aldehyde	Vanilla
Gamma-undecalactone	Peach
Methyl, ethyl, isobutyl, amyl benzoates	Synthesized

Odorous materials are widely utilized in perfumes and cosmetics, in flavoring extracts and essences, and in soaps. The blending of natural and artificial odorous substances to produce high grade perfumes is an art. The introduction of traces of a given substance often causes desirable or undesirable results out of all proportion to the amount of material added, and requires for success one who is expert in the art. (See **Volatile Oils.**) (R.K.S.)

PERIANTH Flower.

PERICARDIAL CAVITY. A portion of the body cavity (coelom) containing the heart. In the fishes it is the entire thoracic part of the cavity but in air-breathing vertebrates the thoracic region also contains the lungs. The cavity surrounding the heart of insects is called the pericardium. It is a division of the **haemocoele.** (A.W.L.)

PERICARDIAL SINUS. The pericardial cavity or pericardium of invertebrates. (A.W.L.)

PERICARDITIS. Inflammation or infection of the **pericardium** which occurs as the result of bacterial spread through the blood stream, by direct extension from neighboring organs, the lungs and pleura, or as the result of injury such as a stab wound. It occurs most frequently as part of rheumatic fever, as extension from

pneumonia, or as tuberculous infection spreading from the lungs. When infection is present the membranous walls of the pericardium become roughened and inflamed and the amount of fluid in the sac is greatly increased. In time the collection of fluid may be so great that it interferes with the function of the heart and results in cardiac tamponade. Excessive fluid may be withdrawn through a needle inserted in the pericardial cavity. If the fluid becomes purulent surgical drainage must be instituted.

Pericarditis without infection occurs as a complication of **coronary occlusion** and infarction of the heart muscle. The muscle which is deprived of its blood supply undergoes **necrosis** and inflammatory changes. The latter frequently involve the adjacent pericardium. On listening over the heart with a stethescope a characteristic rough sound is heard—a "pericardial rub" which represents the movement of the thickened inflamed pericardial sac over the heart with each heart beat.

The symptoms of pericarditis often may be masked by the disease to which it is secondary. Fever, pain in the chest, rapid feeble pulse, and shortness of breath are usually present. X-ray of the chest reveals a characteristic type of enlargement of the heart shadow if fluid is present. (D.M.H.)

PERICARDIUM. 1. The cavity surrounding the **heart** of **insects** and other invertebrates, also called the pericardial sinus. 2. The cellular lining of the **pericardial cavity** in vertebrates and other animals, in which this cavity is a part of the **coelom.** The human pericardium is composed of two layers. The inner layer is adherent to the heart. Between the layers there is about ½ ounce of a thin liquid, the pericardial fluid, which serves as a cushion and prevents friction of the beating heart. (A.W.L., R.S.M.)

PERICARP. Fruit.

PERICLASE. A mineral oxide of magnesium, MgO. Crystallizes in the isometric system. Hardness, 5.5; specific gravity, 3.56±; color, variable with tones of gray, yellow, brown, green and black; transparent. From the Greek, meaning to break around, in reference to the cleavage. (R.M.F.)

PERICYCLE. A layer or cylinder of thin-walled **parenchyma** cells which occurs external to the **xylem** and **phloem.** It is bounded externally by the cells of the cortex, or by the endodermis. In stems it often contains fibers, called pericycle fibers. In roots it gives rise to the meristems which produce lateral roots, and cork cambium which produces the cork and secondary cortex of root bark in most trees. (R.M.W., B.S.M.)

PERIDERM. Lenticels.

PERIDOTITE. The term peridotite is derived from Peridot, the French word for **olivine.**

It is a coarse-grained igneous rock related to *gabbro,* which consists of **olivine** and **proxene** in varying proportions. Certain peridotites contain **spinel, chromite,** or **mica** as accessories. A variety of peridotite made up of **hornblende** and olivine is called cortlandtite because originally described from the township of Cortlandt (not Cortland), N. Y., on the Hudson River south of Peekskill. This rock was formerly called Hudsonite but abandoned as the term hudsonite had been previously applied to a variety of the mineral **pyroxene** found in St. Lawrence County, N. Y.

Rocks consisting essentially of olivine alone are known as dunites, the name coming from the occurrence of this rock in the Dun mountains of New Zealand. In the United States it is found in North Carolina, South Carolina, and Georgia, where corundum is associated with the dunite in commercial quantities. The olivine of peridotites alters readily to the mineral **serpentine,** often to such an extent that the rock itself is called a serpentine. As mentioned above the peridotites may contain **chromite** or other valuable minerals, often to such an extent that they may be commercially exploited, for nickel, platinum, and precious garnet.

Kimberlite from which diamonds are secured is commonly called a mica peridotite, but is more closely related to the **lamprophyres.** (E.S.C.S.)

PERIGYNY. Fruit.

PERIHELION. Perihelion is the point in the **orbit** of any member of the **solar system** when the object is closest to the sun. Since the orbits are all **conic sections** with the sun at one focus, perihelion must lie on the **line of apsides** of the conic.

In orbits of **satellites** and other objects which are referred to primaries other than the sun, terms similar to perihelion are used to indicate points in the orbit closest to the primary. For example, the point in the **moon's** orbit closest to the earth is known as perigee, the corresponding point in an orbit of a satellite of **Jupiter** is known as perijove, etc. (W.K.G.)

PERILLA OIL. Esters.

PERIMORPH. One species of mineral inclosed in another. (R.M.F.)

PERINEUM. The diamond-shaped space at the base of the torso, between the **coccyx** behind and the arch of the pubic bones in front. It is bounded by the thighs on each side. This area comprises the floor of the pelvic cavity. It contains many important muscles which are pierced by the **rectum, urethra** and in the female by the **vagina.** (R.S.M.)

PERIOD. In geology, a major sub-division of an **Era.** The formations which belong in any one period are spoken of as a **System.** (R.M.F.)

PERIOD LUMINOSITY CURVE. Cepheid.

PERIOD LUMINOSITY LAW. Cepheids.

PERIODIC ACID AND PERIODATES. Periodic acid (H_5IO_6) has been isolated as a colorless solid, melting point about 130° C., and at 138° C. begins to decompose, metaperiodic acid (HIO_4) being formed and at higher temperatures iodine pentoxide plus oxygen plus water. $H_4I_2O_9$ and H_3IO_5 have been reported as fairly well established in identity; in solution the evidence points to the presence of HIO_4.

Prepared by reaction of **iodine** and **perchloric acid.**

Sodium periodate ($Na_2H_3IO_6$) is formed by reaction of **sodium** iodate plus sodium hydroxide plus **chlorine** (sodium chloride also formed), and the periodate separates as crystals from the medium. In solution, it is stated, periodate gradually forms ozone (see **Oxygen**) and iodate at the ordinary temperatures.

Metallic periodates are solids, slightly soluble in water. Periodates, when heated, evolve oxygen with simultaneous formation of iodate, which is decomposed at higher temperatures. Periodate in acid solution oxidizes **hydrosulfuric acid** or **sulfurous acid** to **sulfuric acid, oxalic acid** to **carbon dioxide, manganous** to manganate, and with **hydrogen peroxide** yields oxygen and iodate. (R.K.S.)

PERIODIC FUNCTIONS. If $f(x+p) \equiv f(x)$ for every value of x, where p is a constant, then $f(x)$ is said to be periodic, with period p.

The **trigonometric functions** are periodic functions; the sine and cosine have a least period of 2π, and the tangent and cotangent have a least period of π.

The **exponential function** has a pure imaginary period $2\pi i$.

The **elliptic functions** are doubly periodic functions. (L.L.S.)

PERIODIC LAW. This "law" states that the chemical and physical properties of elements are a periodic function of the **atomic number** of the elements. (See **Chemical Composition.**) (R.K.S.)

PERIODOGRAM ANALYSIS. Periodogram analysis consists of a statistical technique used to find the periods in time series in which it is assumed that the values of the function repeat themselves after a certain specified time called the period. Naturally such an analysis is needed in the study of wave motion of any kind or of business cycles.

First the trend must be removed in the data. The trend consists of a general movement either upward or downward or a combination of the two on which the periodic movement is superimposed. The removal of trend is accomplished either by use of a polynomial of high degree or by some method of smoothing. After the trend is removed, the search for cycles of various periods is begun. This is done either by **serial correlation,** the curvilinear coefficient of correlation, or by use of simple sums.

Assume $N = jp$ **variates,** N fixed but p and j varying, $y_{11}, y_{12}, \cdots y_{1j}, y_{21}, y_{22}, \cdots y_{2j}, y_{31}, y_{32}, \cdots y_{3j}, y_{p1}, y_{p2}, \cdots y_{pj}$, in that order. Assume a period p, and calculate the j values $M_{j,p} = \sum_{j=1}^{p} y_{pj}$. From these j values for an assumed p calculate $R_p = |$greatest value of $M_{j,p}$ — least value $M_{j,p}|$, the **absolute value** of the **range** R_p. The values of R_p are plotted against p. Naturally p assumes every value from 1 to N. This forms the periodogram. Wherever the values of R_p are very high comparatively, it is assumed a period of length p has been found. Tests of significance may be applied to R_p under the assumption that the y's are independent. Unfortunately successive y's are generally strongly dependent. Sometimes the technique indicates periods which do not actually occur in the data. Hence care should always be taken in the interpretation of the results of periodogram analysis. In place of R_p we may compute

$$\sigma^2_{M_{j,p}} = \frac{\Sigma(M_{j,p} - \overline{M}_{j,p})^2}{j}, \quad \overline{M}_{j,p} = \frac{\Sigma M_{j,p}}{j}$$

and construct the periodogram of $\sigma^2_{M_{j,p}}$ against p. (See **Serial Correlation.**) (L.A.A.)

PERIOPOD. The thoracic appendages of **crustaceans,** behind those which are associated with the mouth. (A.W.L.)

PERIOSTEUM. The tough fibrous membrane which covers the surface of the **bones** of the body except on their joint surfaces. It is tightly adherent to the bone surface and it is from this membrane that new bone regenerates. (R.S.M.)

PERIOSTITIS. Inflammation, acute or chronic, of the **periosteum.** It may occur following injury to the bone or it may be a complication of infection with **septicemia, typhoid fever,** or **syphilis.** In the acute form, abscesses may develop. (R.S.M.)

PERIOSTRACUM. The outer layer of the shell of **brachiopods** and **mollusks.** In the molluscan shell it is formed of a horny organic material called conchiolin, associated with the prismatic middle layer of the shell. It is also organic material in the brachiopods but here it is separated from the prismatic layer of the shell by a thin layer of **calcium** carbonate. (A.W.L.)

PERIPATUS. Onychophora.

PERIPROCT. The surface of the body immediately surrounding the **anus.** It is applied especially to the sea urchins (**Echinoidea**) which have two leathery areas in the otherwise rigid body wall, one the peristome surrounding the mouth and the other the periproct on the upper surface. (A.W.L.)

PERISARC. A chitinous (**chitin**) sheath surrounding the stalks and branches of the colony in the **hydrozoan coelenterates** and in some cases forming cupped expansions around the **polyps.** (A.W.L.)

PERISSODACTYLA. The odd-toed **ungulates,** an order of hoofed **mammals** in which the axis of the foot passes through the middle digit. This digit is larger than the others and is symmetrical. The order contains the **horses** and related species, the **rhinoceroses,** and the **tapirs.** (A.W.L.)

PERISTALSIS. A wave-like series of muscular contractions progressing along the walls of the gastro-intestinal tract, which serve to propel the contents along from the esophagus to the rectum. (R.S.M.)

PERISTOME. The region surrounding the mouth. The term is used chiefly of the ciliated (**cilia**) zone surrounding the mouth in some of the 1-celled animals and the leathery portion of the body wall of sea urchins (**Echinoidea**) in which the mouth opens. (A.W.L.)

PERISTOMIUM. A modified segment or segments behind the mouth in some of the segmented worms (**Polychaeta**). It bears tentacles and other sensory organs and in some forms is modified as a collar. In the species which live in tubes this collar may form a funnel leading to the mouth or a fold which secretes additions to the tube. (A.W.L.)

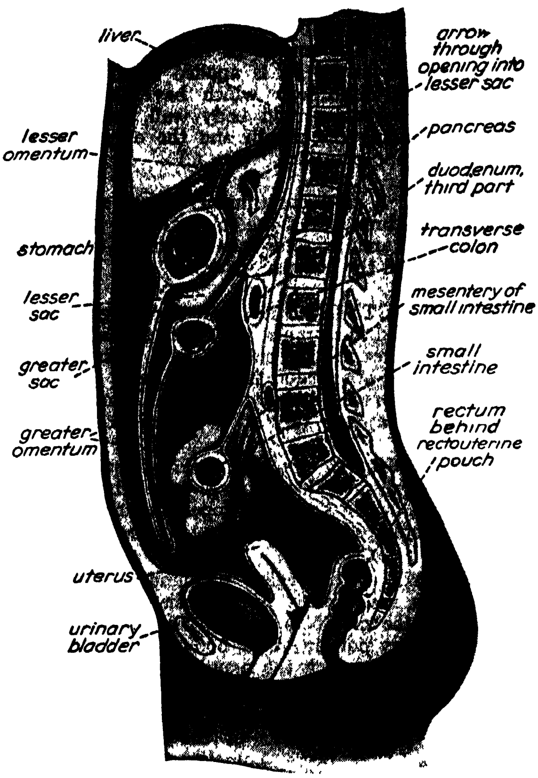
PERITONEUM. The epithelial lining of the body cavity (**coelom**). In the higher vertebrates the lining of the abdominal cavity in particular. The corresponding tissue in the pleural and pericardial cavities of the thorax is called the pleura and the pericardium, respectively. The peritoneum is a thin layer of tissue made up of flat cells. (See figure at top of page 1062.) (A.W.L.)

PERITONITIS. Inflammation or infection of the **peritoneum.** This is a serious complication of many pelvic and abdominal diseases and is an ever present hazard in abdominal surgery. One of the commonest causes of peritonitis is perforation of some part of the gastro-intestinal tract, such as occurs with a gastric or duodenal ulcer which may break through, or rupture of an inflamed and distended appendix. When this happens, contaminated material gets free in the peritoneal cavity, and severe infection may result. The colon bacillus is frequently the causative agent.

Pelvic peritonitis results from infection of the Fallopian tubes, most often with the gonococcus. Tuberculous peritonitis occurs in the course of tuberculous infection of the bowel or the genito-urinary tract. Pneumococcus peritonitis is seen as a complication of nephrosis (see **nephritis**) in children.

The patient with peritonitis is acutely ill, with fever, rapid pulse and respirations and a distended, tender, rigid abdomen. Treatment depends on the cause. Surgery may be indicated, and **sulfonamides** or **penicillin** are useful if the bacterial agent is sensitive to either of these drugs. (D.M.H.)

PERITREME. A plate surrounding the external opening (**spiracle,** stigma) of an air tube (**trachea**)



Diagrammatic median section of female body to show the abdominal cavity and the peritoneum on vertical tracing. (*Cunningham, Textbook of Anatomy, Oxford Press.*)

in some of the **arthropods**. The term is applied to certain mites and insects. (A.W.L.)

PERITRICHIDA. Ciliophora.

PERIWINKLE. Mollusca, Gasteropoda. Marine **snails** with a thick conical spiral shell. They live in shallow water, in the tidal zone, and along the shore. Some of the many species are very widely distributed and the genus *Littorina* is represented in all parts of the world. An edible species has been introduced into the United States and is now common on the Atlantic coast north of Delaware Bay. (A.W.L.)

PERKIN MEDAL AWARDS. History and Evolution of Chemistry.

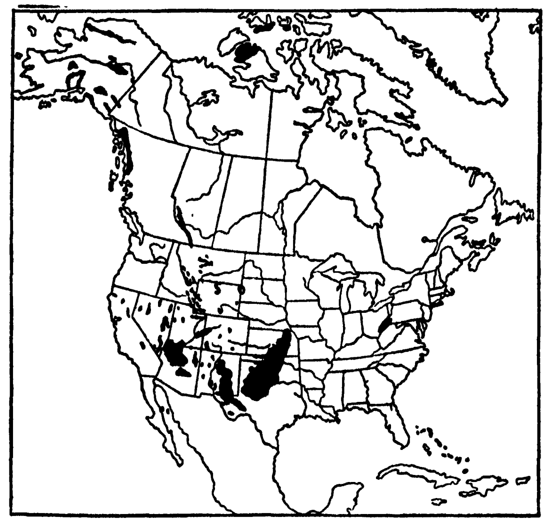
PERLITE. Pearlstone. An unusual form of **siliceous** lava composed of small spherules of about the size of bird shot or peas. It is grayish in color with a soft pearly luster. The spherules often show a concentric structure and are believed to be formed as a result of a peculiar spherical cracking developed while cooling. They may be confused with **oölites** which are classified as concretions. (E.S.C.S.)

PERMALLOY. Nickel Alloys; Magnetic Materials.

PERMANENT MOLDS. Casting.

PERMEABILITY. Magnetism.

PERMIAN PERIOD. The name of a geologic period. Type locality, Province of Perm, Russia. The formations of this system were first studied and described by R. I. Murchison, in 1841. The Permian period began about 230 million years ago, and lasted for about 30 million years. Only the upper Permian appears to be



Map showing known areas of outcrops (surface distribution of Permian strata in North America).

represented in North America. Eastern North America was undergoing uplift and erosion during this period, while the seas invaded the West from the Arctic and Gulf. Increasing uplift of the continents and mountain building culminated in the **Applachian Revolution** (U. S.) and the **Hercynian Revolution** (Europe). Increasing aridity and widespread equatorial continental glaciation are disclosed by **tillites** in Australia, Tasmania, New Zealand, India, South America, and Massachusetts. Some of the fossil animals and plants appear to be the progenitors of Mesozoic forms, but a number of marine invertebrates became extinct, including the **trilobites, eurypterids, primitive insects, goniatites,** etc. The fossil fishes are similar to those of the Pennsylvania. The **Amphibia (Stegocephalians)** are approaching extinction. The first fossil reptiles occur in the Permian, including such highly specialized forms as the **Cotylosaurs** (sail-backed lizards). Important **index fossils** are the fern-like genera, *Sphenopteris* and *Glossopteris*. The distinctly latitudinal distribution of animals and plants between Africa and South America has suggested that the North Atlantic was separated from the South Atlantic by a great east-west continent called **Gondwana Land.** Also during this period the Mediterranean was greatly expanded to the west with easterly and south-easterly outlets into the Pacific. (R.M.F.)

PERMINVAR. Nickel Alloys; Magnetic Materials.

PERMUTATIONS. If we have given a set of things, it is often important to know how many different groups or selections can be made by taking some or all of the things of the set, when we take account of the order of arrangement in each group, and when we do not consider the order of arrangement.

Each different arrangement in a definite order which can be made of all or part of a given set of elements is called a permutation.

We are generally concerned with the number of permutations of n things r at a time.

The number of permutations of n things taken r at a time is denoted by many different symbols by different writers; the most commonly used are ${}_nP_r$, $P_{n,r}$ and $P(n, r)$.

The number of permutations of n different elements taken r at a time is given by ${}_nP_r = n(n-1)(n-2) \cdots (n-r+1)$, ($r$ factors on the right).

The number of permutations of n different elements taken n at a time is

$$_nP_n = n(n-1)(n-2)\cdots 3\cdot 2\cdot 1 = n!$$

If, of n things, p are alike, of one kind, q of another kind, r of another, and so on, the number of permutations of these things taken all together is $\frac{n!}{p!q!r!}$. (L.L.S.)

PERNICIOUS ANEMIA. **Anemia.**

PERONIUM. An ectodermal thickening at the base of a tentacle in some of the jellyfishes. (**Scyphozoa**, order Narcomedusae.) (A.W.L.)

PEROVSKITE. The mineral perovskite is **calcium titanate** $CaTiO_3$, probably **isometric.** It has a cubic **cleavage**; is brittle; hardness, 5.5; specific gravity, 4; luster, adamantine; color, various shades of yellow to reddish-brown or nearly black; transparent to opaque. It is found associated with **chlorite** or **serpentine** rocks occurring in the Urals, Baden, Switzerland, Italy, etc. It was named for a certain Von Perovski. (E.S.C.S.)

PERPETUAL MOTION. The idea of a mechanism which, once started, would operate indefinitely is very old and has been the subject of much discussion and much ridicule. It has never been realized in human invention; yet its impossibility is practical rather than fundamental. It lies in our inability to free moving bodies completely from friction and hence from the dissipation of energy. If one could get away from or neutralize the earth's gravity and other fields of force, so that objects experimented with would not need material support, and if the air and other gases could be completely eliminated from the experimental enclosure, a sphere, for example, set spinning, would continue to spin. Nature approximates these conditions in such mechanisms as the solar system and the atom, but man has hitherto failed to duplicate her arrangements. The only other alternative is to discover an inexhaustible source of energy to supply the loss due to dissipation. The energy from radioactive materials has been used to operate a scientific toy called a "radium clock," but this supply falls off exponentially with time. Solar and cosmic radiation seem inexhaustible, but have not been directly utilized on a large scale. Meanwhile we continue to draw upon apparently limited stores of energy to carry on the activities of what, after all, promises to be only a temporary physical world. (L.D.W.)

PERSEIDS. The Perseids furnish the most reliable of all **meteor showers.** While the **Leonids** have provided some very brilliant displays in the past, about three times each century, their appearance in the intervening years is not at all striking. The Perseids make their appearance during August of each year. Because of the fact that the Perseid showers never are as striking as the Leonids, when at their maximum, we should not expect to find them referred to so frequently in the ancient writings. Extensive search has been made through the old records, however, and we find mention of the Perseids as far back as 830 A.D. The first determination of the **radiant point** in the **constellation** of **Perseus** was apparently made in 1834.

In appearance the members of the Perseid shower are as striking as those from any other radiant point. Coming as they do during the month of August, when the nights are warm, they are seen by large numbers of people who are always impressed by the relatively slow motion, distinctly reddish appearance, and trails, frequently of several seconds' duration, which characterize the members of this swarm. (W.K.G.)

PERSEUS. (Map, page 380.) This is a rich and brilliant **constellation** of the northern sky. Since it lies right in the milky way it presents many beautiful fields for the opera glass or the small telescope. This is particularly true of the bright star Alpha Persei, which lies in the midst of a very rich and beautiful field.

The star **Algol** (Beta Persei) is the famous **eclipsing variable** whose striking changes in light intensity caused the Arabs to name it the demon star.

In Perseus is to be found the famous double-star **cluster** which is one of the finest objects in the whole sky for an observer with a small telescope. On a clear moonless night, using a relatively low power on the instrument, any observer will be well repaid for his search for this wonderful object. (W.K.G.)

PERSIMMON. **Diospyros.** **Ebenaceae.**

PERSON PROCESS. The Person process is a method for controlling the tone separations during photographic printing by means of weak positive masks on film. The masks are made by exposing film under a negative for short intervals so only thin silver deposits or spots are obtained in areas corresponding to the shadow portions of the negative. Usually several masks are made, each differing from the other by a slight change in exposure.

Following exposure, the masks are processed in a manner similar to the negative. One or more of the dried masks are placed in register with the negative, and the edges or corners are fastened to each other with scotch or cellulose tape. Prints are made by exposing through both the negative and the mask, or masks, if more than one is used.

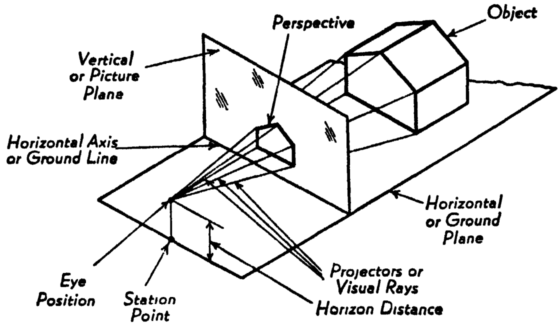
The purpose of the mask is to shade the thin portion of negative so the print will not become blocked, but retain the fine shadow detail of the negative. (S M T.)

PERSONAL EQUATION. In making measurements of any character every observer, no matter how skilled he may be, is bound to make certain errors. These errors are of two kinds: accidental errors which will be small in the case of a good observer and which will be distributed in accordance with the **laws of probability**; and systematic errors or errors which are always in the same direction and of approximately the same magnitude. As an example of systematic errors we may cite the case of the observation of the transit of a star across the **reticle** of a **meridian circle.** In this case a good observer will always press the **chronograph** key either slightly too early or slightly too late, depending upon the observer.

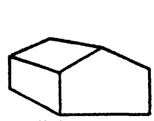
The value of the systematic error is known as the personal equation of the observer. Personal equation must be determined empirically for each observer under a variety of different observing conditions. For a good observer the personal equation remains remarkably constant over long periods of time and may be applied directly to any observation. (W.K.G.)

PERSPECTIVE. A method of representing solid objects on a plane surface, as they would appear to an observer's eye when viewed from a given point. The projectors or visual rays converge from the object to the eye, forming a cone or pyramid of rays. The intersection of these rays with the picture plane results in a perspective drawing. Two types of perspective representation are in common use—parallel and angular. In the former, all horizontal lines parallel to the picture plane, and all vertical lines, appear horizontal and vertical; all other parallel lines will intersect, if extended, at one or more common points, called vanishing points. In

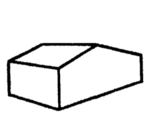
angular perspective, vertical lines appear vertical; all other parallel lines will intersect, if extended, at one or more vanishing points. (H.C.H.)



Conical Projection



Parallel Perspective



Angular Perspective

PERSPIRATION. Sweat. A secretion formed by the **sweat glands** of the skin of some of the mammals. It consists chiefly of water with small quantities of other materials in solution. The dissolved substances include fatty acids, **urea, sodium** and **potassium** chloride, phosphates, lactic acid, and cholesterin. By evaporation at the surface of the skin the sweat plays an important part in the regulation of body temperature when the surrounding air is too warm for adequate radiation. It is also important as an excretory medium. (A.W.L.)

PERSULFURIC ACID AND PERSULFATES. Per (mono) sulfuric acid, "Caro's acid" (H_2SO_5 or $HOO \cdot SO_2OH$) and perdisulfuric acid, "persulfuric acid" ($H_2S_2O_8$ or $HOSO_2O \cdot OSO_2OH$) are solids of melting points 45° C. and 65° C., respectively (the latter melting with decomposition). Both acids combine vigorously with a hissing sound with water, and they cause blackening of paper, sugar and paraffin by separation of carbon. Both acids are formed (1) by reaction of chlorosulfonic acid and water, depending upon the ratio, (2) by **electrolysis of sulfuric acid** under proper conditions. Better yields of persulfate as **ammonium** persulfate ($(NH_4)_2S_2O_8$) are obtained by electrolysis of ammonium sulfate under proper conditions. Permonosulfuric acid may also be made by reaction of **hydrogen peroxide** and **sulfur** trioxide or anhydrous sulfuric acid.

Permonosulfuric acid oxidizes (1) **hydriodic acid** instantly to **iodine,** (2) **hydrochloric acid** to **chlorine,** (3) **aniline** to nitrobenzene, (4) **ferrous** salt solution to **ferric,** (5) **sulfurous acid** to **sulfuric acid,** but (6) does not reduce **permanganate,** (7) does not give yellow coloration with **titanic** salt solutions, (8) does not give blue coloration with **dichromate** solutions of these reactions. Perdisulfuric acid shows only oxidation of ferrous salt solution to ferric.

Persulfates oxidize (1) potassium iodide slowly to iodine, (2) manganous salt solution to manganese dioxide, (3) manganous salt, in the presence of silver nitrate, to permanganate, but (4) do not give yellow coloration with titanic salt solution, (5) do not give blue coloration with dichromate solutions.

The following properties of persulfates aid in their identification: Persulfates decompose in water to form ozone, which liberates iodine from starch-iodide paper (thus persulfates differ from percarbonates and perborates). Persulfates do not react with permanganate or with chromic acid (thus they differ from peroxides). (R.K.S.)

PERTURBATIONS. If there were only two bodies in the universe and if each of these was a homogeneous sphere, the **orbit** of one relative to the other, or the orbits of both relative to the common center of gravity of the system, could be completely determined by the solution of the **two body problem.** In reality, however, there are many more than two bodies in the universe and few of them are homogeneous spheres, with the result that the determination of accurate orbits becomes a problem of tremendous complexity.

Within the **solar system** it fortunately happens that the attraction of one body is dominant, i.e., the attraction of the sun upon any object is far greater than the attractions of all of the other planets combined. In the cases of **satellites,** the attraction of the primary is preponderant. In such cases a close approximation to the true orbit may be obtained by neglecting the attractions of other objects and obtaining a preliminary orbit by the methods of solution of the two body problem.

Using the **Keplerian** ellipse thus obtained it is possible to find at any instant, to a high degree of approximation, the distance of the object from other members of the solar system and hence the attractions of these other objects. The effects of these attractions in changing the motion of the object under consideration may be computed, a second approximation to the true position may be obtained, and this used to obtain more accurate values to the attracting forces. Usually the second approximation is sufficiently accurate for all practical purposes.

The influences which the attractions of the other members of the solar system have on the motions of the object under consideration are known as perturbations. In the case of nearly circular orbits, as in the case of the motions of the planets about the sun, it is possible to obtain, in the form of infinite series, an analytic expression for the perturbations. Such a solution is known as general perturbations. If the orbit is highly eccentric, as in the case of many comet orbits, it is not possible to obtain any general analytic expression and the perturbations are known as special perturbations.

Due to perturbations the orbits of objects have both slow steady changes in the elements, known as secular perturbations, and also relatively short oscillations about an average value, which are known as periodic perturbations. In actual practice it is customary to list both the secular and periodic perturbations in tables from which the accurate position of the planet at any desired instant may be computed. In the case of the perturbations of the Moon, one of the most complicated of all perturbation problems, E. W. Brown's tables of the Moon fill three quarto volumes totalling more than 360 pages.

Perturbations have played an important part in astronomical discovery. After the planet **Uranus** had been discovered and accurately observed, the preliminary orbit, plus perturbations from all known objects, did not accurately represent the observed positions. These deviations could only be explained on the basis of another planet outside of the orbit of Uranus, accurate computations were made and the planet **Neptune** discovered. Deviations of observed positions of Neptune from those computed from the orbit stimulated the search which led to the discovery of the planet **Pluto.** In the case of the planet **Mercury** a perturbation in the longitude of perihelion in the orbit could not be explained on the basis of gravitational theory. This led to a fruitless search for a planet between Mercury and the sun. The perturbation was

later explained on the basis of the **theory of relativity** and was one of the early triumphs of this theory. (W.K.G.)

PERTUSSIS. Whooping Cough.

PESSARY. A device made of metal or rubber which is placed in the **vagina** to support the **uterus**, or to correct muscular relaxation or malposition of the uterus. (D.M.H.)

PESTS. Insect Pests.

PETALITE. The mineral petalite, **lithium aluminum silicate**, $LiAl(Si_2O_5)_2$ is **monoclinic**, although crystals are rare, this mineral usually occurring in cleavable, **foliated** masses, whence the name petalite from the Greek meaning a *leaf*. Its hardness is 6–6.5; specific gravity 2.39–2.46; luster, vitreous, colorless to white or gray but may be greenish or reddish; is transparent to translucent. Petalite has been found in Sweden, on the Island of Elba, and in the United States at Bolton, Massachusetts, and Peru, Maine. It is interesting to note that lithium was first discovered in this mineral. (E.S.C.S.)

PETALOID AREA. A flower-like arrangement of pores on the upper (aboral) surface of some of the sea urchins (**Echinoidae**). (A.W.L.)

PETALS. Flower.

PETIOLE. Leaf.

PETIT MAL. Epilepsy.

PETREL. Aves, Procellariiformes. Marine birds (**Aves**) related to the albatrosses. They are powerful fliers and have the feet webbed for swimming. The group includes the fulmars and shearwaters as well as several forms which bear the name petrel. There are many species and many of them bear one or more names in sailors' vernacular. The Cape pigeon, *Daption capensis*, is a well-known petrel of the Southern Hemisphere and the little stormy petrel of the North Atlantic, *Hydrobates pelagicus*, under the name Mother Carey's chicken is probably the most familiar of all to ocean travelers. (A.W.L.)

PETRIFACTIONS. Paleontology.

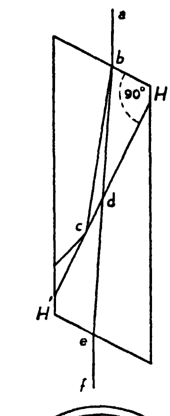
PETROGENESIS. That branch of **petrology** which deals with the origins of rocks. Practically a synonym for petrology unless, as is usually the practice, confined to the **igneous** (and possibly the **metamorphic**) **rocks**. (R.M.F.)

PETROGRAPHIC MICROSCOPE. A type of **microscope** especially adapted for use by the mineralogist and petrologist. As compared with the ordinary high-powered microscope, the petrographic microscope has the following additional apparatus:

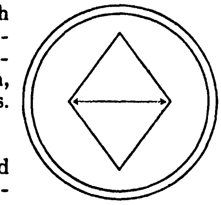
1. A polarizer, or apparatus for **polarizing** light.
2. An analyzer, or apparatus for analyzing the rays of light after they have passed through the polarizer, and the thin section of rock which is being examined.
3. A rotating stage, which rotates about an axis which is the line-of-sight of the microscope.

The polarizer, sometimes called the **Nicol prism**, is described as "a cleavage rhombohedron of **calcite** (variety, Iceland spar) having four large and two small rhombohedral faces opposite each other, which is modified in the following manner:

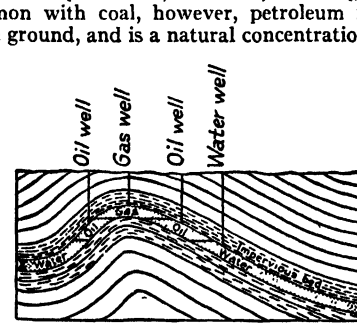
"In place of the latter planes, two new surfaces are cut, making angles of 68° (instead of 71°) with the obtuse vertical edges. These then form the terminal faces of the prism. In addition to this, the prism is cut through in the plane HH', the parts then polished and cemented together again with Canada balsam. A ray of light, $a\ b$, entering the prism, is divided into two rays polarized at right angles to each other. One of these, $b\ c$, on meeting the layer of balsam (whose refractive index is less than that of the ray $b\ c$) suffers total reflection, and is deflected against the blackened sides of the prism and extinguished. The other, $b\ d$, passes through and emerges at c, a completely polarized ray of light, that is, a ray with vibrations in one direction only, and that direction of the shorter diagonal prism." Dana. (R.M.F.)



PETROGRAPHY. The branch of **petrology** that has to do with the study and systematic description, both **macroscopic** and microscopic, of the mineral composition, texture and structure of rocks. (R.M.F.)



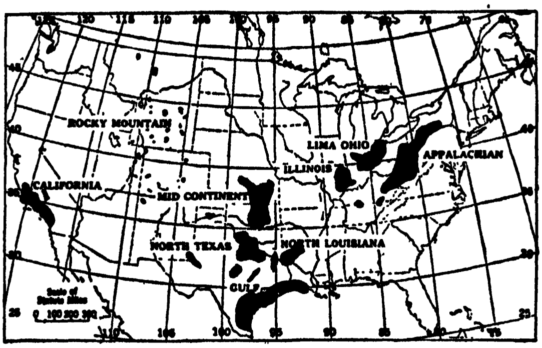
PETROLEUM. Petroleum and its associated natural gases are mixtures of **hydrocarbons**, or mixtures of many chemical compounds consisting chiefly of the elements, carbon and hydrogen, which have been derived from buried organic matter. The old term, **mineral oil**, used to distinguish this product from whale oil, is a misnomer because petroleum, like **coal**, is of organic origin. In common with coal, however, petroleum is procured from the ground, and is a natural concentration of energy



Structure section to show a typical occurrence of gas, oil, and water in an anticlinal structure. (*After U. S. Geological Survey.*)

easily expended but not reproducible except in terms of geologic time. Whatever may be the original sources of materials from which petroleum is formed, it is generally believed that petroleum in commercial amounts from wells, has migrated into the porous formations (**oil sands**) where it is obtained from oil pools in favorable underground structures. Like coal, the products of **oil wells** are extremely variable, there being no such thing as a common **crude**. The physical chemistry of petroleum is exceedingly complex and intimately connected with the technology of the **cracking**. Practically speaking, the product of oil wells may range all the way from **natural** gas, through natural **gasoline** and petroleum, to **asphalt** and **paraffin**. When an oil reservoir is tapped by means of a drilled well, the pressure is relieved and the gas comes out of solution, forcing the oil to the surface. The pressure and gas content are, therefore, exceedingly important in the production of petroleum, the deeper wells usually producing the largest and longest yields. The United States produces approximately ⅔ of the world production of crude petroleum. First-class powers which have no petroleum, or a great

deficiency thereof, within their sovereign territory are: Great Britain, Italy, Japan, France and Germany. (R.M.F.)



Map showing the principal oil fields of the United States. (*Modified after Geological Survey of Kansas.*)

PETROLEUM PRODUCTS. The use of petroleum products is well described by the American Petroleum Institute, in "Petroleum Facts and Figures," pp. 158–160 (1929), from which the following is quoted:

"Among these are fuel gas, which is utilized for burning under boilers in the refineries, and another derivative, gas black, which is used in the making of rubber tires, inks and paints. A series of **alcohols**, including isopropyl, secondary butyl, secondary amyl and secondary hexyl are also recovered from these gases, which are utilized as solvents for the making of **lacquers**, **soaps** and **essential oils.** Liquefied gases, also yielded from the hydrocarbon gases, are utilized in metal cutting and for illumination. Another product, petroleum ether, is used for priming motors and for laboratory work. Natural gasoline, also thus derived, yields light naphthas which, in turn, yield gas-machine gasoline; pentane, used for candle-power standardization; hexane, utilized in laboratories; and chemical solvents for drug extraction.

"So-called white distillates, next derived from the refining of crude petroleum, include the naphthas and kerosene. From the naphthas are derived aviation gasoline, motor gasoline, commercial solvents, blending naphtha, varnishmakers' and painters' naphtha and dyers' and cleaners' benzine. The refined oils, including kerosene, are used for illuminating oil, stove oil, tractor oil, signal oil by railroads and lighthouses, and mineral seal oil for coach and ship illumination and gas absorption.

"The next important product is furnace oil, used as a fuel in oil-burning furnaces in office buildings and homes.

"Intermediate distillates, next derived, yield gas oil and absorber oil. Gas oil is used by gas manufacturing plants in the carburetion of water gas; is an important metallurgical fuel; yields gasoline by the 'cracking' process and also Diesel fuel oil. Absorber oil enters into gasoline and benzol recovery.

"From the heavy distillates next derived come technical heavy oils, waxes and lubricating oil. Technical heavy oils, upon treating, are made into a variety of products. From one of these—white oils—is derived so-called technical oil, used for lubricating special machinery, such as bakers' and candymakers' machinery, and for packing fruit and eggs; also medicinal oil for internal and external use and for the manufacture of salves, creams and ointments. Ink oils are derived from technical heavy oil; also saturating oil, which enters into wool and twine manufacture; emulsifying oil; electrical oils, used for transformers and switches; and flotation oils, used in metal recovery processes.

"From heavy distillates are derived waxes which are used for making candles, chewing gum and candy. Wax also enters the laundry as a detergent and as an iron wax; has a wide use for sealing purposes, such as for the preserving of fruits and vegetables, and is used by etchers. Saturating wax is applied to cardboard, matches, and paper.

"Lubricating oils derived from petroleum are used wherever there is machinery, special oils or compounds being made for different types.

"From the residues of distillation are derived greases, such as gear grease, switch grease, and cup grease. By a refining process petrolatum is derived from greases. This enters the medicinal field, compounded with other products, in the form of salves, creams and ointments and as petroleum jelly. It is also used for metal coating and lubrication. Residual fuel oil is used for burning under boilers in industrial plants, on ships and in railroad locomotives. Fuel oil is also used for making gasoline by "cracking" processes. Road oil is a residual product of petroleum, as are asphalts and pitches used for roofing, paving, felt saturating, briquetting, rubber making and plastic composition. Another product is coke used for making carbon brushes, carbon electrodes, and also consumed as fuel.

"From refinery sludges are made acid coke used as a fuel; sulfonic acid, utilized as a saponification and de-emulsifying agent; oils and pitches; and **sulfuric acid**, used in fertilizer manufacture." (R.K.S.)

PETROLOGY. Petrology is that branch of geology which deals with the rocks forming the **lithosphere** or "crust" of the earth. The term is derived from the Greek, meaning rock and reason, hence a more comprehensive term than **petrography,** which deals only with systematic descriptions of rocks, including their mineral composition, texture, structure, and occurrence. Petrology includes petrography and also methods of classification as founded on systematic description and genetic theories, both experimental and theoretical. Important branches of petrology are **geochemistry** and **geophysics.** (R.M.F.)

PETROMYZONTIA. **Cyclostomata.**

PETROSILEX. A term frequently encountered in the older literature which refers to those very fine-grained crystalline aggregates which microscopic studies have revealed as devitrified glasses, and may in general be classified as **felsites.** (E.S.C.S.)

PETZITE. A mineral telluride of silver and gold, Ag_3AuTe_2. Crystallizes in the isometric system only at high temperatures. Hardness, 2.5–3; specific gravity, 8.7–9.02; color, gray to black with metallic luster; opaque. Named after W. Petz. (R.M.F.)

pH. **Reactions Involving Recombination of Ions.**

PHACOLITH. A lens-shaped mass of **igneous** rock found either in the trough or crest of a folded structure. It is believed that the shape and position of a phacolith is determined by the **orogenic** conditions, and that the folding is not a result of their intrusion. The term phacolith comes from the Greek words meaning lens and stone. (E.S.C.S.)

PHAGOCYTE. A cell of the multicellular animal's body which is capable of ingesting foreign particles. In the **sponges** and **coelenterates** and to a limited extent in other more complex animals digestion is carried on wholly or in part by this process. In many animals **bacteria** and particles of dead **tissues** or **cells** are engulfed by such cells. Phagocytes are amoeboid (**Pseudopodium**) in action and some of them move about in the tissue to which they belong by this means. Others are in fixed tissues, carrying on their amoeboid processes at the free end only. Phagocytes may be a part of the en-

dodermal lining of the enteric cavity or wandering cells derived from endoderm, or they may be mesodermal. In the connective tissues and blood mesodermal phagocytes occur, and in the lining of the circulatory system cells may act as phagocytes.

Large phagocytes are called macrophages, a term which includes wandering cells of the connective tissues. The opposite, microphage, is rarely met. In the blood of vertebrates all white cells (leukocytes) are phagocytic to some extent, the lymphocytes least of all. (A.W.L.)

PHAGOCYTOSIS. The ingestion of bacteria and other foreign particles by **phagocytes** in the bodies of complex animals. The process is an important part of the defense of animals against microorganisms which cause disease and is also a means of disposing of cells which have served their purpose, such as worn-out red blood corpuscles. (A.W.L.)

PHALANGER. Mammalia, Marsupialia. Pouched mammals of an extensive family found only in the Australian and Oriental regions. They are small or medium animals with thick woolly fur. Some resemble mice or squirrels superficially and all are arboreal. With the one exception of the koala they have prehensile tails.

In addition to the true phalangers the group includes the cuscuses, the flying phalangers, long-snouted phalangers, and several other forms. The **koala** is an aberrant species. (A.W.L.)

PHALANGIDA. The **harvestmen** or daddy longlegs, an order of **Arachnida.** (A.W.L.)

Phalangida.

PHALANX, PHALANGES. The small bones of the toes and fingers of **vertebrates.** (A.W.L.)

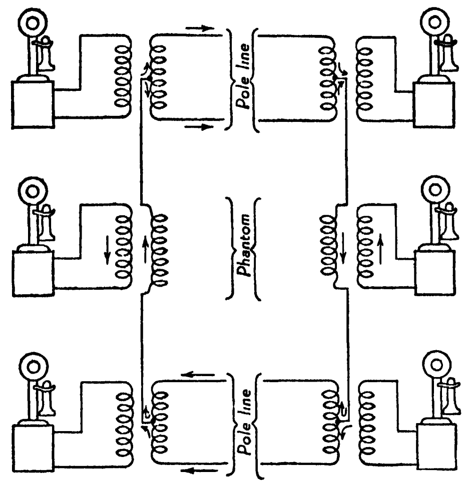
PHALAROPE. Aves, Charadriiformes. Wading birds (**Aves**) of several species, with long legs, lobed toes, and a moderately long beak. The red (*Phalaropus fulicaris*) and northern (*Lobipes lobatus*) phalaropes breed throughout the northern part of the northern hemisphere, and both the Old and New Worlds have their own species as well. Wilson's phalarope, *Steganopus tricolor*, of North America is one of our most beautiful waders. These birds are unusual in the reversal of ordinary sex behavior and appearance. Females are larger, more brightly colored, and take an aggressive part in courtship, while the males build the nests and incubate the eggs. Phalaropes migrate into the southern hemisphere in winter. (A.W.L.)

PHANATRON. This is a gas-filled hot-cathode type rectifier **tube.** (L.R.Q.)

PHANEROCRYSTALLINE. An adjective applied to an **igneous rock**, the essential constituents of which are distinguishable with the unaided eye. Compare with **macroscopic.** The term is derived from the Greek word meaning visible, plus crystalline. (R.M.F.)

PHANEROZONIA. Starfishes with one or two rows of large plates along the margins of the rays. An order of the class **Asteroidea.** (A.W.L.)

PHANTOM CIRCUIT. Two metallic communication circuits can be made to do the work of three by the addition of certain equipment. Since the third circuit has no wires definitely set aside to its use, it is called a phantom circuit. The phantom circuit may be obtained by using repeating or **impedance** coils. A setup of a phantom circuit sent over two side circuits by phantom repeating coils is shown in the accompanying figure. The instantaneous direction of current in the



Illustrating a circuit "Phantomed" on two standard circuits (arrows give current flow when phantom is in use.)

phantom circuit is shown by arrows. The repeating coils are **transformers** which are tapped at their electrical center, so that the current in the phantom circuit divides equally in those coils. If the current flow in the side lines (called physical circuits) is equal, and moving oppositely so far as the side line circuit is concerned, their voltages will neutralize, and no induced currents will be present in the side circuits. Thus the side circuit is not affected by the phantom. Good results depend on the use of side circuits which are identical electrically. (F.T.M.)

PHANTOM MEMBER. Graphical Statics.

PHARMACOPEIA. A book containing a list of the **drugs** used in medicine with their formulae, descriptions, chemical tests for identification, purity, and dosage. The United States Pharmacopeia is the standard which is revised and re-issued every 10 years under the supervision of a national committee. (R.S.M.)

PHARYNGEAL CLEFT. Gill Slit.

PHARYNGEAL POUCH. A lateral pouch of the vertebrate **pharynx** which joins a depression in the outer surface of the body wall to form a **gill slit** in all forms which have these openings. In mammals the pouches form in the embryo without breaking through to the exterior.

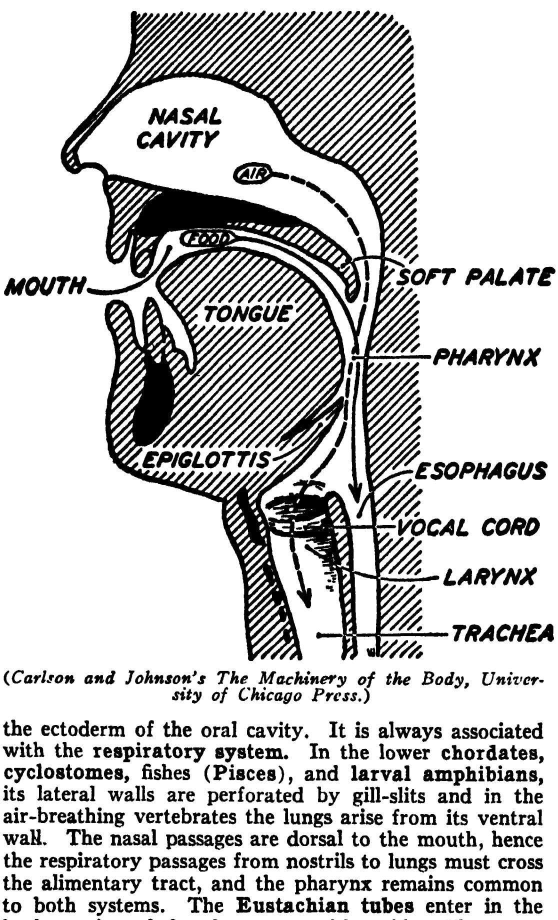
Pharyngeal pouches are also important as the source of adult anatomical structures. The first pair persist as the cavities of the middle ears and their connections with the pharynx become the **Eustachian tubes.** The palatine **tonsils** arise in the walls of the second pair. The third and fourth pairs give rise to dorsal and ventral outgrowths which become the **parathyroid** and **thymus** glands, respectively. A pair of small postbranchial bodies are interpreted by some anatomists as outgrowths of the fourth pouches and by some as the vestiges of a fifth pair of pouches. (A.W.L.)

PHARYNGITIS ("Sore Throat"). Infection or inflammation of the **pharynx.** Commonly it occurs as part of an upper respiratory infection, a "cold," **tonsillitis**, and hemolytic streptococcal infection.

The principal symptoms are tickling and irritation causing cough. Pain is present on swallowing. The

constitutional symptoms of pharyngitis are rarely severe; there is usually only slight fever and malaise. The treatment is similar to that of **coryza** and tonsillitis. Soothing gargles relieve the pain. Severe streptococcal sore throat occurs alone or with **scarlet fever**. It is accompanied by marked redness and swelling of the throat, high fever, and sometimes prostration. (D.M.H.)

PHARYNX. 1. A muscular portion of the alimentary tract (**digestive system**) of invertebrates of various **phyla**, between the mouth and the **oesophagus**. In some species it acts as a suctorial organ. The pharynx of flatworms is lined with ectoderm, as is the portion of the tubular tract of other invertebrates which receives this name. In some species the region can be everted through the mouth as a proboscis, and in some of the marine annelids (**Polychaeta**) its lining bears teeth which are brought into position to catch prey when it is everted. 2. The pharynx of **vertebrates** is a region of the endodermal part of the gut just behind its union with



(Carlson and Johnson's The Machinery of the Body, University of Chicago Press.)

the ectoderm of the oral cavity. It is always associated with the **respiratory system**. In the lower **chordates**, **cyclostomes**, fishes (**Pisces**), and **larval amphibians**, its lateral walls are perforated by gill-slits and in the air-breathing vertebrates the lungs arise from its ventral wall. The nasal passages are dorsal to the mouth, hence the respiratory passages from nostrils to lungs must cross the alimentary tract, and the pharynx remains common to both systems. The **Eustachian tubes** enter in the back portion of the pharynx on either side. The upper portion is called the nasopharynx and is located directly behind the nasal passages. The lower portion is divided into two parts, the oropharynx which is behind and continuous with the mouth, and the laryngo-pharynx which is continuous with the larynx and esophagus.

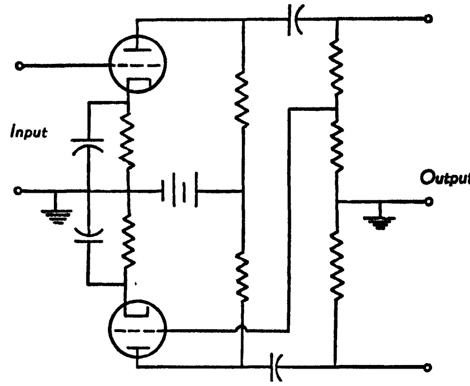
In man and other vertebrates, the pharynx is important as the source of ductless glands and other structures which arise from the pharyngeal pouches. (R.S.M., A.W.L.)

PHASCOLOGALE. Dasyure.

PHASE. Alternating-Current Circuits.

PHASE CONVERTER. If single-phase voltage is applied to one **phase** of a rotating three-phase **induction motor** it will be found that approximately balanced three-phase voltages may be obtained from the three terminals of the machine. This is because the rotating field induces voltages in the various phase windings which are not much different from the applied voltage. Since the single-phase field is not quite uniform and since the impedance drop in the windings affects the terminal voltage, the output voltages are not quite equal but nearly enough so that they may be used for much three-phase work. This method is used quite widely in a-c railway electrification since the necessity of three conductors makes transmission of three-phase power to the locomotive difficult. (L.R.Q.)

PHASE INVERTER. The push-pull **amplifier** has numerous advantages over single-ended ones but does require a push-pull connection for driving the **grids**. Since the usual amplifier has low-level stages operating single-ended this requires some method of getting two equal voltages 180° out of phase to drive the push-pull grids. One method is to use a **transformer** to couple the single **plate** to the push-pull grids by center-tapping the **secondary**. However, for resistance coupling a phase inverter may be used. Referring to the figure, part of the output voltage of the upper tube is coupled back



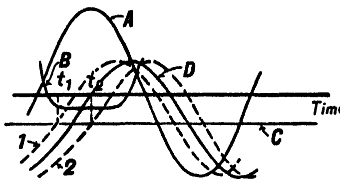
into the grid of the lower tube. Since the output of a tube is 180° out of phase with the input, the input to the second tube is 180° from that of the first tube, hence their outputs are likewise displaced. If the tap on the output resistor of the first tube is adjusted correctly just enough voltage is applied to the grid of the second to cause its output to be equal that of the first. These equal and opposite voltages may then be applied to the push-pull grids of the following stage. (L.R.Q.)

PHASE MODULATION. Modulation.

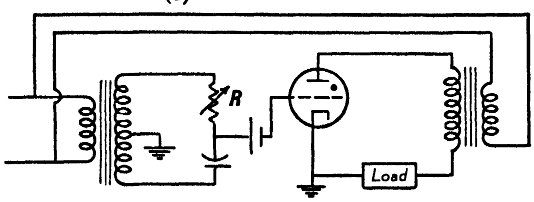
PHASE RULE. Used by **geochemists and petrologists** as a thermodynamic formula in describing the origin of an **igneous** rock in which the **magma** is considered in terms of any system, $P + f = n + z$, when P = number of coexisting chemical phases in the system, f = degrees of freedom, and n = number of independent **components** in the system. (See **Equilibrium, Chemical; States of Matter.**) (R.M.F.)

PHASE SHIFT CONTROL. This control is commonly applied to **thyratrons** or **ignitrons** operated on a.c. and consists of controlling the breakdown point by shifting the phase of the grid voltage with respect to the anode voltage. Fig. 1*a* shows the anode voltage

(A), the grid characteristic (B), the d-c grid **bias** (C) and the a-c grid voltage (D). These are all plotted against time along the horizontal axis. If at any instant



(a)



(b)

the net **grid** voltage, i.e., the d-c plus the a-c value, goes above the characteristic (B) the tube breaks down and conducts for the rest of that half-cycle. Thus if the grid wave is shifted to position (1) the tube breaks down at time t_1 while if it is shifted to (2) the tube breaks down at t_2. By making the phase continuously variable the average output of the tube may be varied by varying the part of the cycle over which the tube conducts. A simple circuit for doing this is shown at (b). The voltage applied to the **grid** may be varied over nearly 180° by varying the value of the resistor *R*. This method of controlling tubes is widely used for motor speed control and for resistance welding control. (L.R.Q.)

PHEASANT. Aves, Galliformes. Game birds (**Aves**) native to the Old World, especially of southeastern Asia and the high altitudes of China and Tibet. The males of many species are gorgeously colored and have much longer tails than the females.

Pheasants are raised in large numbers for game both in Europe and in North America. In some parts of the United States the ring-necked pheasant, *Phasianus colchicis*, has apparently become established after some years of careful protection. The introduction of other species has met with little success although the golden and silver pheasants are listed as introduced species in the fauna of Oregon and Protection Island, Washington. All of these species are Chinese.

The group includes many species with the name pheasant, in addition to the true pheasants of the genus *Phasianus*. Other forms are the tragopans or horned pheasants, the blood pheasants, the monals, the fire-backed pheasants, eared pheasants, golden pheasant, jungle fowls, and argus pheasants. Some of the Indian species bear the names kallege and pukra.

The ruffed **grouse** of North America is known in the southern states as a pheasant but with no scientific reason. (A.W.L.)

PHELLOGEN or CORK CAMBIUM. In most **dicotyledons** this is a **tissue** of living **cells** developed either from the cells of the epidermis or from cells lying just beneath the epidermis, or in the case of roots from cells of the **pericycle**. It is a secondary meristematic tissue, from which cork tissue or phellem and secondary cortex or phelloderm are formed. (R.M.W., B.S.M.)

PHENACITE. The mineral phenacite is an **orthosilicate** of **beryllium** corresponding to the formula Be_2SiO_4. It is **hexagonal** but the crystals are usually **rhombohedral** in habit. It has a conchoidal **fracture;** is brittle, hardness, 7.5–8; specific gravity, 3; luster, vitreous; colorless to yellowish or reddish, sometimes brown; transparent to translucent. Phenacite is found in **pegmatites** with **topaz, quartz** and microcline, and occurs also in **emerald**-bearing **mica schists** of the Ural Mountains. It is found also in France, Norway, Switzerland, Africa, Brazil, and Mexico, and in the United States in Oxford County, Maine; Carroll County, New Hampshire; and in Chaffee and El Paso Counties in Colorado. It derives its name from the Greek meaning deceiver, as it resembles quartz and topaz with which it is associated. It is sometimes spelled phenakite. It has been somewhat used as a gem. (E.S.C.S.)

PHENOCLAST. A textural term proposed by R. M. Field in 1916 for coarsely graded **clastic sedimentary rocks** in which the largest or "show" particles or fragments are referred to as phenoclasts, regardless of their shape or composition. The term implies that the larger constituents of the glomerate have been derived from prelithified rock. Rounded fragments are called pebbles or spheroclasts, which when lithified by means of matrix (sand and clay) and cement form a conglomerate. Angular fragments are called anguclasts (Field), which when lithified by means of matrix (sand and clay) and cement form a **breccia.** (R.M.F.)

PHENOCOPY. A term used in genetics to designate an organic character resembling some inherited Mendelian unit character but developed in the individual in response to some environmental condition and so not transmitted by inheritance. A Lamarckian character superficially like a Mendelian character. (A.W.L.)

PHENOCRYST. A textural term proposed by Iddings in 1892 for macroscopic crystals which are relatively much larger than the crystalline matrix of the **igneous** rock in which they occur. Rocks which have phenocrysts are called **porphyritic.** The term phenocryst is derived from the Greek, meaning show, and crystal. (R.M.F.)

PHENOL. (For phenols, see article below on **Phenols and Quinones.**) Phenol, carbolic acid, hydroxybenzene (C_6H_5OH), is a colorless solid of characteristic odor, poisonous, and corrosive to the skin, melting point 41° C., boiling point 182° C., slightly soluble in water at 20° C. (8.3 grams phenol per 100 grams solution), but at 68.3° C., critical temperature, each layer contains 33.4 grams phenol per 100 grams solution and the layers are miscible; upon cooling the change is reversible; very soluble in ether and miscible in all proportions with alcohol, glycerol, chloroform, absorbs water on exposure to the atmosphere and acquires a reddish color on exposure to air. Phenol reacts (1) with **sodium** hydroxide, yielding sodium phenate (C_6H_5ONa), which with **carbon dioxide** forms phenol plus sodium carbonate (phenol insoluble in **sodium** carbonate or sodium hydrogen carbonate solution), (2) with **phosphorus** pentachloride, yielding chlorobenzene plus phosphorus oxychloride, (3) with **bromine** (or chlorine) in water, yielding 2,4,6-tribromo- (or chloro-) phenol, white precipitate, melting point 96° C. (chloro- 68° C.), (4) with **zinc** heated, yielding **benzene** (C_6H_6) distillate plus zinc oxide residue, (5) with ferric chloride solution, yielding violet solution, (6) with **sodium** nitrate plus concentrated **sulfuric acid,** yielding para-nitrosophenol ($C_6H_4(OH)(NO)(1,4)$), brown when cold, blue upon warming, red upon pouring into water, blue upon addition to this of excess

sodium hydroxide (Liebermann's reaction), (7) with nitric acid (and concentrated sulfuric acid) yields nitrophenols (para- $C_6H_4(OH)(NO_2)(4)$, ortho- $C_6H_4(OH)(NO_2)(2)$, 2,4-di- $C_6H_3(OH)(NO_2)_2(2,4)$, 2,4,6-tri- $C_6H_2(OH)(NO_2)_3(2,4,6)$), this last substance known as "picric acid" made in this way is an important high explosive. Phenol is obtained (1) from coal tar, in the fraction distilling between 170° C. and 230° C. The reaction with sodium hydroxide is applied in the recovery, followed by treatment with carbon dioxide, and distillation of the separated phenol, (2) from benzene sulfonic acid ($C_6H_5SO_3H$) by heating with sodium hydroxide or calcium hydroxide, (3) from chlorobenzene by heating under pressure with sodium hydroxide in the presence of diphenyl oxide, (4) of scientific interest is the reaction of diazobenzene upon boiling, whereupon phenol is formed. Phenol gives a violet coloration with solutions of ferric salts. Phenol is used (1) as an antiseptic, germicide, and disinfectant, (2) in the manufacture of certain dyes, (3) in the manufacture of picric acid. (For Phenols, see **Phenols and Quinones.**)
(R.K.S.)

PHENOLOGY. A biological science which deals with the relations of living things to physical conditions in the environment depending on latitude, longitude, and altitude. Zones in which similar conditions prevail are populated by similar animals and within a given zone the same periodical fluctuations are to be expected. Such zones are indicated on phenological maps by **isophanes.**
(A.W.L.)

PHENOLPHTHALEIN. Phthalic Acid.

PHENOLS AND QUINONES: Phenols (containing hydroxyl group, —OH, attached to a benzenoid carbon) are characterized by a wide variety of chemical reactions, illustrated by reference to **phenol.** There are several types of phenols, depending upon the number of **hydroxyl** groups contained (1) monohydroxy, e.g., phenol (C_6H_5OH), cresol ($CH_3C_6H_4OH(2)$), betanaphthol ($C_{10}H_7OH(2)$), (2) di-hydroxy, e.g., resorcinol ($C_6H_4(OH)_2(1,3)$), (3) tri-hydroxy, e.g., pyrogallol ($C_6H_3(OH)_3(1,2,3)$). Phenols possess acidic properties, although in very slight degree, and give rise to ethers and esters. Upon regulated oxidation 1,4- and 1,2-dihydroxy phenols yield para- and ortho-quinones, respectively. Thus,

hydroquinone  forms "quinone" or benzoquinone 
yellow solid

catechol  forms ortho-benzoquinone 
Two forms: green solid, and red solid.

TABLE OF SELECTED REPRESENTATIVE PHENOLS

Phenol	Formula	Melting Point, °C.	Boiling Point, °C.
1. Phenol * (carbolic acid)	$C_6H_5\cdot OH$	41	182
2. Ortho-cresol (2-hydroxyl toluene)	$CH_3C_6H_4OH$ (2)	30	191
3. Meta-cresol (3-hydroxyl toluene)	$CH_3C_6H_4(OH)$ (3)	12	203
4. Para-cresol (4-hydroxy toluene)	$CH_3C_6H_4(OH)$ (4)	34	203
5. Ortho-ethyl phenol (1-ethyl-2 hydroxybenzene)	$C_2H_5C_6H_4(OH)$ (2)	−18	207
6. Meta-ethyl phenol (1-ethyl-3-hydroxybenzene)	$C_2H_5C_6H_4(OH)$ (3)	−4	214
7. Para-ethylphenol (1-ethyl-4-hydroxybenzene)	$C_2H_5C_6H_4(OH)$ (4)	46	219
8. 1,2-Dihydroxybenzene (catechol)	$C_6H_4(OH)_2(1,2)$	105	245
9. 1,3-Dihydroxybenzene (resorcinol)	$C_6H_4(OH)_2(1,3)$	110	276
10. 1,4-Dihydroxybenzene (hydroquinol)	$C_6H_4(OH)_2(1,4)$	170	286
11. 1,2,3-Trihydroxybenzene (pyrogallol)	$C_6H_3(OH)_3(1,2,3)$	133	293 dec.
12. 1,3,5-Trihydroxybenzene (phloroglucinol)	$C_6H_3(OH)_3(1,3,5)$	219	subl. dec.
13. 1,2,4-Trihydroxybenzene	$C_6H_3(OH)_3(1,2,4)$	141	
14. Para-para-biphenol	(4) $OHC_6H_4\cdot C_6H_4OH$ (4)	272	subl.
15. Thymol (5-methyl-2-isopropyl phenol)	$C_6H_3(OH)(CH_3)(5)(CH(CH_3)_2)(2)$	51	
16. Carvacrol (2-methyl-5-isopropyl phenol)	$C_6H_3(OH)(CH_3)(2)(CH(CH_3)_2)(5)$		237
17. Guaicol (2-methoxyphenol)	$C_6H_4(OH)(OCH_3)$ (2)		
18. Eugenol (2-methoxy-4-allyl phenol)	$C_6H_3(OH)(OCH_3)$ (2) $(CH_2CH{:}CH_2)$ (4)		254
19. Alpha-naphthol	$C_{10}H_7OH$ (1)	96	280
20. Beta-naphthol	$C_{10}H_7OH$ (2)	122	286
21. 1,2-dihydroxy naphthalene	$C_{10}H_6(OH)_2(1,2)$	60	
22. Anthranol (9-hydroxy anthracene)	$C_6H_4\langle{}^{COH}_{CH}\rangle C_6H_4$	170 dec.	
23. Anthrol (1) (1-hydroxyanthracene)	$C_6H_4\langle{}^{CH}_{CH}\rangle C_6H_3OH$ (1)	151 dec.	
24. Anthrol (2) (2-hydroxyanthracene)	$C_6H_4\langle{}^{CH}_{CH}\rangle C_6H_3(OH)$ (2)	200 dec.	

* Discussed separately under Phenol.

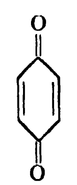
TABLE OF SELECTED REPRESENTATIVE QUINONES

Quinone	Color	Formula	Melting Point, °C.	Boiling Point, °C.
1. Benzoquinone (quinone)	Yellow	$C_6H_4(O)_2(1,4)$	116	subl.
2. Ortho-benzoquinone	Red	$C_6H_4(O)_2(1,2)$	60–70 dec.	
3. Naphthaquinone	Yellow	$C_{10}H_6(O)_2(1,4)$	125	100 subl.
4. Ortho-naphthaquinone	Red	$C_{10}H_6(O)_2(1,2)$	115 dec.	
5. 2,6-naphthaquinone	Red	$C_{10}H_6(O)_2(2,6)$		
6. Anthraquinone, 9, 10*	Yellow	$C_6H_4\langle{}^{CO}_{CO}\rangle C_6H_4$	286	380
7. Ortho-anthraquinone,1,2	Orange	$C_6H_4\langle{}^{CH}_{CH}\rangle C_6H_2(O)_2(1,2)$	185 dec.	
8. Para-anthraquinone,1,4	Yellow	$C_6H_4\langle{}^{CH}_{CH}\rangle C_6H_2(O)_2(1,4)$	210 dec.	
9. Alizarin (1,2-dihydroxyanthraquinone)	Red	$C_6H_4(CO)_2C_6H_2(OH)_2(1,2)$	289 dec.	

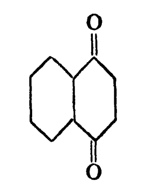
* Discussed separately under Anthraquinone

(R.K.S.)

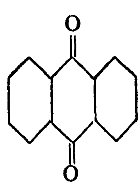
The commonly encountered quinones are of the para type, thus,



benzoquinone (1,4), yellow solid ($C_6H_4(O)_2$)



naphthoquinone (1,4), yellow solid ($C_{10}H_6(O)_2$)



anthraquinone (9,10), yellow solid ($C_{14}H_8(O)_2$)

Hydroquinone plus benzoquinone forms the complex known as quinhydrone, dark green solid. Quinhydrone or benzoquinone is readily reduced to hydroquinone (e.g., by **sulfurous acid.**) Quinhydrone, hydroquinone, or **aniline** ($C_6H_5NH_2$), which is commonly used to produce benzoquinone, is readily oxidized to benzoquinone (e.g., by **sodium** dichromate plus **sulfuric acid**). When **naphthalene** or alpha-naphthylamine ($C_{10}H_6(NH_2)(1)(OH)(4)$) is similarly oxidized, naphthoquinone is obtained, and **anthracene** similarly yields anthraquinone (9,10).

The higher phenols are soluble in water, and in alkaline solution usually absorb **oxygen** and act as reducing agents, e.g., pyrogallol in alkaline solution is used to estimate the percentage of oxygen in gas mixtures, and in photography as a developer. As reducing agents these phenols generally react with alkaline **cupric** tartrate (Fehling's solution), and with ammonio-**silver** nitrate (Tollen's solution). Phenols produce a characteristic color with **ferric** chloride solution.

Quinones stand alone among the compounds of carbon-hydrogen-oxygen in possessing, as a class, marked color, para are yellow, ortho red. It is believed that the benzenoid structure  gives place to the quinoid structure  in this case. Quinones, in general, react with **hydroxylamine** or **phenylhydrazine** to form mono- and dioximes or mono- and diphenylhydrazones of characteristic properties, e.g., melting point.

PHENOMERIDIAN. Isophane.

PHENOTYPE. Heredity.

PHENYL. Radicals.

PHENYLHYDRAZINE. Hydrazine.

PHENYLHYDRAZONES. Hydrazines, Hydrazones, and Osazones.

PHILLIPSITE. The mineral phillipsite is a **zeolite,** a hydrous silicate of **potassium, calcium,** and **aluminum,** of somewhat uncertain formula. It is **monoclinic,** forming penetration twins, and sometimes crosses resembling **orthorhombic** or **tetragonal** forms. It also may occur in radial groups. Phillipsite is a brittle mineral; hardness, 4–4.5; specific gravity, 2.2; luster, vitreous; color, white to light red; translucent to opaque. Like other **zeolites** phillipsite is found in **veins** and cavities in **basalts,** and sometimes in more **acidic** rocks. It is believed to be a low-temperature mineral. Found in Italy, especially in the lavas of Vesuvius and Monte Somma, and in the basalts of Germany, Ireland, and Australia. Has been reported from Greenland. This mineral was named in honor of the British mineralogist William Phillips. (E.S.C.S.)

PHIMOSIS. An excessively tight foreskin over the head of the **penis** or **clitoris** so that it cannot be pushed back over the organ. The condition is corrected by circumcision. (D.M.H.)

PHLEBITIS. Inflammation or infection of the wall of a vein. This is almost invariably associated with some degree of **thrombosis.** (See **Thrombophlebitis.**) (D.M.H.)

PHLEBOTOMY. Venesection or withdrawing of blood from a **vein** in the body in order to reduce the venous pressure. (R.S.M.)

PHLOEM. The phloem is that part of the plant through which foods move from one part of the plant to another. In **stems** the phloem forms a considerable portion of the **bark**, and is found outside the **cambium.**

In **angiosperms**, the phloem consists of **parenchyma** cells, **fibers**, sieve tubes, and companion cells. The parenchyma cells are thin-walled, somewhat irregular in shape, and contain protoplasm. The fibers are long, slender, thick-walled cells having no protoplasm. The sieve tubes are made up of long, thin-walled cells with a peripheral layer of **cytoplasm**, no nucleus, and a large central **vacuole.** The walls are perforated in restricted spots called sieve plates. In the more advanced plants these sieve plates occur only at the ends of the cells; in the more primitive plants they are found both at the ends and along the sides of the cells. Sieve tubes thus extend throughout the plant and provide continuous strands of living protoplasm capable of conducting food rapidly from the leaves to its various destinations. A companion cell is a small cell, usually much elongated, which is found adjoining a sieve tube. It has a dense cytoplasm and a distinct nucleus. (R.M.W.)

PHLOGOPITE. The mineral phlogopite is a **magnesium**-bearing **mica,** with but little **iron,** corresponding essentially to the formula $H_2KMg_3Al(SiO_4)_3$. **Fluorine** is sometimes present. This mica is **monoclinic** like **muscovite, biotite** and **lepidolite,** forming prismatic crystals, occasionally very large, and occurring also in scales and plates. Its **cleavage** is basal and highly perfect with elastic laminae; hardness, 2.5–3; specific gravity, 2.78–2.85; luster, pearly to submetallic; color, yellowish-brown, green, white and colorless; transparent to translucent; may exhibit asterism, probably due to minute inclusions. Phlogopite is more nearly a characteristic of **metamorphic** than **igneous** rocks although occasionally occurring in the latter if they are rich in magnesia and with but little iron. Phlogopite is found especially in Rumania, Switzerland, Italy, Finland, Sweden and Madagascar where it occurs in the crystalline limestones in huge crystals. In the United States it occurs in New York State at Edwards, Hammond, DeKalb, Monroe and, in New Jersey, at Franklin. In Canada it is found at many places in Ontario and Quebec.

The name phlogopite comes from the Greek word meaning like fire, referring to the copper-like reflections often observed in the reddish-brown varieties.

Phlogopite is in demand commercially by the electrical industry for use as an insulator. (E.S.C.S.)

PHOEBE. Aves, Passeriformes. One of the smaller species of North American birds (**Aves**) belonging with the pewees and kingbirds in the group known as **flycatchers.** It builds its nest commonly on beams below bridges and in deserted buildings. Also called the pewit. Both names are descriptive of its call. Two related species of the western half of the continent and the southwestern states respectively, are the Say phoebe, *Sayornis saya,* and the black phoebe, *S. nigricans.* (A.W.L.)

Phoebe. *Sayornis phoebe.* Dusky brown above, head darker, with a crest. Yellowish white below. Inconspicuous white wing bars.

PHOLIDOTA. A small order of mammals containing only the scaly anteaters or **pangolins** of the Malay archipelago, Africa, and southeastern Asia. (A.W.L.)

PHONODEIK. **Musical Sounds.**

PHONOGRAPH. **Sound Recording.**

PHONOLITE. A dense extrusive rock, the equivalent of a **nephelite syenite.** The name is derived from the Greek word meaning sound, referring to the brilliant metallic ringing sound emitted by certain phonolites when struck. Most if not all of the "clink stones" of the older literature were phonolites. (E.S.C.S.)

PHORONIDEA. A group of marine animals of uncertain relationship. They live in tubes at the bottom of the ocean and are slender animals with a **lophophore** bearing a series of tentacles about the mouth. In this feature they resemble **Bryozoa** and **Brachiopoda.** As in the Bryozoa, the alimentary tract is sharply bent. Phoronids have a closed tubular **circulatory system** and red **blood.** They have sometimes been grouped with the primitive chordates but are usually placed as a separate **phylum.** (A.W.L.)

PHOSGENE, CARBONYL CHLORIDE. **Carbon.**

PHOSGENITE. The mineral is a rare **chloro-carbonate** of lead found with **cerussite.** (E.S.C.S.)

PHOSPHATE. **Phosphoric Acid.**

PHOSPHINES AND RELATED COMPOUNDS. Phosphines are compounds of **phosphorus** and **hydrogen.** By replacement of one or more hydrogen atoms a wide variety of derivatives can be formulated, many of which are known. A table showing the relationship of these compounds is given on the following page, and some of their reactions are described.

Representative reactions of phosphines and their derivatives are as follows:

Mono-substituted phosphines oxidized (by **nitric acid**) to mono-substituted phosphinic acids.

Di-substituted phosphines oxidized (by nitric acid) to di-substituted phosphinic acids.

Tri-substituted phosphines:

1. Oxidized (by nitric acid) to tri-substituted phosphine oxides (not easily reduced).
2. With **chlorine** to tri-substituted phosphine dichlorides.
3. With sulfur to tri-substituted phosphine sulfides.
4. With carbon disulfide to tri-substituted phosphine carbon disulfide addition compounds.
5. With methyl (etc.) iodide to tetra-substituted phosphonium iodides.
6. With ethyl azide to tri-substituted phosphine ethyl amine $(CH_3)_3P{:}NC_2H_5$) plus nitrogen gas (N_2).

Tetra-substituted phosphonium iodides with **silver oxide** form tetra-substituted phosphonium hydroxides ($[(CH_3)_4P]OH$).

Tetra-substituted phosphonium hydroxides when heated yield tri-substituted phosphine oxides ($(CH_3)_3PO$), plus hydrocarbon (e.g., CH_4).

Benzene plus phosphorus trichloride in the presence of **aluminum** chloride forms phenyl dichlorophosphine

TABLE SHOWING PROPERTIES OF PHOSPHINES AND RELATED COMPOUNDS.

PHOSPHINES AND THEIR ALKYL-SUBSTITUTION COMPOUNDS	FORMULA	M.P. °C.	B.P. °C.	RELATED OXYGEN COMPOUNDS	FORMULA	M.P. °C.	B.P. °C.
Phosphine	PH_3	−134	−87				
	$PH_2 \cdot PH_2$	−10	57 (735 mm.)				
	$(P_4H_2)_3$	Yellow solid, ignition temperature 160° C.					
Methyl phosphine	CH_3PH_2		−14	Methyl phosphinic acid	$CH_3PO(OH)_2$	105	
Ethyl phosphine	$C_2H_5PH_2$		25	Ethyl phosphinic acid	$C_2H_5PO(OH)_2$		
Phenyl phosphine	$C_6H_5PH_2$		160	Phenyl phosphinic acid	$C_6H_5PO(OH)_2$		
Dimethyl phosphine	$(CH_3)_2PH$		25	Dimethyl phosphinic acid	$(CH_3)_2PO(OH)$	76	
Diethyl phosphine	$(C_2H_5)_2PH$		85	Diethyl phosphinic acid	$(C_2H_5)_2PO(OH)$		
Trimethyl phosphine	$(CH_3)_3P$		42	Trimethyl phosphine oxide	$(CH_3)_3PO$		
Triethyl phosphine	$(C_2H_5)_3P$		128	Triethyl phosphine oxide	$(C_2H_5)_3PO$	53	243
Tetramethyl phosphonium iodide	$[(CH_3)_4P]I$						
Tetraethyl phosphonium iodide	$[(C_2H_5)_4P]I$						

(phosphenyl chloride ($C_6H_5PCl_2$), (boiling point 225° C.), plus hydrogen chloride.

Phenyldichlorophosphine plus water forms phenyl phosphinous acid ($C_6H_5P(OH)_2$).

Phenyl phosphinous acid plus hydrogen peroxide forms phenyl phosphinic acid ($C_6H_5PO(OH)_2$).

Phenyldichlorophosphine plus hydrogen forms phenyl phosphine $C_6H_5PH_2$.

Phenyldichlorophosphine plus phenyl phosphine forms phosphobenzene ($C_6H_5P{:}PC_6H_5$), melting point 149° C., yellow solid (similar to azo-compound. Chromophore group —P:P—).

Phosphinobenzene ($C_6H_5PO_2$) similar to nitrobenzene ($C_6H_5NO_2$). (R.K S.)

PHOSPHORESCENCE. A term commonly applied to the production of light by living things and to the resulting luminosity of ocean water when small luminous animals are abundant in it. Luminosity of animals is only superficially like that of phosphorus, however. It results from the oxidation of organic compounds in some animals, including the common **fireflies**, and is probably never a true phosphorescence as this term is defined by the physicist. (See **Luminescence.**)

Phosphorescence of the ocean is often due to a multitude of luminous 1-celled animals although a limited show of light may result from larger animals of many forms. Animals capable of producing light are known in every **phylum.** (A.W.L.)

PHOSPHORIC ACID AND PHOSPHATES. Phosphoric acid (H_3PO_4) is a colorless solution, commercially of strength 50% H_3PO_4 (specific gravity at 17.5° C., 1.340); 75% H_3PO_4 (specific gravity at 17.5° C., 1.588); 93% H_3PO_4 (specific gravity at 17.5° C., 1.800). A solution of phosphoric acid of 64% strength has minimum freezing point of −85° C. Phosphoric acid 100% may be made by the proper admixture of **phosphorus pentoxide** and water. Conversely, by concentration of phosphoric acid solution in a vacuum or by heating to 140° C., orthophosphoric acid (H_3PO_4) is obtained as a solid, melting point 42.3° C. When heated at 250° C., pyrophosphoric acid ($H_4P_2O_7$) is obtained (salts tetra- and dipyrophosphates), and at a red heat metaphosphoric acid, "glacial phosphoric acid" (HPO_3) (salts monometaphosphates) melting point 40° C., which upon cooling yields a glassy solid.

Phosphoric acid reacts with such metals as **magnesium, zinc,** or **iron,** yielding **hydrogen** gas and the corresponding phosphate in solution. Phosphoric acid is (1) a remarkably stable acid from the point of view of oxidation and reduction, and is frequently desirable to use on that account, (2) an esterification agent (see **esters**), e.g., **glycerol** esterified to glycerophosphoric acid ($C_3H_5(OH)_2 \cdot OPO(OH)_2$), ethyl alcohol to triethyl phosphate ($(C_2H_5O)_3PO$), boiling point 216° C., (3) a non-volatile acid upon heating, e.g., with **sodium** chloride or nitrate, **hydrogen chloride** or nitric acid, respectively, is volatilized and sodium dihydrogen phosphate remains as a residue when slight excess phosphoric acid is used; diethyl phosphoric acid ($(C_2H_5O)_2PO(OH)$), boiling point 59° C.

In order to obtain phosphoric acid from **calcium** phosphate the latter may be subjected to either of two treatments, (1) by addition of the proper amount of **sulfuric acid,** calcium phosphate is transposed to calcium sulfate, insoluble, plus phosphoric acid solution. This reaction is followed by separation of the solution by sedimentation or filtration, and subsequent evaporation; (2) by addition of **silicon** oxide and **carbon** and subjection to **electric furnace** temperature, phosphorus is volatilized and the vapor may be burned in air to form phosphorus pentoxide. By solution of the oxide, various phosphoric acids are obtained.

The uses of phosphoric acid have been suggested by the chemical reactions previously cited, and the largest quantities are used as an acid to prepare phosphates.

Dilute phosphoric acid reacts with **hydroxides** to form three series of phosphates (the acid is tribasic), e.g., monosodium dihydrogen phosphate (NaH_2PO_4), disodium (mono) hydrogen phosphate (Na_2HPO_4), trisodium phosphate (Na_3PO_4), depending upon the ratio of acid to base reacting. The tribasic and dibasic phosphates, other than those of **sodium, potassium, ammonium,** are insoluble, monobasic phosphates are soluble. Tricalcium phosphate, when treated with the proper ratios of sulfuric acid, yields phosphoric acid (H_3PO_4), monocalcium phosphate ($Ca(H_2PO_4)_2$), dicalcium phosphate ($CaHPO_4$), with accompanying calcium sulfate in each of the three cases. Phosphates are dissolved or transposed by **nitric acid, hydrochloric acid, sulfuric**

acid, phosphoric acid (except those of **lead, tin, mercury, bismuth**), and **acetic acid** (except those of lead, **aluminum**, ferric). Upon heating, tribasic phosphates are stable, dibasic phosphates lose water to form pyrophosphates, monobasic phosphates lose water to form metaphosphates, and in such reactions ammonium volatilizes at high temperatures resembling hydrogen, e.g., sodium ammonium hydrogen phosphate (dibasic) upon heating yields sodium metaphosphate residue. Common tests for metaphosphate are as follows:

1. Addition of **magnesium** salts to boiling solution of metaphosphate produces no precipitate (difference from orthophosphate).
2. **Silver** nitrate forms a white precipitate (difference from orthophosphate).
3. **Albumin** is coagulated by aqueous solution of the free acid (difference from pyrophosphate and orthophosphate).

Common tests for orthophosphate are:

1. Silver nitrate gives a yellow precipitate.
2. Ammonium molybdate in nitric acid solution gives a yellow precipitate of ammonium phosphomolybdate, soluble in ammonium hydroxide.
3. Magnesium sulfate in ammonium hydroxide solution gives a white precipitate of magnesium ammonium phosphate. (R.K.S.)

PHOSPHORITE. Phosphorite or **phosphate** rock is the term applied to accumulations of **calcium** phosphate in nodular or compact masses often associated with **limestones**. The phosphates are derived in part from marine **invertebrates** which secrete shells of phosphate of calcium, and largely from the bones and excrement of vertebrates. While some phosphorite deposits are doubtless original, others are secondary, resulting from the leaching out of the original phosphates and their subsequent deposition elsewhere. Phosphorite is found in the United States in Florida, Idaho, Montana, South Carolina, Tennessee, Wyoming and Utah; also in Russia, France, Algeria, the West Indies and elsewhere. Phosphate rock is economically valuable in the manufacture of **fertilizers**. (E.S.C.S.)

PHOSPHOROUS ACID AND PHOSPHITES. Phosphorous acid (H_3PO_3, or H_2PO_3H) is a white soluble solid, melting point 74° C.

Phosphorous acid is used in solution, and is usually a reducing agent, e.g., in air changes to **phosphoric acid**, with hot concentrated **sulfuric acid** yields phosphoric acid plus **sulfur** dioxide, with **copper** sulfate yields finely divided copper metal, with **silver** nitrate yields finely divided silver metal, with **permanganate** after some time yields manganous, but occasionally is an oxidizing agent, e.g., **zinc** plus dilute sulfuric acid yields phosphine.

Phosphorous acid is formed by reaction (1) of **phosphorous** trioxide and water, (2) of phosphorous trichloride and water (**hydrogen chloride** evolved, and probably pyrophosphorous acid ($H_4P_2O_5$) first formed). The solution is evaporated to 180° C., and then cooled, whereupon phosphorous acid crystallizes.

Sodium phosphite (disodium phosphite, Na_2PO_3H) and sodium hydrogen phosphite ($NaHPO_3H$) are formed by reaction of phosphorous acid and sodium hydroxide solution in the proper proportions, and then evaporating. Sodium phosphite dry, upon heating, yields sodium phosphate and phosphine.

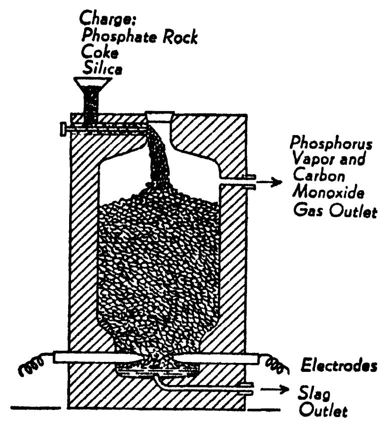
As an esterification agent (see **Ester**), phosphorous acid forms, with ethyl alcohol, triethyl phosphite ($(C_2H_5O)_3P$), boiling point 156° C. An unsymmetrical, related compound $(C_2H_5O)_2(C_2H_5)PO$ is known. (R.K.S.)

PHOSPHORUS. Symbol: P. Atomic number: 15. Atomic weight: 31.02. No isotope, but of single atomic form: 31.

The chemical element **phosphorus is known** in four different forms, namely, (1) yellow phosphorus, density 1.82, melting point 44.1° C., ignition temperature in air 34° C. (preserved under water), boiling point 280° C., reactive with warm **sodium** hydroxide solution, (2) red phosphorus, density 2.20, melting point 590° C. at 43 atmospheres pressure, **ignition** temperature 260° C., not reactive with warm sodium hydroxide solution, (3) violet phosphorus, density 2.36, melting point about 600° C., ignition temperature 260° C., insoluble in solvents, (4) black phosphorus, density 2.70, incombustible. Of these varieties, yellow phosphorus is soluble in **carbon disulfide**, and when the solution is allowed to evaporate spontaneously in air, the residual phosphorus burns spontaneously. Volatilized phosphorus condenses as the yellow variety. Yellow phosphorus reacts with **chlorine, sulfur, nitric acid** (yielding phosphoric acid), sodium hydroxide solution (yielding sodium hypophosphite plus phosphine gas).

Phosphorus was discovered by Brandt in 1669.

Phosphorus is an important element in plant nutrition, e.g., in the form of phosphate, and in animal nutrition, especially in bone formation. To maintain health, a phosphorus balance must be maintained in the body; that is, intake must equal excretion. Phosphorus plays a part in complex chemical processes in the body about which little is known. It is important in bone formation and here it is linked up with **calcium, vitamin** D and sunlight. It is present in the **blood** stream and its concentration remains fixed unless changed by disease such as in **rickets**, etc. Under normal conditions a varied ordinary diet supplies this element in sufficient quantity. Phosphorus is extensively used as phosphate in **fertilizers**; as sulfide in ignition tips for friction matches, and as red phosphorus in safety matches. Yellow phosphorus is poisonous, and in contact with the skin causes dangerous wounds. A striking phenomena is the phosphorescence exhibited when yellow phosphorus is heated in darkness in boiling water and the vapors condensed. A phosphorescent region is visible at the place of condensation.



Manufacture of elementary phosphorus in electric furnace.

Phosphorus occurs as calcium phosphate (**phosphorite**, phosphate rock, ($Ca_3(PO_4)_2$) in Florida and Northern Africa, (**apatite**, $Ca_3(PO_4)_2 \cdot CaCl_2$ or CaF_2) in Quebec, and in the ash of bones. Calcium phosphate is treated in an **electric furnace** with **silicon** oxide and **carbon** (diagram, above), whereupon there is formed calcium silicate fused **slag** (drawn off as liquid), **carbon monoxide gas**, and phosphorus vapor, which last is condensed to yellow phosphorus and collected under water. The phosphorus content of iron ore in part determines the value of the ore, an acid-lined furnace such as acid Bessemer does not remove phosphorus, and the basic open hearth furnace operation which does is costly. The phosphorus content of most steel must

	Phosphobenzene				Phosphinobenzene

be low, only for certain grades used for free machining is the content appreciable.

Red phosphorus is made by heating yellow phosphorus out of contact with oxygen, under pressure, and in the presence of trace of **iodine** at a temperature of about 200° C.; violet phosphorus, by allowing red phosphorus dissolved in molten **lead** at 580° C. under pressure to crystallize; black phosphorus, by heating yellow phosphorus at 200° C. under very high pressure (12,000 kilograms per sq. cm. or 165,000 lbs. per sq. in.).

Acids: Phosphorus is a constituent of several acids. In increasing order of oxidation the following are those which do not contain carbon: hypophosphorous acid (H_3PO_2); **phosphorous acid** (H_3PO_3); hypophosphoric acid ($H_4P_2O_6$); **phosphoric acid** (H_3PO_4). Glycerophosphoric acid is $C_3H_5(OH)_2PO(OH)_2$.

Bases: Phosphine (PH_3) resembles **ammonia** chemically; phosphonium hydroxide ($PH_4 \cdot OH$) resembles **ammonium** hydroxide chemically.

Bromides: Phosphorus tribromide, phosphorus bromide (PBr_3), colorless liquid, boiling point 173° C., fumes in air, made by reaction of **bromine** and phosphorus, under control of kind of phosphorus, temperature and solvent (e.g., carbon disulfide) to regulate the rate of the reaction; phosphorus pentabromide, phosphoric bromide (PBr_5), yellow solid, fuming in moist air; phosphorus oxybromide ($POBr_3$), white solid, melting point 56° C., boiling point 193° C.

Chlorides: Phosphorus trichloride, phosphorous chloride (PCl_3), colorless liquid, boiling point 73.5° C., fumes in air, made by reaction of **chlorine** and phosphorus, under control of kind of phosphorus, temperature and solvent (e.g., carbon disulfide) to regulate the rate of the reaction; phosphorus pentachloride, phosphoric chloride (PCl_5), yellow solid, fuming in moist air; phosphorus oxychloride ($POCl_3$), colorless liquid, melting point 1° C., boiling point 107° C. These compounds are important reagents in organic chemistry to replace by halogen an hydroxyl (OH) that is attached to **carbon**, e.g., benzoic acid into benzoyl chloride.

Hydrides: Phosphine (PH_3), colorless gas, of characteristic odor, poisonous, boiling point −86° C., burns in air by heating when pure to 100° C. (ordinarily contains diphosphorus tetrahydride inflammable at room temperature); made by reaction of yellow phosphorus and **sodium** hydroxide solution heated, accompanied by diphosphorus tetrahydride (P_2H_4), colorless liquid, boiling point 57° C., spontaneously inflammable in air, accompanies phosphine as prepared above, removable by condensation upon cooling.

Iodide: Phosphorus diiodide (P_2I_4), orange solid, melting point 110° C.; phosphorus triiodide (PI_3), red solid, melting point 61° C., decomposes upon heating; with water it forms **phosphorous acid** and hydriodic acid.

Nitride: Phosphorus nitride (P_3N_5), white solid, reactive with warm water to yield phosphate plus **ammonia.**

Oxides: Phosphorus trioxide, phosphorous oxide (P_2O_3), white solid, melting point 22.5° C., boiling point 173° C., formed by reaction of phosphorus and a deficiency of air, dissolves in cold water to form **phosphorous acid**; phosphorus tetroxide (P_2O_4), white solid formed by heating phosphorus trioxide in a sealed tube at about 440° C., reactive with water to form a mixture of phosphorus and **phosphoric acids**; phosphorus pentoxide (P_2O_5), white solid, sublimes at 347° C., excellent dehydrating agent, absorbs water avidly, made by burning phosphorus in excess of air or oxygen.

Phosphides: Many metallic phosphides have been described, some seven phosphides of **tin,** and six of **copper.** Formed by reaction of the metal plus phosphorus. Reactive with water or acid to form phosphine or phosphonium salt.

Sulfide: Phosphorus and **sulfur** do not react at low temperatures, nor in **carbon disulfide** solution, but, upon heating with caution, three sulfides of phosphorus have been formed, namely, P_4S_3, P_4S_7, P_4S_{10} (or P_2S_5) of melting points, 172° C., 303° C., 280° C., respectively. Tetraphosphorus trisulfide (P_4S_3), non-poisonous, not attacked by atmospheric moisture, is used to replace yellow phosphorus on match tips.

Other compounds of phosphorus are discussed as follows:

Esters. (See **Phosphoric Acid and Phosphates; Hypophosphoric Acid and Hypophosphites; Phosphorous Acid and Phosphites.**)
Glycerophosphoric acid. (See **Phosphoric acid and Phosphates.**)
Hypophosphates. (See **Hypophosphoric Acid and Hypophosphates.**)
Hypophosphites. (See **Hypophosphorous Acid and Hypophosphites.**)
Hypophosphoric Acid.
Hypophosphorous Acid.
Phosphates. (See **Phosphoric Acid and Phosphates.**)
Phosphines.
Phosphine oxides. (See **Phosphines and Related Compounds.**)
Phosphinic acids. (See **Phosphines and Related Compounds.**)
Phosphinobenzene. (See **Phosphines and Related Compounds.**)

Phosphites. (See **Phosphorous Acid and Phosphites.**)
Phosphobenzene. (See **Phosphines and Related Compounds.**)
Phosphonium-compounds. (See **Phosphines and Related Compounds.**)
Phosphoproteins. (See **Aminoacids, Polypeptides and Proteins.**) (R.K.S.)

PHOSPHORUS POISONING. This type of poisoning, whether by accident, or intent, is less common since the advent of safety matches which do not contain **phosphorus.** Phosphorus is still used in many of the rat and vermin pastes. The mortality in untreated poisoning is very high since the phosphorus has a special affinity for **liver** cells, which it destroys. The symptoms are early gastrointestinal irritation, abdominal pain and collapse. If the patient lives 2 or 3 days, evidence of liver damage appear, such as marked **jaundice.** Later, drowsiness, delirium and coma develop, and death occurs in a day or two. In the early stages treatment consists of washing out the stomach with dilute solutions of **hydrogen peroxide.** A diet rich in **carbohydrates** and protein should be given to protect the liver. In the acute stage, glucose by vein is indicated. (R.S.M., D.M.H.)

PHOTOCELL. This term is the old designation for all photoelectric devices but is more properly applied only to those which would not be called electronic **tubes.** Thus the two principal types of photocells are the photoconductive cell and the photovoltaic cell. The first of these usually employs selenium as the active element. This is spread across two conductors separated by a short gap (the whole is commonly applied to a base of glass or other insulating material) so the selenium will bridge the gap. After proper heat treatment the conductivity of the selenium will be sensitive to light, being very high when dark and increasing when illuminated by visible light. Such cells are not overly sensitive but are suitable for many applications. The photovoltaic cell is probably most familiar as the exposure meter used in photography. Certain composite surfaces composed of an overlay of one substance on a backing of another will produce a voltage difference across the barrier surface between the two when subjected to light. Cuprous oxide on copper and selenium on iron are two widely used examples of this type cell. Contact is made to the front face by means of an extremely thin layer of metal sputtered over the surface and contacting more substantial connections at the edge. This film is thin enough to allow light to penetrate it and act on the photosensitive materials. When connection is made to an outside circuit current will flow although there is no source of e.m.f. other than that generated by the action of light. While these currents are very small, being of the order of microamperes, they are nevertheless sufficient to operate sensitive current meters and **relays.** In the exposure meter, a microammeter is connected across the terminals of the cell and the deflection is a function of the illumination. By calibrating the instrument in terms of **foot-candles** it may be used as a light meter, or in terms of film exposure as a photographer's aid. (L.R.Q.)

PHOTOCHEMISTRY. When certain substances are subjected to light a chemical change is produced. The production of an image in the photographic plate is possibly the most familiar instance of this, but the reaction of **photosynthesis** in the green leaf of the plant operates on the largest scale. Conversely, the production of light from the heat developed in chemical reactions is a common occurrence. The burning of **magnesium** metal in air produces a high temperature and light of high actinic value which is utilized in photography.

In photochemical reactions **light** supplies the energy necessary for the activation of the reacting **molecules** (Grotthus, 1818, and Draper, 1839). Sometimes the light waves which are absorbed by a body produce only an increase in temperature, sometimes **fluorescence** as in the cases of eosin and fluorescein, and sometimes chemical change. The reaction of **hydrogen** and **chlorine** in light was studied by Bunsen and Roscoe (1862), and they discovered that the amount of chemical change is proportional to the intensity of the light and to the length of time of exposure to the light. The first law of photochemistry (Draper-Grotthus) states that light that is absorbed causes chemical change. The energy of light is measured in quanta

$$E = Nhc/\lambda$$

N is Avagadro's number.
h is Planck's constant.
c is velocity of light.
λ is wave length of light.

Photochemical processes are of two kinds—primary and secondary. The primary process in a photochemical reaction is limited by the Einstein law to the absorption of one quantum by a molecule or atom. A knowledge of the spectrum of the reactants is necessary to determine what happens in this process. The **molecule** may be disrupted into fragments or an **electron** may be excited from a lower orbit to a higher one. Which of these events takes place can often be determined by spectroscopic studies. The secondary process deals with the fate of the molecular fragments or of the excited molecules. The excited molecule may emit its extra energy as light—causing fluorescence; it may lose it by transferring it to other molecules as thermal energy; or it may cause a chemical reaction. On the other hand the molecular fragments may either recombine to give the original reactant or cause further chemical reactions. The study of the quantum yield (which is the number of molecules reacting divided by the number of quanta absorbed), is used as a means of formulating the secondary processes. If the quantum yield is less than one, fluorescence, deactivation or recombination of fragments must take place. If the quantum yield is unity every photon absorbed decomposes one molecule. When the quantum yield is greater than unity (and in some reactions it may be as high as a million) chain reactions are involved. The classical example of such a reaction is the combination of hydrogen and chlorine. The primary reaction is Cl_2 and light $\rightarrow$ 2Cl. The chain propagation reactions are

$$Cl + H_2 \rightarrow HCl + H$$

$$H + Cl_2 \rightarrow HCl + Cl$$

creating a cycle which is only stopped by

$$Cl + Cl \rightarrow Cl_2$$

$$H + H \rightarrow H_2$$

Since the last two processes are slow compared to the two before them, one quantum of light can bring about a combination of a million molecules of hydrogen and chlorine. (R.K.S.)

PHOTOCONDUCTIVITY. Many substances exhibit a marked increase in electric conductivity when illuminated. Thus gases may be ionized by light as well as by ultra-violet radiation or x-rays. But the term photoconductivity is commonly applied to crystals which, ordinarily very poor conductors, become distinctly conducting under the action of light.

The most noted example of this phenomenon is found in **selenium,** whose photoconductivity has been known since its discovery in 1873 by May. Unfortunately selenium is far from typical in its manifestations of the property, and the hundreds of researches on it have given many conflicting data. It has finally been recog-

nized, from the work of Gudden and Pohl, that photoconduction is of two general types: primary or true photoconduction, which is the direct result of radiation penetrating the substance; and secondary effects set up by the photoconduction itself. The case is somewhat analogous to the primary and secondary ionization of a gas, so much utilized in **photoelectric cells.** The fact that in selenium the several secondary effects quite obscure the primary photoconduction is what has occasioned so much confusion. The primary photoconduction current in a crystal is in general proportional to the intensity of the illumination; the secondary is not, and, in the case of "light-negative" selenium, it may actually neutralize the primary and render the crystal less conductive than when in the dark. Some crystals, said to be "idiochromatic," are photoconductive in the pure state, while others, called "allochromatic," acquire the property only by reason of impurities or of previous exposure to suitable radiation.

Films of photoconductive selenium provided with electrodes, and called "selenium cells," have found practical application in the past. They have now, however, been superseded largely by **photoelectric** and **photovoltaic cells.** (L.D.W.)

PHOTOELASTICITY. This badly chosen term refers to certain changes in the optical properties of isotropic, transparent dielectrics when subjected to stresses. For example, a block of glass, free from optical flaws, exhibits "forced" **double refraction** when put under compression or tension parallel to one of its dimensions. If the block is placed between crossed **Nicol prisms,** the field remains dark so long as the glass is in its normal condition, but as stress is applied, colored fringes appear which are characteristic of the internal deformations of the glass. In 1893 Marsten adapted this principle to the study of elastic stresses in glass or celluloid models of structural parts; and in 1913 Coker developed an apparatus, using circularly- instead of plane-polarized light, for the same purpose. Maris analyzed the altered polarization by means of a **compensator.**

Ewell discovered that torsion imparts to a dielectric cylinder a certain amount of optical activity, i.e., the property of rotating the plane of polarized light. The rotation is in the opposite direction to the torsion, and varies approximately as the fourth power of the torsion. (L.D.W.)

PHOTOELECTRIC CELL. Phototube.

PHOTOELECTRIC PHENOMENA. Our knowledge of what is known as the photoelectric effect dates from the observation of Hallwachs (1888), who found that a negatively charged body may be discharged when **ultra-violet** radiation falls upon it in a vacuum. We are now mostly interested in the photoelectric effect of visible light, but the general theory applies to radiation of all higher frequencies. Every solid electric conductor is supposed to contain numerous "free" electrons which wander about from atom to atom within the substance. Ordinarily they do not leave the conductor because of the attraction of the positive atoms about them. If, however, such a wandering electron encounters a quantum of radiation, it may receive therefrom sufficient kinetic energy to tear itself loose from the attraction and pass out of the conductor; it then becomes a "photoelectron." (Some physicists have assumed that these electrons are released by the photon energy from the orbital system of the atom instead of being originally free, but this is now considered doubtful.) If there is a suitable electric field between the conductor and a neighboring conductor, the electrons thus released pass across from one to the other, thus setting up a photoelectric current.

The emission of photoelectrons is subject to certain well-known laws. For every conductor there is a photoelectric **work function** p, which represents the kinetic energy which the electron must have in order to escape. Obviously the radiation quantum responsible for the emission must have at least this energy; and if it has more, the electron, taking it all, escapes with a surplus. These facts are embodied in the Einstein photoelectric equation $\frac{1}{2}mv^2 = h\nu - p$, in which ν is the frequency of the radiation, h is the Planck constant, and m and v are the mass and speed of the emitted electron. This expresses the excess kinetic energy after an electron, receiving the quantum $h\nu$, passes the surface with energy loss p. (See **Quantum Theory** and **Planck's Law.**) It follows that radiation of lower than a certain frequency, called the photoelectric threshold frequency, and equal to p/h, cannot cause photoelectric emission from the given conductor. For most metals p is so great that none but the highest frequencies give any result. There are only seven (**sodium, potassium, caesium, rubidium, lithium, barium, strontium**) which react to visible light.

The "photoelectric yield" of a metal, i.e., the emission per unit radiant flux of a given frequency, varies largely with the metal, the condition of its surface, its potential, and the presence of surface films. Careful studies of these factors are necessary in the design or the selection of a **photoelectric cell** for any given purpose. Closely allied phenomena are **photoconductivity** and the **photovoltaic effects.** (L.D.W.)

PHOTOENGRAVING. Photomechanical Reproduction Processes.

PHOTOGENIC ORGAN. An organ that produces light. In all known cases of light production a complex substance, probably a **protein,** known as luciferin, is oxidized in the production of light. The action may take place inside the cell or outside. The marine protozoan, *Noctiluca,* for example, contains scattered granules which become luminous under the proper stimulus, and the marine worm, *Chaetopterus,* has gland cells at the surface of the body which produce a luminous secretion.

Among the more complex animals, including the **fireflies** and various fishes, photogenic organs are more complex and are extremely varied in form.

The production of light has been interpreted in various ways. It may be incidental to some normal reaction in the body, it may be a warning to other animals, it may serve to attract prey, and it may be for recognition, particularly in connection with mating. (A.W.L.)

PHOTOGRAMMETRIC SURVEYING. Surveying.

PHOTOGRAMMETRY. Photogrammetry is the application of photographic principles to the science of mapping. In general it consists of taking photographs of small parts of the earth's surface with specially constructed cameras and using these photographs directly to form a picture or indirectly to make a scale map. Terrestrial photogrammetry refers to the use of photographs taken with the optical axis of the camera lens horizontal or oblique from high ground points of known position and elevation overlooking the section to be photographed. Aerial photogrammetry utilizes photographs taken from an airplane with the optical axis of the lens vertical or oblique. Terrestrial photogrammetry is used principally where aerial photographs would not indicate abrupt changes in ground slope such as cliffs. This method is also employed in the preparation of contour maps for sections where it would be extremely difficult to make a topographic survey. (See **Topographic Surveying.**) Since aerial photogrammetry has the greater practical application, the remainder of this article will be devoted to this phase of the subject.

Aerial photographs are pictures taken with an aerial camera while the airplane is in flight. The altitude of the plane should be kept as nearly constant as practicable if more than one exposure is to be made. A series of photographs taken while the plane is proceeding in a fixed direction is called a strip. When the area to be photographed is large, flights must be made in opposite directions. Adjacent exposures must overlap if they are to be satisfactory for practical use.

If it were possible to keep the optical axis truly vertical and all objects were at the same elevation, the aerial photograph would be a true scale map so far as the relative position of the objects is concerned. Since the optical axis usually is tilted a small amount as a result of flight conditions, there is a distortion due to tilt. However, it is normally eliminated by the procedure which is followed in the use of aerial photographs. If this distortion is perceptible, the exposure should be discarded or rectified. Rectification consists of taking a picture of the photograph with a camera having the optical axis of the lens tilted with respect to the plane of the photograph. The main reason why an aerial photograph cannot be used as a scale map is the fact that all points not at the same elevation and not in line with the optical axis (assumed to be vertical) will have a relative displacement on the photograph. This is known as relief displacement.

The scale of an aerial photograph is the ratio of the scaled distance between the images of two ground points on the photograph to the actual distance between these points measured in the same units as those used in scaling the images. The photographic scaled distance should be corrected for relief displacement if large enough to affect the scale.

Aerial photographs may be used to form a mosaic. This is a group of parts of matched photographs which have been reduced or enlarged to a common scale. The part of each common scale photograph used for a mosaic depends upon the required precision. If high precision is desired, the central portion only should be used since there is comparatively little relief displacement and tilt distortion in this area. Before matching, each print is trimmed along natural lines of the photographic detail such as fence lines and boundaries of woods or fields where the match lines will be least likely to show. A mosaic may be constructed without reference to ground points, or its construction may depend on a system of plotted points known as ground control points whose relative position has been established by a ground survey. The latter is a controlled mosaic.

If aerial photographs are to be used for a controlled mosaic or in the construction of a planimetric map or a topographic map, it is necessary to have a series of ground control points which are easily recognizable on the photographs. It is also customary to have a secondary control system because the primary system (ground control) itself is not sufficient for matching the adjacent photographs properly or locating details on planimetric or topographic maps. The secondary contról, also known as the photographic control, consists of points which are easily recognizable on two or more photographs and are not a part of the ground control. The first step in making a controlled mosaic or either of the two maps previously mentioned is to plot the ground control points. The second step is the location of the secondary control relative to the ground control. Two methods are used. One is the principal-point traverse method which is applicable only to flat terrain; the other is the radial-line method which can be used for any terrain.

After the secondary control has been located, the plot may be used to match photographs for a mosaic or to make a planimetric or topographic map. Details from aerial photographs are transferred to the control plot by the usual drafting methods or by automatic plotting machines. These machines are also used to establish contours for topographic maps. If drafting procedure is followed, each photograph in turn is placed under the control plot, which must be on tracing paper or acetate film, and properly oriented with respect to the control points. The details are then traced directly on the plot. Due to relief displacement or tilt it may be impossible to orient the photograph so that all control points will match. Under these circumstances parts of the photograph are oriented and traced as separate units.

Automatic plotting machines make use of the principle of stereoscopic observation combined with a drawing attachment. A simple stereoscope is a device which gives a three-dimensional view when applied to a pair of photographs of the same object taken from two different points. It consists of two eye lenses fixed in position above the plane of the photographs. In order to obtain the proper perspective of aerial photographs, a stereoscopic pair is arranged in a certain fixed position with respect to each other. The stereoscope may be used to study photographic details but an additional instrument is required if differences of elevation are to be determined. This is known as the floating-mark system. It may be a part of the stereoscope or a separate unit. The floating-mark system consists of two pieces of glass with a dot at the center of each piece and a micrometer adjustment which makes it possible to move one piece with respect to the other. When viewed through the stereoscope, the two dots appear as one dot which is called the floating mark. When actual elevations are required, the elevation of at least one point on the photographs must be known. The use of additional control points will make it possible to eliminate tilt effects and will permit a more accurate determination of elevations or contours.

In automatic plotting instruments the floating-mark system is connected to a parallel motion having a pencil attachment. Planimetric details are traced by keeping the floating mark in contact with details on the photographs. A contour line corresponding to a given elevation is traced by locking the micrometer at a predetermined reading and then keeping the floating mark in apparent contact with the ground during the tracing.

A theoretical development of the basic principles of these machines and detailed descriptions of the various types are found in texts and pamphlets on photogrammetry. (C.W.C.)

PHOTOGRAPHIC DEVELOPERS. Photographic developers are chemical solutions containing a number of different compounds so proportioned as to produce the controlled reduction of exposed silver halide grains. During reduction the exposed silver halides are reduced to metallic silver, the invisible latent image formed by exposure being converted into a silver deposit or visible image. Developing solutions normally contain components which can be classified according to their functions into the following heads:

Developing agents.
Preservatives.
Activators.
Restrainers.

Occasionally, developers are encountered which contain less than four components. In these cases, one of the components exhibits more than one function. In other cases additional components are added according to the result desired. These are discussed under developer additions.

Developer Components. 1. Developing agents. Developing agents are selective chemical reducers, usually organic compounds, which possess only sufficient energy to reduce exposed silver halides. Reducers which are too energetic are undesirable as they reduce more than the exposed silver halide grains and thereby fog or block the image. To obtain results desired, many formulae contain two or more reducers. Organic reducers that are good developing agent‹ include:

Amidol.
Glycin.
Hydroquinone.
Metol.
Para-aminophenol.
Paraphenylene diamine.
Pyrogallol. (See **Developing Agents.**)

2. Preservative. Since developing agents in solution are readily oxidized by air, it is necessary to protect the agent from premature oxidation due to contact with the air or dissolved oxygen. Oxidized developing agents lose their reducing power and are thus rendered incapable of development. The preservative most commonly employed in photographic developers is sodium sulfite. Either the desiccated, Na_2SO_3, or the crystal, $Na_2SO_3 \cdot 7H_2O$, form may be used. Sodium bisulfite, $NaHSO_3$, and potassium metabisulfite, $K_2S_2O_5$, are added as extra preservatives when additional sulfite without an increase in the pH of the solution is desired. Many developers containing bisulfite have excellent keeping qualities and are particularly adapted for tank use.

While it is usually assumed that the sulfite is oxidized directly to the sulfate, there is considerable evidence to show that the reaction is more complicated. The exact mechanism is not fully known.

Preservative action may be complicated by a number of effects. While sulfite is normally added to preserve the developing agent, the developing agent may exert a preservative effect on the sulfite as in the case of hydroquinone. Frequently, in solutions containing two developing agents, one agent acts to preserve the other against aerial oxidation. Examples of this is metol preserving amidol and hydroquinone preserving metol.

Sodium sulfite may play more than one role, as protecting the developing agents against aerial oxidation, preventing the formation of certain oxidation products causing stains or dye images, forming complexes which act as silver halide solvents, and acting as a weak alkali to increase the rate of development or the maximum density.

Factors that affect the rate of oxidation and determine the amount of preservative required are:

a. Susceptibility of developing agent to oxidation.
b. Alkalinity of the solution.
c. Concentration of the solution
d. Method of development employed
e. Temperature at which the developer is kept and used.
f Keeping quality desired.

Other preservatives, many of which are used with sodium sulfite, are:

Acetone bisulfite.
Formaldehyde sodium sulphoxylate.
Stannous chloride.
Mannitol.
Sorbitol.
Bengoic acid.
Glycolic acid.
Salicylic acid.

3. Activators. Activators, also known as accelerators, are compounds that increase the activity of developing agents. Normally, these compounds are alkalis, or compounds which combine with sulfite to form complexes that hydrolyze to liberate a hydroxyl ion and produce the necessary alkali. Experimental evidence shows that the activity of developing agents increases with an increase in alkalinity and that the rate of development is largely a function of the pH of the solution.

The choice of alkalis for a particular formula may be made on considerations other than alkalinity. While it is generally true that increasing the concentration of alkali increases the alkalinity, the concentration of the solution may reach a limit where further additions of alkali lowers the pH, reducing the alkalinity. Alkalis like the alkali hydroxide are highly ionized whereas salts, as borax and metasilicate, are ionized to a much lower degree. Each developing agent has pH limits within which it functions satisfactorily. Metol develops at a pH of 6, while hydroquinone requires a pH of 9. Low alkalinities are necessary for certain effects, as fine-grain development. The small amount of strong alkalis that can be used in these cases would be such as to produce solutions with short life and poor keeping qualities because of the lack of an alkali reserve. It is better to use larger concentrations of weak alkalis and obtain more stable solutions. Ammonia in ammonium hydroxide is a volatile gas and also a silver halide solvent; properties that may be objectionable. During warm weather it is advisable to use alkalis, like trisodium phosphate and borax, that do not cause blistering due to the generation of a gas, when the emulsion is placed in acid fixing baths. Solutions with strong alkalis produce marked swelling of gelatin and cause softening of the emulsion. Pairs of strong and weak alkalis can be employed to produce buffer combinations, as sodium hydroxide and borax, which produce developers that have a long working life at a constant pH. Some organic acids, as salicyclic, soften gelatin and increase the penetration and diffusion of developer throughout the emulsion.

The alkali in widest use, in most formulae, is sodium carbonate, which is available in either the desiccated, Na_2CO_3, or the monohydrate, $Na_2CO_3 \cdot H_2O$, form. Next in popularity are the borates—sodium metaborate and borax. Others, as trisodium phosphate, sodium sulfite and borax, are used chiefly for fine-grain development. Sodium and potassium hydroxide find application in process or line developers, while paraformaldehyde is restricted to photomechanical processes, as lithography and offset. Organic alkalis, like triethanolamine, are finding some use in color and fine-grain development.

The approximate pH for certain standard developers containing different alkalis are given below:

	pH
Sodium metasilicate	8.5
Borax	9.2
Triethanalamine	10.1
Ammonium hydroxide	10.7
Sodium carbonate	10.4–11.6
Trisodium phosphate	12
Sodium hydroxide	13

Less popular alkalis include: acetone-bisulfite, acetone-formaldehyde, paraformaldehyde, hexmethylenetetramine, sodium aminoacetate, and sodium hexametaphosphate.

4. Restrainers. Unless developing solutions contain restrainers, the developed images are fogged to a greater or lesser degree, depending on the characteristics of the emulsion, the developing agents, and the alkalinity of the developer solution. The selective action of developers for exposed silver halide grains is greatly affected by the above factors. The addition of small amounts of restrainers produces a marked differential in the developer for exposed silver halide grains.

The presence of alkaline restrainers, as potassium bromide, potassium iodide, or sodium chloride, in developers lowers the ionization of the corresponding silver halides, reducing the concentration of the silver ions and consequently restrains development.

Of the restrainers the alkaline bromides are the most common. These are added as fog preventatives because the restraining effect is greater on fog than on the latent image. The addition of alkaline bromide permits longer development, which in turn produces a higher contrast. Where maximum contrast is desired high concentrations of bromide are required. Restraining action can also be accomplished by other ways, e.g., dissolving out the free bromide incorporated in emulsions during development, or by adding quantities of used developer to condition new developers before use.

During recent years, a number of organic nitrogen compounds which are powerful restrainers have been discovered. These antifoggants restrain fog satisfactorily when employed in concentrations as weak as 1:10,000 to 1:100,000, but delay the initial appearance of the image and make longer development necessary.

So far as is known, antifoggants form complexes, through the nitrogen atom, with silver halides. It is believed that the antifoggants are adsorbed at interface between the silver sulfide or the sensitivity speck and the silver halide, and that they form addition products with silver halides, which are stable in alkaline developers. Many of the restrainers are thioanalines. Among the more satisfactory are:

6-Nitrobenzimidazole.
Benzotriazole.
5-Chlorbenzimidazole.
Thioacetanilide.
Tetrazole.

5. Special agents. Since developers are used for many purposes and under a wide variety of conditions, it often is necessary to add special agents to overcome the difficulties encountered. These include:

Solvents. Methyl, ethyl, isopropyl alcohols, or dioxan, are frequently added in order to dissolve more of the developing agents and obtain solutions with high concentrations, or to keep developing agents in solution, particularly during cold weather.

Water Softeners. Salts producing hardness in water react with the alkalis and sulfite of the developer and reduce its energy, causing the developed images to have lower than normal contrasts. Films processed with developers made up with hard waters have a greater tendency to show water spots, due to salt crust formation around edge of droplet during drying. Calgon (sodium hexametaphosphate) is an interesting water softener because it reacts with the hardness ions, calcium, magnesium, and ion, forming complexes that are soluble.

Wetting Agents. Wetting agents are compounds that reduce the surface tension between a solution and a surface. In photography wetting agents are used to insure instant wetting and uniform processing over entire emulsion surface. Generally speaking, wetting agents are organic compounds having long fatty-acid chains with sulfonic or carboxyl groups attached.

Antiswelling Agents. These compounds prevent gelatin emulsions from absorbing water to the extent that there is danger of excessive softening and frilling. Difficulties of this type are encountered in warm weather and in tropical climates. Sodium sulfate, Na_2SO_4 or $Na_2SO_4 \cdot 10H_2O$, because it is inert and is very soluble, has become an almost universal antiswelling agent for photographic purposes. Additions in amounts sufficient to produce 6–10% concentrations in processing solutions are generally satisfactory.

Hardeners. Alum, chrom alum, aluminum sulfate, formaldehyde and tannic acid have been used as hardeners in developers. Normally special hardening is accomplished in rinse or predeveloper baths.

Penetration Control Agents. Inert materials forming viscous solutions like sugar, corn syrup, dextrin and glycerol, are used to control penetration in both fine-grain and color processing.

Tone Control Agents. The desire for procuring blue-black tones with paper emulsions, particularly the chlorides, bromides, and brom-chlorides, has led to the discovery of numerous agents for the production of blue-black tones. Included in this group are: benzotriazol, nitrobenzimidazol, nitroimidazol, nitrosoguanidine, quinoline, quinone chloride, and thiosemicarbazide. Potassium thiocyanate can also be used but is not as effective.

Silver Halide Solvents. Silver halide solvents have three functions in developers. In fine-grain development, potassium thiocyanate, ammonium chloride, and high concentrations of sodium sulfite exert a solvent action of the silver halide grain. In reversal processing, ammonia, ammonium salts, and thiocyanates prevent blocking of highlights, fogging and insure neutral tones. With developers for positive materials—prints, lantern slides and transparencies—the concentration of the halide solvents control the warmth of the image tones. (S.M.T.)

PHOTOGRAPHIC EMULSIONS. Photographic emulsions are not true emulsions but suspensions of minute silver halide crystals dispered in a protective colloid medium as gelatin, collodion, albumen, casein or agar. Attempts at using cellulose esters have been made recently; however, only gelatin and collodion are of commercial importance.

Gelatin is preferred as a photographic colloid, because the sensitizing bodies present in the gelatin make possible emulsions with greater sensitivity or speed. Gelatin is an excellent emulsifying agent and is readily transformed, from gel to a liquid or the reverse, by changes in temperature. The latter property makes coating of supports, and emulsion processing and working, feasible. The strong protective action of gelatin lowers the rate of reduction of unexposed silver halide crystals in developers so that image formation is readily obtained.

Silver halides employed in emulsions are, the chloride, the bromide and the iodide. Negative emulsions are composed of silver bromide with a small amount of silver iodide. Positive emulsions for films and paper contain silver chloride, or mixtures of silver chloride and silver bromide in varying amounts, according to the tone, speed, and contrast desired.

In **photomicrographs** of negative emulsions, the crystals of silver bromide appear as flat triangular or hexagonal plates with rounded corners. Some globular and needle-shaped crystals are also observed. The thickness of the flat plates is approximately 1/10 of their diameter. The size of silver bromide crystals range from less than 1 micron to 4 microns. Crystals of silver chloride, or mixtures of silver chloride and silver bromide, as used in positive emulsions, are quite uniform and seldom exceed 0.5 micron in diameter. Multi-layered emulsions contain approximately 1 billion, 10^9, crystals per sq. cm. The areas of individual crystals range from 0.1×10^{-8} cms. for low-speed emulsions to 1.0×10^{-8} cms. for high-speed negative emulsions.

The characteristics of an individual emulsion are primarily dependent on two factors, the size-frequency distribution of the crystals and the composition of the silver halide crystals. The chief problems of the emulsion-maker are the production of uniform suspensions of silver halide crystals with proper size-frequency distribution and correct composition in gelatin, and the ability to reproduce results.

Photographic emulsions are classified as follows:

1. Printing-out emulsions. These emulsions produce images on exposure without development. They are used largely for making portrait proofs which are distinguished by their red or purplish color. Emulsions of this type differ from others in that they usually contain silver nitrate, some free silver, silver salt of an organic acid and a weak free acid. These are known as P.O.P. Proof Papers.

2. Developing-out emulsions. Emulsions for development have an excess of alkaline halides. By varying the composition of the silver halide and treatment, developing-out emulsions may be prepared which are suitable for either negative or positive purposes.

a. Negative emulsions. Negative emulsions are prepared by adding a small amount of a soluble iodide to the bromide used in making the silver halide. The mixed crystals of silver-bromiodide formed are more sensitive to light and produce emulsions with greater speed than silver bromide alone. Negative emulsions are referred to as neutral emulsions if precipitation of the silver halide is carried out in a gelatin solution with an excess of soluble bromide, and ammonia emul-

sions if the precipitation takes place in a gelatin solution with an excess of soluble bromide in the presence of ammonia or ammoniacal silver. The latter method produces emulsions witht coarser grains which have the highest sensitivity.

b. Positive emulsions. Positive emulsions are prepared by precipitating silver halides containing chloride or mixtures of chloride and bromide in gelatin. The size of the crystals formed are smaller than those of negative emulsions and have a lower sensitivity. Positive emulsions are divided into four classes, according to the composition of the silver halides and their properties.

(1) Chloride emulsions. Because of their slow speed chloride emulsions are used largely for contact printing.

(2) Bromide emulsions. Bromide emulsions are very sensitive and fast. They are used for projection printing exclusively.

(3) Chlor-bromide emulsions. In chlor-bromide emulsions the amount of silver chloride is greater than that of silver bromide. These emulsions are somewhat faster than chloride emulsions and used for contact or slow projection printing. Chlor-bromide emulsions produce warm-toned silver images with a brown or brown-black color.

(4) Brom-chloride emulsions. Brom-chloride emulsions contain more silver bromide than silver chloride. They are faster than chlor-bromide emulsions and used for projection printing where black images and speed printing are desired. Image tones of brom-chloride emulsions are not as warm as chlor-bromide images nor as cold as bromide images.

The preparation of commercial emulsions are trade secrets but the basic procedures are known:

A portion of the gelatin in the formula is swelled by soaking in water and later dissolved with heat. Mixtures of soluble bromides and iodides, or chlorides, are placed in water solution and added to the gelatin solution. Precipitation of silver halides is accomplished by slowly adding a solution of silver nitrate, while stirring, to the mixture. The relative concentration of the solutions, the rate of addition and temperature during mixing, are factors which control the formation, size and dispersion of the crystals in gelatin. The emulsion is then heated or "ripened" at 40–80° C. to recrystallize the silver halides and readjust the size-frequency distribution. Following ripening, more gelatin is added and the emulsion is chilled so it will set quickly. The emulsion is then placed in a press and forced through a screen to break it into shreds or noodles, which are washed, in cold running water to remove the potassium nitrate formed, the excess soluble halides, and certain soluble by-products of the reaction. Chloride emulsions are often prepared without washing or with only a limited washing. After washing, the emulsion is drained, remelted, and additional gelatin and certain agents, such as fog preventatives, are added. The emulsion is then heated, or "after-ripened," to form sensitizing nuclei on the silver halide crystals. This operation increases the sensitivity and contrast of the emulsion and is necessary for the preparation of high-speed negative emulsions. Certain preservatives, or stabilizers, are added so the emulsion can be stored in refrigerated rooms until needed. Before coating the emulsion is melted and sensitizing dyes, hardening agents, wetting agents, etc., are added. After thorough mixing, filtering and heating to coating temperature, it is placed in a coating machine. Supports, as film, paper, or glass, with substratum coatings are fed through machines at proper rates so they become coated with emulsions in uniform layers of desired thickness. The coated supports pass over chill boxes to set the emulsion and then through a series of drying compartments where the rate of drying is carefully controlled so as not to change the sensitivity on the surface. Following drying, the coatings are inspected under proper safelights and the film or paper is cut to desired size and packaged. (S.M.T.)

PHOTOGRAPHIC PRINTING PROCESSES. Photographic printing processes may be classified, in accordance with the substance comprising the image, as follows:

1. Silver.
   a. Printing-out processes: gelatino-chloride, collodio-chloride.
   b. Developing-out processes: silver chloride, silver bromide, silver chloro-bromide.
2. Iron.
   a. Ferroprussiate (blue print).
   b. Cyanotype (positive blue print).
3. Iron and silver.
   a. Kallitype.
   b. Vandyke.
4. Platinum (platinotype).
5. Palladium.
6. Pigment processes.
   a. Carbon and carbro.
   b. Gum-bichromate.
   c. Fresson, Sury's process.
   d. Glue-print, Resinopigmentype.
   e. Oil-pigment processes (oil, bromoil).
7. Dye processes.
   a. Diazo- dye processes (ozalid).
   b. Dye-mordanting processes.
   c. Dye-bleaching processes.
   d. Dye-development processes.

All of these processes may be used for positive prints on paper, or other supports, to be viewed by reflected light or on glass, film, paper and other transparent supports for viewing by transmitted light.

Silver **printing-out** papers are almost obsolete, having been replaced by developing-out papers.

The only important process employing light-sensitive iron salts is ferro-prussiate (blue print) still widely used in the reproduction of mechanical plans, architect's drawings, etc., but being slowly replaced even in this field by processes employing diazo- dyes (ozalid). The **Vandyke** (silver-iron process) is used for the same purpose and for copies of tracings from which blue prints are to be made. Kallitype, a silver-iron process, is now obsolete.

The platinum and palladium processes employ iron salts as the primary light-sensitive material and from the standpoint of photochemistry should be considered as platinum-iron and palladium-iron processes. Both are now practically obsolete.

Of the various pigment processes listed only carbro is important, being in general use for the making of color prints from color-separation negatives. Bromoil is still used by a few of the older pictorialists for exhibition prints. The other processes mentioned are now obsolete.

Printing processes employing diazo- dyes have come into general use within the last decade and are now serious competitors to the older blue print for copies of tracings, plans, etc.

Dye-mordanting processes have been used principally for the color images required in making color prints from color-separation negatives. In recent years investigation along these lines has been dropped in favor of dye transfer (**imbibition**) processes, e.g., wash-off relief.

The other dye processes listed are confined to color photography, and there only to a limited degree. (C.B.N.)

PHOTOGRAPHIC REDUCTION. In photography, the term reduction is commonly applied to the processes by which the density of the image is lessened or reduced. Since photographic reduction is not chemically a reduction process, the terms (weakening) used in French and German literature are less open to confusion.

Photographic reducers may be classified as follows:

1. Subtractive. Reducing processes of this type remove the same amount of silver from every density. Thus, while the average density of the image is decreased, the contrast is increased.
2. Proportional. With proportional reducers, the amount of Ag removed from each density is approximately proportional to the original density. In this case, the over-all density is lessened without greatly changing the contrast of the image.
3. Superproportional. With superproportional reducers, the amount of Ag removed from the higher densities is relatively greater than that removed from the lower densities. Thus, the density of the highlights is lessened to a greater degree than the shadow portions of the image.

Photographic reducers are substances capable of converting metallic silver into a compound which is soluble in water, an acid, or other suitable solvent. A typical example is the ferricyanide-hypo reducer, commonly termed Farmer's reducer after its originator Howard Farmer (1883).

(a) $4Ag + 4K_3Fe(CN)_6 = Ag_4(CN)_6 + 3K_4Fe(CN)_6$,

(b) $3Ag_4Fe(CN)_6 + 16Na_2SO_3$
$$= 4Na_5Ag_3(S_2O_3)_4 + 3Na_4Fe(CN)_6.$$

In other words, the silver of the image is oxidized by the ferricyanide, forming silver ferrocyanide which is dissolved by the hypo (sodium thiosulfate). (See also **Superproportional Reducers, Proportional Reducers, Photographic Subtractive Reducers.**) (C.B.N.)

PHOTOGRAPHIC RELIEF ETCHING. A method of obtaining a dye-absorbing gelatin (or other colloid)-relief image for printing by color photography. The emulsion containing the silver image is treated with a solution which releases nascent oxygen. This oxygen attacks the colloid surrounding the finely divided silver grains and eventually "dissolves" the gelatin. If the silver image is a negative, a positive gelatin-relief image remains. Such a relief image may be dyed for transfer by **imbibition.** (H.C.C.)

PHOTOGRAPHIC SUBTRACTIVE REDUCERS. The majority of photographic reducers are of the subtractive type. Some of the more important subtractive reducers are:

Ferricyanide—hypo.
Ferricyanide—thiocyanate.
Ferricyanide—cyanide.
Iodine—hypo.
Iodine—cyanide.
Mercuric chloride—cyanide.
Cupric sulfate—sodium chloride.
Potassium permanganate.
Ferric chloride—hypo.

Some of these are highly poisonous and still others either soften or stain the emulsion. Practically either the ferricyanide-hypo or ferricyanide-thiocyanate reducers meet every requirement. The former is more widely used but the latter deserves to be better known as it is more stable and less likely to stain. (See also **Photographic Reduction and Proportional Reducers.**) (C.B.N.)

PHOTOGRAPHY. The word photography is derived from the Greek roots *photos* (light) and *graphos* (to draw). It is usually attributed to Herschel, although there is some doubt that he was the first to use it publicly. No earlier use of the word photography, however, can be found than in a letter from Herschel to Fox-Talbot dated January 17, 1839. His first published paper using the word photography appeared on March 14 the same year.

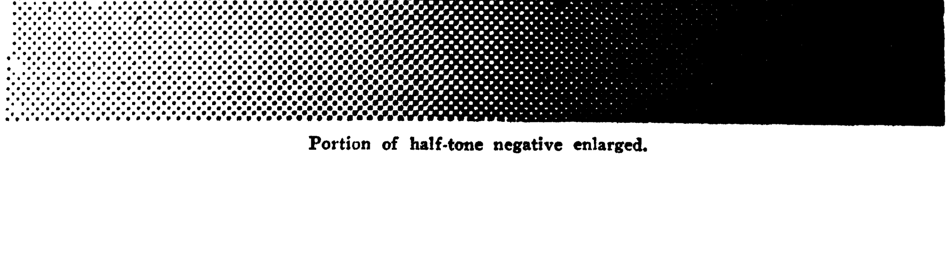
Modern photography includes all useful processes for the production of images through the action of radiant energy. Thus all processes employing materials sensitive to light, or to other forms of radiant energy such as the ultra-violet and infra-red, x-rays, the radiation of radium and other **radioactive substances,** are included in the scope of photography. These materials may or may not be used in a camera; the making of a blue print, for example, is a form of photography but does not involve the use of a camera. (C.B.N.)

PHOTOLITHOGRAPHY. Photomechanical Reproduction Processes.

PHOTOMECHANICAL REPRODUCTION PROCESSES. These processes include photoengraving, photolithography, photogravure and all photographic processes employed in the reproduction of photographs, drawings, paintings or type mechanically by the printing press.

Printing is usually divided into three classes: (1) relief printing, also called letterpress printing, (2) intaglio printing, and (3) planographic printing. In relief printing, the ink is transferred from the *raised* portions of the printing surface as in printing from ordinary type. In intaglio printing, the ink contained in the *depressed* portions of the printing surface is transferred to the paper to form an image, while in planographic printing the ink adheres only to certain parts of the printing surface and is repelled by the rest. Thus, in printing the ink which adheres to the plate is transferred to the paper to form an image.

Photoengraving. The process employed in the reproduction of photographs, drawings and the like by letter press printing is termed photoengraving. A brief description of the photoengraving process follows. The first step is to make a negative of the photograph, drawing or painting to be reproduced. If the subject is a photograph, or a subject with many different tones from light to dark, a *half-tone screen* is placed directly in front of the film, or plate, on which the photographic copy negative is made. This screen consists of two series of parallel lines at an angle of about 90° to each other, the clear spaces between the lines being approximately the same width as the opaque lines. The number of lines varies in different screens from about 60 to 150 per in., the coarser being used for newspapers, the finer for books and other printed matter employing smooth- or glossy-surfaced papers. The half-tone screen results in a dot image—the highlights being represented by large dots, the shadows by small dots. The accompanying illustration, which represents a portion of a half-tone negative enlarged, shows how the size of the dots vary with the tones of the subject. If this reproduction is examined from a distance, the dots are no longer seen individually but merge to form a continuous image.



Portion of half-tone negative enlarged.

The wet collodion process is still widely used in making the half-tone negative but is being superseded by sensitized glass plates and film made especially for the purpose.

To make a printing block for letterpress printing from the half-tone negative, a copper or zinc plate is first cleaned and then coated with fish glue which has been sensitized with ammonium bichromate. When this is dry, the sensitized metal plate is exposed beneath the half-tone negative to a powerful arc light. This renders the exposed portions of the glue insoluble in water; hence when the metal plate is washed in warm water, the unexposed (soluble) glue is washed away leaving parts of the surface bare. The next step is to etch the surface of the metal so as to form an image in relief. When the plate is of copper, ferric chloride is used for etching; while nitric acid is generally used for etching zinc plates. The exposed parts of the metal are attacked by the etching solution and a slight relief is built up. If the process is allowed to continue, however, the etching solution will begin to attack the copper lying beneath the resist. To prevent this, the plate is removed from the etching solution, washed in water and dried, after which a resin, known as Dragon's Blood, is applied to the edges of the relief image and finally this is "burned in" by holding the plate over a gas flame. The plate is now immersed a second time in the etching bath and the process continued until it is necessary to apply the resin a second time. This operation of dusting with the resin and etching may be repeated several times before the relief is sufficiently high to produce a good impression on the press. If part of the image should require deeper etching than the rest, asphaltum paint is applied with a brush to protect the portions which do not require further etching and the plate placed again in the etching bath. This operation of local etching is known as staging. When the work is completed, the asphaltum is removed with suitable solvents.

Zinc, rather than copper, is often employed for line and coarse-screen plates. The procedure is much the same as with copper except that the zinc plate is coated with shellac which has been sensitized with ammonium bichromate. After exposure beneath the negative the unexposed portions of the shellac coating are removed with alcohol leaving the exposed portions to form a resist for the etching process. Dilute nitric acid is used in etching.

Photolithography. Photolithography and offset (offset lithography) are alike except that in photolithography the ink is transferred directly from the plate to the paper while in offset the ink is first transferred from the plate to a rubber roller (blanket) and from this to the paper.

For photolithography and offset a half-tone negative is first made in essentially the same way as for photoengraving. This negative is printed on a zinc or aluminum plate sensitized with a solution of egg albumen and ammonium bichromate. After exposure beneath the negative, the plate is covered with a greasy ink and then washed in warm water to remove the soluble albumen, leaving on the plate an image of hardened albumen and the adhering ink.

To print directly from such a plate, it is first moistened with dampening rollers. The water is taken up by the clear areas but is repelled by the greasy ink which is retained by the hardened albumen. Thus when the water-charged plate is brought into contact with the ink rollers, the hardened albumen accepts the ink but the metal repels it, so that the distribution of ink on the plate reproduces the tone gradations of the image as recorded in the negative. Then when the plate is brought into contact with the paper in the printing press, the ink is transferred to the paper.

In offset (offset lithography) the inked image is first transferred to a rubber roller or "blanket" and then to the printing paper. The offset process enables prints to be made on coarse, rough papers because a more complete transfer of ink can be obtained on such papers from a pliable rubber surface than the harder surface of a metal plate. A further advantage of offset printing is that a larger number of copies can be made since contact with the rubber blanket is less damaging to the image on the metal plate than direct transfer to paper. Offset lithography has spread rapidly in recent years and its use is still on the increase.

For large runs—25,000 copies or more—the so-called deep-etch process is employed. Despite the term "deep etch" the degree of etching is so slight that the process is still properly classified as planographic printing. In the deep-etch process the plate is exposed beneath a positive rather than a negative. After exposure, the plate is washed in warm water to remove the soluble albumen and the exposed parts of the metal plate are lightly etched—grained would perhaps be a more descriptive term—with a weak acid solution. It is then rinsed in water, dried and inked. The hardened albumen is removed by scrubbing the plate with a stiff brush after which the plate is coated with a gum solution. This is retained by the bare parts of the metal (where the hardened albumen had been) but is repelled by the etched areas which are filled with the greasy ink. To print from such a plate, it is first moistened by dampening rollers. The water is absorbed by the areas coated with the gum solution, and repelled by the etched areas which are filled with an ink. Thus the etched portions accept the ink from the inking rollers on the printing press while the water in the gum-coated portions repel it to form an image in which the variations in the quantity of ink correspond with the densities of the positive from which the plate was made.

Gravure. The gravure, or intaglio, processes include photogravure and rotogravure, the latter familiar to most as the process used for the illustrated supplement of Sunday newspapers. Photogravure and rotogravure differ only in minor details. Grained plates are employed in photogravure and the plates printed on a flatbed press while a gravure screen is used in rotogravure and the image is engraved on large copper cylinders from which prints are made in a cylinder (rotary) press. Both photogravure and rotogravure, however, are continuous-tone processes; the screen used does not break up the image into a dot formation as does the halftone screen. Both processes differ from photoengraving and photolithography in requiring a positive rather than a negative. The positive is made directly from the negative (without a screen of any kind) on a slow gravure film which usually has a matt surface to facilitate local retouching. In use, it is exposed and developed much like any other slow, blue-sensitive film emulsion. This positive is next printed on a sheet of gravure tissue which is a gelatin-coated paper sensitized with ammonium bichromate. The effect of exposure beneath the positive is to render the gelatin insoluble to varying depths depending upon the densities of the positive. In other words, the depth of hardening is directly proportional to the amount of exposure under the different densities of the negative, being greatest in the highlight and least in the shadow portions of the subject.

After exposure beneath the positive, the gravure tissue is exposed again but this time beneath the gravure screen. The gravure screen consists of thin transparent lines at right angles to each other with large opaque rectangles between. The object in using the screen is to produce a pattern of fine lines in the image which will enable the wiping blades on the printing press to remove the ink from all but the depressed portions of the printing surface and thus maintain clear, ink-free highlights. The screen has little or no effect on tone rendering and is hardly noticeable.

After this second exposure, the carbon tissue is applied to the copper plate or cylinder so as to obtain intimate contact between the gelatin and the metal plate. Hot water is then poured over the back of the tissue to soften the soluble gelatin. When the gelatin has softened sufficiently, the paper backing is stripped, leaving the gelatin adhering to the metal. Further washing in warm water removes the soluble gelatin, leaving an image in hardened gelatin firmly attached to the surface of the copper.

The plate, or cylinder, is now ready for etching. Ferric chloride is used for this purpose. The action of the etching solution varies with the gelatin image, being directly proportional to its thickness so that the variation of tone from dark to light in the subject is represented by proportional differences in the depth of the etched portions.

In printing from such a plate, the ink taken up from the inking rollers varies with the depth of etching, so that the shadow portions of the image contain the most ink, the half-tones less and the highlights still less. The ink is removed from all but the depressed (etched) areas by wiping or "doctor" blades. Then, on contact with the paper, the ink remaining on the plate is transferred to the paper to form the image. (C.B.N.)

PHOTOMETRY. The measurement of luminous intensity, of luminous flux density, or of **illumination** is known as photometry. The intensity of a light source may be expressed in candles or other arbitrarily defined source-units (see **Candle Power**), while luminous flux density and illumination are expressed in lumens per unit area of cross-section or of surface. A "lumen" is the amount of light or luminous flux received upon a unit surface, all points of which are at a unit distance from a concentrated source of one spherical candle intensity.

Photometers are of many types. Those used for flux-density and candle-power measurement are ordinarily designed to compare the unknown with a known source by balancing in some way the flux densities from the two sources. The most common representatives of this type are the various forms of **bench photometer, of wedge photometer, of polarization photometer,** and of **integrating photometer.** An important aspect of light-source photometry is the study of the distribution of luminous intensity in different directions,—a variable which the integration photometer is designed to average. Direct indications of luminous flux density or of illumination are afforded by photometers utilizing the **photoelectric cell, the selenium cell,** or the photronic cell (see **Photovoltaic Effects**). **Spectral energy distribution** is analyzed by means of various types of **spectrophotometer.**

Since the energy of **radiation** is not at all equally stimulating to the optic nerve, we must recognize two different measures of its intensity: (1) the luminous flux density, in lumens per sq. cm. of cross-section, corresponding to the visual sensation evoked, and (2) the actual flow of power, in watts, per sq. cm., called the radiant flux density. The ratio of the one to the other for any wavelength is the "visibility factor" for that wavelength, while for the whole of any emission (all wavelengths) the corresponding ratio is called the "luminous efficiency" of the emission. The efficiency of a light source is expressed in lumens of visible output per watt of input power. For example, 10 lumens per watt would be typical for modern incandescent lamps such as are in domestic use.

The problem of determination of the brightness of the stars and other objects external to the earth will be found discussed under the heading of **Stellar Photometry.** (L.D.W.)

PHOTOMICROGRAPHY. The photography of objects with the microscope. It should be distinguished from microphotography which is the term applied to production of small images. (See **Microphotography; Metallography.**)

The apparatus for photomicrography consists of a light source, the microscope and a camera (Fig. 1) all

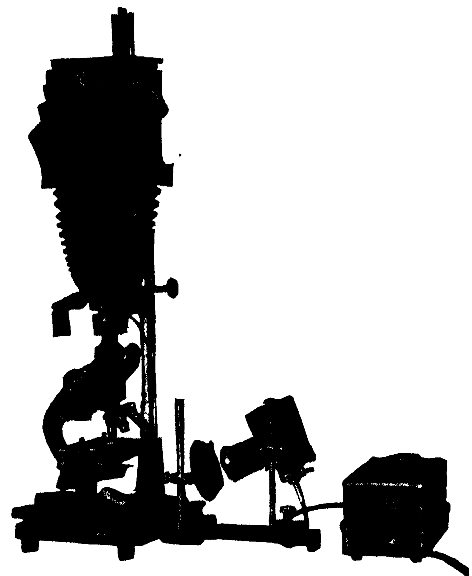


Fig. 1. Leitz vertical photomicrographic camera, with microscope and lamp in position. (*Allen's Photo-Micrography.*)

mounted on a rigid base. The procedures usually employed in preparing specimens for microscopic examination are followed in the preparation of materials for photomicrography. Biological materials are cut into thin sections with a microtome, stained with dyes, if necessary, to disclose their structure, mounted on glass slides and photographed by *transmitted* light. Opaque objects, such as metals, alloys, stones, etc., are ground to a smooth, flat surface, polished, and etched chemically to reveal the structure and photographed by *reflected* light, using a special type of microscope frequently termed a *metalloscope.*

Usually, the advantage of photomicrography over visual examination with the microscope is that a permanent record is obtained. This permanent record is available for study and comparison with others at any time. This is particularly important in the study of changes occurring in an organism or the effect of stress, heat, or chemical treatment on a metal or an alloy. Used with ultra-violet radiation, photomicrography almost doubles the resolving power of the microscope. The increased resolving power is of great value in the study of colloidal particles, the mechanism of filtration and adsorption, pigments and filters, etc. Ultra-violet photomicrography has the further advantage of enabling many organisms and organic structures to be photographed without the staining which is necessary for visual examination. Thus living tissue, which cannot be stained, may be photographed. With certain subjects, the possibility of using infra-red radiation is of special value.

Ciné-photomicrography, motion pictures with the microscope, is of particular value in studying the growth of organisms, movements of colloidal particles, chemical processes, etc., and is rapidly assuming considerable importance.

Photomicrographs in color can be made by most processes although the integral tripack processes (see **Color Photography**) are the most convenient. (C.B.N.)

PHOTON. Light.

PHOTOPERIODISM. This term is applied to the reaction of plants to the daily length of the period of illumination. It is one of the most noteworthy of the reactions of plants to an environmental factor. In most parts of the world marked seasonal variations occur in the length of the daylight period. In temperate zones the length of the daylight period varies from about 8 or 10 hours at the winter solstice to about 14–16 hours at the summer solstice. At higher latitudes the annual variation in day length is greater; at lower latitudes less. In arctic and sub-arctic regions the length of day varies from 24 hours on the longest summer days to zero hours on the "shortest" days; in the equatorial zone day lengths approximate 12 hours the year round.

Although the length of the photoperiod (number of hours of illumination per day) also has effects upon the vegetative development of plants its most significant influences are upon flowering and other phases of the reproductive development of plants. Plants fall into three fairly well defined categories: 1. "Long-day" species, which flower more or less readily in a range of photoperiods longer than a certain critical period, developing only vegetatively under shorter photoperiods. 2. "Short-day" species, which flower more or less readily in photoperiods shorter than a certain critical period, developing only vegetatively at all longer photoperiods. 3. "Indeterminate" species, which exhibit no critical photoperiod, developing both vegetatively and reproductively over a wide range of photoperiods. The length of the critical photoperiod differs according to species but for many plants of both the long-day and short-day types lies in the range of 12 to 14 hours. Examples of short-day species are dahlias, chrysanthemums, asters, cocklebur, and salvia; of long-day species, radish, beets, dill, spinach, lettuce, and grains; of indeterminate species, tomato, cotton, sunflower and buckwheat. Both long-day and short-day varieties may exist even within the same species. Some varieties of soybeans, for example, are short-day plants, while others are long-day plants.

In temperate regions the season of blooming of a plant is largely determined by its photoperiodic reaction. In general short-day plants bloom in the early spring or early fall; long-day plants in the late spring or summer. The geographical distribution of some kinds of plants is at least partly controlled by their photoperiodic reaction. A species cannot maintain itself in a climate in which it is impossible for the cycle of reproductive processes to be completed. Pronounced long-day species, for example, would not as a rule be found in tropical regions.

The leaves are the loci of the reactions leading to the initiation of flower development in plants. If the leaves of short-day Biloxi soybean plants are exposed to long days while the meristems at which flowers are initiated are exposed to short days, no development of flowers takes place. If, however, the leaves are exposed to short photoperiods while the meristems are exposed to long photoperiods, differentiation of flowers soon starts. In like manner, if only the leaves of a long-day dill plant are exposed to photoperiods of suitable length, development of flowers begins very shortly. The mechanism of the photoperiodic reaction is clearly such that the influences of certain processes which occur in the leaves must be transmitted to the meristems, inducing the initiation of flower development. It seems highly probable, therefore, that a hormone-like substance, which is synthesized in the leaves only under suitable photoperiodic conditions, is translocated to the meristems, inducing differentiation of floral parts. The name "florigen" has been suggested for this hypothetical flower-inducing hormone.

If a vegetative short-day plant is transferred from a long day to a short day, exposed to a suitable number of short-day cycles and then returned to a long day, flowers will develop even under long-day conditions. This phenomenon is called "photoperiodic induction" and occurs in long-day as well as in short-day species. The number of suitable cycles required for photoperiodic induction varies according to species.

A fundamental physiological difference between short-day plants and long-day or indeterminate plants is that the former require a cyclic alternation of light and dark periods if flowers are to develop, while the latter do not. In the short-day Biloxi soybean, for example, flowering is induced only if the plants are exposed to a suitable number of dark periods, each more than 10 hours in length, alternating with light periods of not less than 2 nor more than 20 hours, and optimally about 11 hours in length. Furthermore the dark period must proceed without interruption for at least a certain minimum length of time. For example, in the cocklebur a dark period of sufficient length to induce flower initiation becomes completely ineffective if interrupted at its midpoint by as little as one minute of light of even a relatively low intensity. Long-day and indeterminate plants do not require an alternating cycle of light and dark periods. Most if not all such species will bloom under continuous illumination. Long-day species do, however, require a light period of minimum duration out of each 24-hour day in order for flowers to develop. For dill, a good example of a long-day species, the minimum length of photoperiod which will induce flower differentiation is between 11 and 14 hours. Indeterminate species seem to differ from long-day species chiefly in the fact that they can bloom under shorter photoperiods than the latter.

Practical applications of the principles of photoperiodism have been made in the growing of floricultural greenhouse crops. Short-day species such as chrysanthemums, can be brought into bloom earlier in the fall by decreasing the length of their daily exposure to light. Likewise the time required for long-day floricultural species to attain the flowering stage during the winter months can be shortened by increasing the day length with artificial illumination. (B.S.M.)

PHOTOPHORESIS. Very fine solid or liquid particles suspended in a gas or falling through a vacuum are sometimes given a unidirectional motion by a strong beam of light, and the motion is called photophoresis. If the particles move with the light, the effect is said to be positive; if against the light, it is called negative. Positive photophoresis is usually ascribed to **radiation pressure,** or regarded as the resultant of radiation pressure and the Crookes radiometer effect of the surrounding gas. Negative photophoresis, observed in fine suspended particles of sulfur or selenium by Ehrenhaft (1917), is thought by some to be due primarily to the radiometer effect. If there is present also a strong electric or magnetic field, the motion may have a component in the direction of the field. (L.D.W.)

PHOTORECEPTOR. A sensory organ which responds to the stimulus of light waves. **Eyes** are the most familiar organs of this kind but many 1-celled animals are sensitive to light and some of the more complex forms have the surface of the body sensitive to it. True eyes serve for the formation of a visual image whereas the more simple photoreceptors merely indicate the luminosity of the animal's surroundings. In some cases adjustment to light is necessary and the simple light-sensitive organ is adequate for the initial step in the animal's orientation. Eyes serve the very different purpose of enabling the animal to perceive objects about it and are not primarily associated with its adjustment to light. Man depends to an extreme degree on his vision but his skin is sensitive to light in an entirely different way which becomes evident only in the degree of pigmentation. (A.W.L.)

PHOTOSPHERE. The intensely bright portion of the sun which is visible to the unaided eye is known

as the photosphere. In reality it is a layer not more than a few hundred miles in thickness which marks the boundary between the dense interior gases of the sun and the cooler, more attenuated gases which go to make up the solar atmosphere. The photosphere radiates with a continuous **spectrum** and the application of the **laws of radiation** indicates that its temperature is about 5750° K.

In appearance the photosphere is brilliantly white, somewhat brighter at the center than at the limb, and is distinctly granular in character. These granules are in reality very large, as much as several hundred miles in diameter, and are relatively short-lived, photographs taken at intervals of less than a minute showing distinct changes. Larger irregular bright areas known as faculae may be frequently seen. Spectroscopic analysis of the light from the faculae indicates that they are masses of heated gases which are rising out through the photosphere to the atmosphere.

Spectroheliographic studies of the photosphere show the presence of areas of hydrogen and calcium vapor, known as flocculi which are somewhat smaller than the faculae and larger than the "granules."

The **sun spots** are relatively dark areas which appear on the photosphere. (W.K.G.)

PHOTOSTAT. Drawing Reproduction.

PHOTOSYNTHESIS. It has long been known that the green parts of plants, when exposed to light under suitable conditions of temperature and water supply, use carbon dioxide from the atmosphere and release oxygen to it. These gaseous exchanges are the opposite of those which occur in **respiration** and are the external manifestation of the process of photosynthesis. In this process hexose **carbohydrates** are synthesized from carbon dioxide and water by the chloroplasts of living plant cells in the presence of light, oxygen being a by-product of the reaction. For each molecule of carbon dioxide used one molecule of oxygen is released. The summary chemical equation for photosynthesis is:

$$6CO_2 + 6H_2O + 673 \text{ kg.-cal.} \rightarrow C_6H_{12}O_6 + 6O_2.$$

As a result of this process radiant energy of sunlight is stored up as chemical energy in the molecules of carbohydrates and other compounds which are derived from them.

In the vascular plants photosynthesis occurs chiefly in the leaves. Carbon dioxide diffuses into the intercellular spaces of the leaf from the atmosphere chiefly through the **stomates,** and then dissolves in the moist walls of the mesophyll cells. The carbon dioxide then diffuses, in solution, to the surface of the **chloroplasts,** which are the actual seat of the process. In most plants the water used in photosynthesis is absorbed by the roots from the soil whence it is translocated to the leaves (see **Ascent of Sap**). In most plants only a very small fraction of the water which reaches the leaves is used in photosynthesis, the bulk of it being lost from the plant in **transpiration.** Except for a usually small portion used in respiration the oxygen set free in the process diffuses out of the leaf into the atmosphere, mostly through the stomates.

Other carbohydrates besides hexoses are synthesized in the leaves, apparently as a result of secondary reactions which follow photosynthesis. Sucrose invariably accumulates in actively photosynthesizing leaf cells. This more complex sugar is built up from the molecules of the simpler hexoses. In most plants insoluble starch also accumulates in leaf cells during photosynthesis. This carbohydrate is synthesized by the condensation of numerous glucose molecules. The sucrose and starch content of leaves decreases during the night as a result of continued **translocation** out of the leaves into other parts of the plant. The sucrose is probably translocated as such, but the starch, being insoluble, must first be converted into simpler, soluble sugars before it can move out of the leaves. The synthesis of starch is not restricted to the green parts of plants but also occurs in many non-green parts as well. A familiar example is the accumulation of starch in potato tubers. The starch in the non-green cells is made out of glucose which comes from the leaves or other photosynthetic organs. Starch occurs in cells in the form of small grains, the type of grain being formed in each kind of plant being more or less characteristic of that species.

Photosynthesis takes place in chlorophyll-containing cells only when carbon dioxide, water and light are available, and when a suitable temperature prevails. Although carbon dioxide constitutes, on the average, only 0.03% of the atmosphere, land plants are entirely dependent upon this source for the carbon dioxide used in photosynthesis. It can be shown experimentally that increasing the carbon dioxide concentration of the atmosphere results, under otherwise suitable conditions, in an increased rate of photosynthesis. If the concentration of this gas in the atmosphere were higher than it is, many plants, much of the time, would photosynthesize at a more rapid rate than they do. In nature sunlight is the source of radiant energy used in photosynthesis although plants will also photosynthesize under artificial light sources of suitable quality and intensity. The intensity, quality, and daily duration of illumination all have an influence on the amount of photosynthesis accomplished per day. The minimum light intensity at which a measurable rate of photosynthesis occurs varies according to species, but is seldom less than 1% of full mid-day summer sunlight. Under natural conditions maximum rates of photosynthesis are attained in single leaves of many species at 25–35% of full sunlight intensity and in some shade species at even lower intensities. The rate of photosynthesis for an entire tree or for a field of grain usually increases with increase in sunlight intensity up to the maximum possible value, which at noon on a clear summer's day in temperate regions is about 1.3 gram-calories per cm.^{2} per min. This relation holds because in a tree or plot of vegetation many of the leaves are shaded by other leaves and hence the higher the incident light intensity the higher the average intensity actually reaching the surface of the leaves. For equal intensities more photosynthesis appears to occur in the orange-short red and blue parts of the spectrum than in the green and yellow. In general the longer the daily period of illumination the more photosynthesis will be accomplished by a plant in the course of a day. A deficiency of water results in a reduced rate of photosynthesis. One of the detrimental effects of prolonged drought upon plants is the marked resulting reduction in the amount of sugar manufactured in photosynthesis. The range of temperatures most suitable for relatively rapid rates of photosynthesis is not the same for all kinds of plants. In general it is higher in tropical than in temperate species, and higher in temperate species than in those of sub-arctic regions. Most photosynthesis in temperate zone plants occurs within the range of 10–35° C. Increase in temperature results in an increase in the rate of photosynthesis up to an optimum which is not the same for all kinds of plants, but which for most temperate zone species lies within the range of 20–30° C. With increase in temperature above the optimum the rate of photosynthesis decreases progressively.

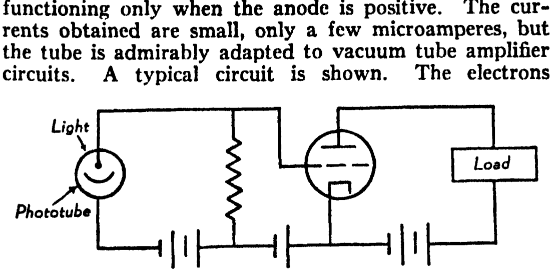
Photosynthesis is the most important of all biological processes. The existence of the entire biological world of plants and animals, with negligible exceptions, hinges upon this process. From a few simple inorganic compounds and from the sugar made in photosynthesis are built up all of the complex kinds of molecules essential in the construction of the bodies of plants and animals or to the maintenance of their existence. Some of these subsequent synthetic processes occur in the plant body; others in the bodies of animals after they have ingested plant materials as foods. Likewise the energy used by

plants and animals all represents sunlight energy which was entrapped in sugar molecules during photosynthesis. The entire organic world runs by the gradual expenditure of the energy capital accumulated in photosynthesis.

The magnitude of the photosynthetic process is a question of great biological significance. Corn plants yielding 100 bushels to the acre synthesize about 8700 kg. (nearly 10 tons) of sugar in a growing season. About 33 million kilogram-calories of radiant energy must be transformed into chemical energy in order to accomplish the synthesis of this quantity of sugar. The efficiency of the process is relatively low, however. Only about 1.6% of the radiant energy falling on the acre during the growing season is actually utilized in photosynthesis. The annual world production of sugar by terrestrial plants is estimated at 4×10^{18} kilograms; this represents the transformation of 1.6×10^{17} kg.-cal. of radiant energy into chemical energy. The annual production of sugar by marine plants, mostly **diatoms,** is estimated to be at least twice as great as the production of terrestrial plants and may be considerably greater. (B.S.M.)

PHOTOTROPISM. **Movement in Plants; Tropism.**

PHOTOTUBE. This is a photosensitive or light-actuated electron **tube,** often popularly referred to as an electric eye. Basically the tube consists of a **cathode** which is photosensitive, i.e., it will emit electrons when illuminated, and an **anode** for collecting the **electrons** emitted by the cathode. There are several materials which are suitable for use as the cathode, some being better suited for a given range of the spectrum than others so the choice is often on the basis of the color light to be used. A widely used cathode for general purposes is a composite of silver which has been coated with caesium and then subjected to an oxygen treatment so the surface is a mixture of silver, caesium and caesium and silver oxides. This surface is one of the most sensitive and at the same time is very sensitive to visible and infra-red light. Other tubes are constructed with **cathodes** which are sensitive to ultra-violet radiation. The exact structure of the tubes varies, some being made by coating the inside of the glass tube with sensitive material and having a center wire for an anode, others by having a semi-cylindrical, a W- or a V-shaped cathode base coated with the sensitive material and a vertical wire located to allow easy collection of the electrons with minimum interference with the light. Since the electrons emitted by the cathode must be drawn to the anode an external source of voltage is required for the operation of the tubes. This voltage normally ranges from a few volts to approximately 100 volts and while usually d.c. it may be a.c., the tube functioning only when the anode is positive. The currents obtained are small, only a few microamperes, but the tube is admirably adapted to vacuum tube amplifier circuits. A typical circuit is shown. The electrons



emitted by the action of light cause a current to flow around the phototube loop and thus produce a voltage drop in the resistor in the grid circuit of the vacuum tube. This grid voltage in turn causes a variation in the plate current and for a linear circuit this current will be an amplified image of the phototube current. Gas at a low pressure is often put in the tube to amplify the currents by **ionization** of the gas. When this is done care is necessary to keep the gas from breaking into a self-maintaining discharge. The intense ionization of a self-maintaining discharge would produce excessive bombardment of the cathode and soon destroy the sensitized surface. The gas-tube currents may also be amplified by vacuum tubes. Phototubes are used in innumerable industrial control applications where interruption of a beam of light is all that is necessary to bring about the desired operation. They are also the basis of the reproducing system of the sound-on-film talking picture systems. (See also **Facsimile.**) (L.R.Q.)

PHOTOVOLTAIC EFFECTS. Several possibly related but very imperfectly understood phenomena are classified under this term. They are characterized by the creation of an **electromotive force** through the incidence of **light.** Two cases only will be described.

The first, discovered by Becquerel and known as the Becquerel effect, employed an electrolytic cell, for example, one with silver electrodes coated with silver iodide and immersed in dilute sulfuric acid. The electrodes being exactly alike, nothing happened so long as the cell was in the dark or even when it was uniformly illuminated. But if one electrode was illuminated more than the other, the cell set up an electromotive force.

A recent type of photovoltaic cell, developed by Lange and much studied, has for one electrode a copper plate, covered by a thin layer of its own oxide (a semiconductor). This "blocking layer" of oxide is, in turn, sputtered with a film of conducting metal, such as aluminum, so thin that it is nearly transparent, but still capable of acting as an electrode. Such an assemblage, in the dark, acts as a **rectifier.** But when light falls on the copper oxide layer, the cell also produces an electromotive force of its own, and if placed in a circuit, causes a current nearly proportional to the illumination. The uses of this device promise to be many. For example, a form having a **selenium** film and known commercially as the "photronic cell," coupled with a sensitive milliammeter, is now used as a direct reading **illumination photometer.** This instrument is familiar to photographers in the rôle of an exposure meter. (L.D.W.)

PHOTRONIC CELL. **Photovoltaic Effects.**

PHREATIC. The term proposed by Daubree in 1887 for the waters of the **ground water** reservoir, as distinct from the underground waters above the water table, called **vadose.** (R.M.F.)

PHRENIC NERVES. The nerves which control the movement of the **diaphragm.** (D.M.H.)

PHTHALEINS. **Phthalic Acid.**

PHTHALIC ACID, PHTHALATES, AND PHTHALEINS. Ortho-phthalic acid, benzene-orthodicarboxylic acid ($C_6H_4(COOH)_2(1,2)$) is a white solid, melting point 191° C., decomposes, insoluble in cold but soluble in hot water, when heated loses water to form phthalic anhydride $\left(C_6H_4{<}\begin{matrix}CO\\CO\end{matrix}{>}O\right)$, a white solid, melting point 128° C., boiling point 285° C. Reacts with **phosphorus** pentachloride to form phthalyl chloride $\left(C_6H_4{<}\begin{matrix}COCl\\COCl\end{matrix}\right)$, which further reacts with aluminum chloride to form unsymmetrical phthalyl chloride $\left(C_6H_4{<}\begin{matrix}CCl_2\\CO\end{matrix}{>}O\right)$. Both chlorides react (1) with **zinc** plus **acetic acid** to form unsymmetrical phthalide $\left(C_6H_4{<}\begin{matrix}CH_2\\CO\end{matrix}{>}O\right)$, and (2) with **benzene** plus **aluminum**

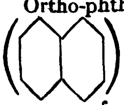
chloride to form unsymmetrical-diphenylphthalide phthalophenone $\left(C_6H_4{<}^{C(C_6H_5)_2}_{CO}{>}O\right)$.

Phthalic anhydride reacts (1) with **ammonia** to form phthalimide $\left(C_6H_4{<}^{CO}_{CO}{>}NH\right)$, white solid, melting point 238° C., which latter compound reacts (a) with **potassium** hydroxide in alcohol to form potassium phthalimide $\left(C_6H_4{<}^{CO}_{CO}{>}NK\right)$. When potassium phthalimide is treated with an alkyl halide, e.g., ethyl iodide, ethyl phthalimide $\left(C_6H_4{<}^{CO}_{CO}{>}N\cdot C_2H_5\right)$ is formed, from which the primary **amine**, ethyl amine ($C_2H_5NH_2$) may be obtained (plus phthalic acid) by heating with fuming **hydrochloric acid** (Gabriel's synthesis for primary amines), (b) with sodium hypochlorite, to form sodium anthranilate $\left(C_6H_4{<}^{NH_2}_{COONa}\right)$, which yields, upon treatment with an acid, anthranilic acid $\left(C_6H_4{<}^{NH_2}_{COOH}\right)$; (2) with phenol to form phthaleins, e.g., (a) **phenol** plus phthalic anhydride at 120°, in the presence of sulfuric acid concentrated, forms phenolphthalein $\left(C_6H_4{<}^{C{<}^{C_6H_4\cdot OH(4)}_{C_6H_4\cdot OH(4)}}_{CO}{>}O\right)$, white solid, melting point 261° C., soluble in alkali ot form a red solution, and used as an indicator to determine the neutral point in **titrating** acidic or basic solutions, (b) resorcinol plus phthalic anhydride, similarly, forms resorcinolphthalein, fluorescein $\left(C_6H_4{<}^{C{<}^{C_6H_3{<}^{OH(4)}_{O(2)}}_{C_6H_3{<}OH(4)}}_{CO}{>}O\right)$ dark yellow solid, decomposes above 290° C., dissolves in alkali to yellow-red solution, which exhibits green fluorescence when dilute. When fluorescein and **bromine** react tetra-bromofluorescein $\left(C_6H_4{<}^{C{<}^{C_6HBr_2{<}^{OH(4)}_{O(2)}}_{C_6HBr_2{<}OH(4)}}_{CO}{>}O\right)$ is formed, the **potassium** salt of which is known as eosin, and used as a red dye for wool and silk, (c) N-diethyl-meta-aminophenol plus phthalic anhydride, similarly, forms N-diethyl-meta-amino-phenol phthalein, rhodamine

$$\left(C_6H_4{<}^{C{<}^{C_6H_3{<}^{N(C_2H_5)_2(4)}_{O(2)}}_{C_6H_3{<}N(C_2H_5)_2(4)}}_{CO}{>}O\right)$$

a red dye.

Ortho-phthalic acid is made by oxidation of **naphthalene**

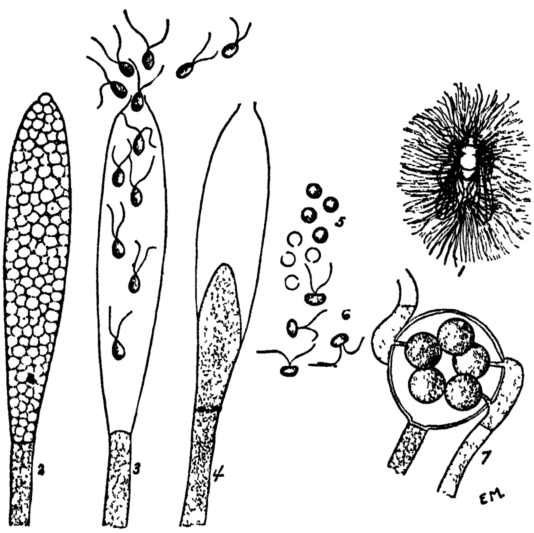


(1) with **sulfuric acid** fuming heated, in the presence of mercuric sulfate, (**sulfur** dioxide also formed, and recovered), (2) with air in the presence of vanadium pentoxide at 450° to 520° C. Ortho-phthalic acid is also formed when **benzene** compounds, containing carbon ortho-substituted groups, are oxidized. Ortho-phthalic acid is used in the manufacture of **indigo** and other dyes. (R.K.S.)

PHTHISIS. Pulmonary **tuberculosis.** (D.M.H.)

PHYCOMYCETES. The Phycomycetes form a group of **fungi** so diverse in habit as to suggest **polyphyletic** origin, quite probably from several different groups of green **algae,** to which many of them show remarkable similarity. Simpler members of the Phycomycetes consist of but a single cell, while other species have a well-developed branching **mycelium,** always composed of **hyphae** possessing no cross-walls. Many species grow in water and are known as water molds. Others grow out of water. Among the latter are some of the common destructive **parasites.**

In the water-inhabiting species reproduction by asexual **zoöspores** is common. These zoöspores are produced in **zoösporangia,** which are cut off by cross-walls from the ends of the otherwise non-septate



Saprolegnia. Stages in development. 1, fungus growing on a dead fly in water; 2, sporangium with newly formed spores; 3, sporangium discharging zoospores; 4, formation of new sporangium; 5, resting stage following first motile stage 3; 6, second motile stage following resting stage 5; 7, fertilization of eggs in oogonium.

mycelium. Each zoöspore possesses two apical **cilia,** by means of which it swims about for a time. After this it becomes quiet and secretes around itself a cell wall. From this it may escape as a second type of zoöspore possessing two laterally inserted cilia. After a period of quiescence and wall-formation this second zoöspore puts out a germ tube which develops into an extensive mycelium. The significance of the two kinds of zoöspores, which do not appear in all species of water molds, is not entirely understood. In the non-water inhabiting Phycomycetes asexual reproduction is by means of conidia, minute cells formed in chains or in large masses borne in various ways on the tips of special branches called conidiophores. The conidia are discharged in the air and are borne about by air-currents.

Sexual reproduction occurs in many Phycomycetes, varying considerably in the different orders, and is a basis for the separation of this group of fungi into two subclasses, the Oömycetes and the Zygomycetes. In the first the sexual cells are distinctly unlike in size, or heterogamous, while in the second they are alike or isogamous. Seven orders are recognized in the Phycomycetes, three of them being important. One of these is the Water-molds or Saprolegniales, the members of which are aquatic and closely resemble certain algae, but are without **chlorophyll.** These fungi include **saprophytes** living on both animal and plant remains, and **parasites,** many of the latter being serious pests in aquaria and fish hatcheries, attacking both fish and eggs. Sexual reproduction is by means of **oögonia** and **antheridia,** although in many species antheridia seem to be functionless and in other species completely lacking. In such cases the oögonia develop

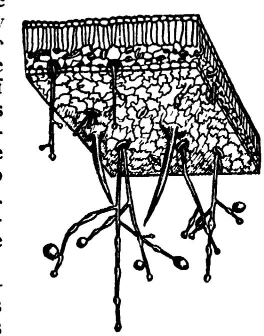
without the aid of antheridia, such development being called parthenogenesis. The oögonia are rounded bodies cut off from the tips of hyphae. The antheridia, when present, appear as branches from the hypha which bears the oögonium. These branches grow up around the oögonium into which they develop lateral fertilization tubes penetrating the oögonial wall. When mature, the contents of the oögonium break up to form several spherical eggs, each of which is reached by a fertilization tube. Through this tube a nucleus passes from the antheridium to the egg, where it unites with the egg nucleus. Subsequently a thick wall is formed around each egg, which then passes through a prolonged resting period. Germination of this resting cell is by a germ tube.

The similarity between green algae such as *Vaucheria* species and the Water molds has been frequently noted, and suggests a relationship between them, and lends support to the idea that the Phycomycetes have developed from such green algae through the loss of their chlorophyll and the assumption of a saprophytic habit. According to another theory, the simpler members of the Phycomycetes fall into a line of evolution which starts from non-pigmented unicellular organisms called Flagellates and gradually gives rise to the whole series of Fungi today existing.

A second order of Phycomycetes is made up of parasites on higher plants, many of them being of great importance because of the injury they do to cultivated crops. This order is the Peronosporales, and contains fungi known as Blights and Downy Mildews. In this order the mycelium is composed of hyphae which penetrate between the cells of the host plant tissue, sending into those cells short absorbing tubes called haustoria. Asexual reproduction in this order is by means of conidia, which in some genera are borne in chains in extensive areas beneath the epidermis of the host plant, and liberated by the breaking of this epidermis, and in other genera by conidia borne on the tips of the branches of hyphae which extend outward above the epidermis of the host. These conidia are scattered by the wind and, if they reach a suitable host, give rise to several small laterally biciliate zoöspores; the latter form germ tubes which penetrate the tissues of the host plant, thus causing new infections. Sexual reproduction occurs in the deeper tissues of the infected plant and is very similar to that occurring in the Water-molds. However, each oögonium develops only one egg. This egg is fertilized within the host tissues and remains there until the latter disintegrate. After this the egg germinates, giving rise to biciliate zoöspores or in some species producing a mycelium directly.

Many members of this order are of great importance, because of their parasitic nature. One of these is the Downy Mildew of Grapes, *Plasmopara viticola,* which was introduced from America into Europe where it became a grave menace to the grape vines. This unfortunate introduction, however, led to the discovery of a control, **Bordeaux mixture.** Originally this mixture was used as a spray to grapevines along the highway as a means of preventing pilfering. It was noticed that the plants so treated were not infected by the fungus, while others were. So the treatment was extended and led to a control of the fungus.

A second serious disease caused by one of the Peronosporales is Potato Blight, due to *Phytophthora infestans.* This fungus attacks the entire plant and in serious cases may completely kill all parts above ground. It appears as a white mold on the under surface of leaves. This whiteness is caused by the abundant conidiophores. It is this disease which caused the great potato famine in Ireland in 1845. Frequent spraying with Bordeaux mixture is an effective control.



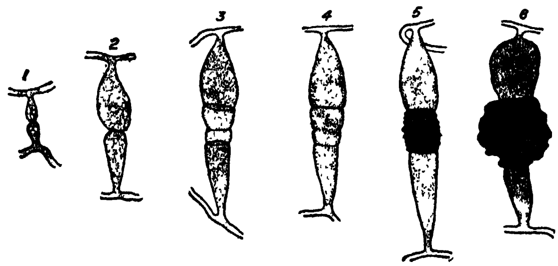
Perspective view of potato leaf with conidiophores of *Phytophthora infestans* protruding from stomata and bearing conidia.

Damping-off is another disease caused by fungi of this order. The causal organisms are usually species of the genus *Pythium,* which attack the stems of seedling plants near the level of the ground and so weaken them that they fall over and the plant dies. Since moisture favors the growth of this fungus, partial control is obtained by aeration and the avoidance of high humidity.

A third order of Phycomycetes is the Mucorales, and contains the familiar black mold of bread, *Rhizopus nigricans,* a very common species. In this fungus there is an extensive much-branched colorless mycelium which

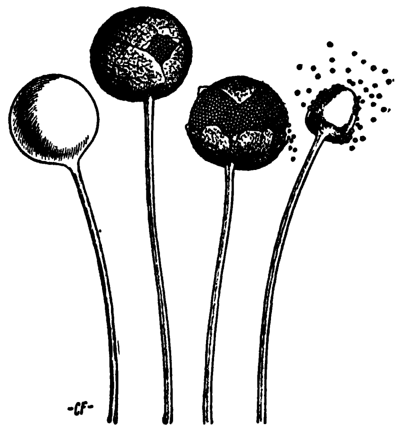
Left, a potato plant affected with late blight; right, potato leaves showing infected areas.
(New York Agricultural Experiment Station, Geneva, Bulletin 241.)

spreads over and within the substratum. Short branches of the mycelium penetrate the substratum and extract from it nutrient materials; erect branches from the mycelium terminate in sporangia, or spore-bearing bodies. The spores of *Rhizopus* are minute spherical bodies pro-



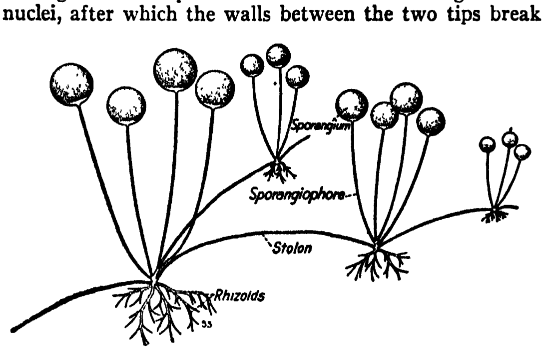
The formation of the zygote of *Rhizopus nigricans.*

duced in immense numbers. When mature they are scattered far and wide. Exposure of a piece of moistened bread anywhere will soon demonstrate how widely scattered and abundant these spores must be: seldom does such a piece of bread fail to nourish a luxuriant growth of this black mold. Sexual reproduction in this order



Sporangia of *Rhizopus* of different ages.

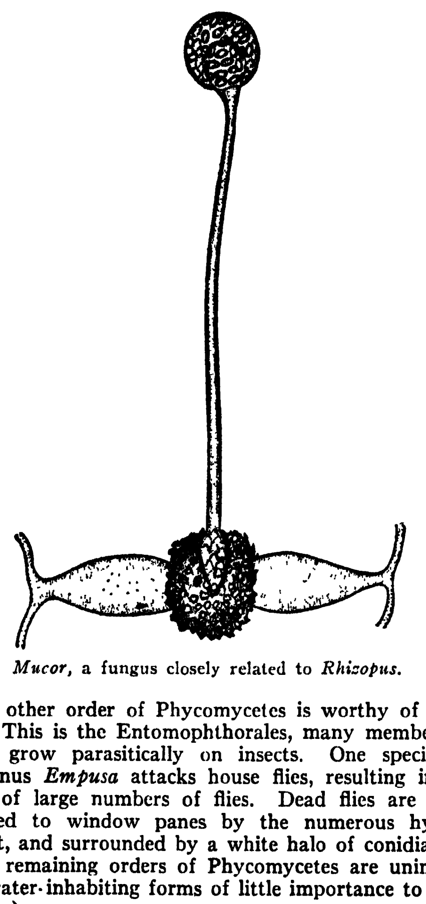
is entirely unlike that in the two described earlier. In this group, tips of branches from two different plants come together. Each tip enlarges considerably and becomes densely filled with protoplasm. A wall forms, cutting off the tip of each branch containing several nuclei, after which the walls between the two tips break



Rhizopus. Plant spreading by stolons and bearing sporangia on sporangiophores.

down and their contents fuse. The resulting cell, called a zygospore, enlarges conspicuously and becomes invested in a thick dark-colored wall. This zygospore usually undergoes a prolonged resting period before germinating. Nuclear fusion in pairs occurs during the formation of the zygospore. Zygospore formation occurs in a similar fashion in other members of the Mucorales.

In many species, zygospores are formed but rarely. One reason for this is that many species are heterothallic, that is, require the union of hyphae from two plants which look exactly alike but are of very different nature. These hyphae must come from spores which are likewise different, and are usually described as + and − hyphae; often the terms female and male are applied to them, the +, or female, strain showing a more vigorous habit. Species in which the spores are all alike are called homothallic; in these, zygospores are readily formed between hyphae from a single spore, or branches of the same mycelium. Many species in the Mucorales show much-branched conidiophores and are objects of rare beauty when observed with a microscope.



Mucor, a fungus closely related to *Rhizopus.*

One other order of Phycomycetes is worthy of mention. This is the Entomophthorales, many members of which grow parasitically on insects. One species in the genus *Empusa* attacks house flies, resulting in the death of large numbers of flies. Dead flies are often attached to window panes by the numerous hyphae present, and surrounded by a white halo of conidia.

The remaining orders of Phycomycetes are unimportant water-inhabiting forms of little importance to man. (R.M.W.)

PHYLACTOLAEMATA. Ectoprocta.

PHYLLITE. A metamorphic rock intermediate between **slate** and **schist** and characterized by a crinkly surface with the development of much **mica** or micaceous minerals such as **chlorite.** Phyllites may be white due to the presence of **sericite,** green if **chlorite** is present, or red or black due to various organic and mineral substances. Phyllite as a term is derived from the Greek word meaning a leaf, referring to the **cleavage,** though this physical property is much better developed in slates and some schists. Some phyllites are highly **metamorphosed** clay sediments, others represent metamorphosed tuffs, and even felsites, also phyl-

lites have been formed by **mylonitization** of **graywackes, granites,** and other rocks. (E.S.C.S.)

PHYLLOPODA. **Crustacea.**

PHYLLOPODIUM. A form of the biramous appendage of crustaceans in which the general structure is in broad thin plates, with thin walls. They are often associated with the mouth and function in feeding and in respiration. In a few forms they are swimming appendages. (A.W.L.)

PHYLLOTAXY. **Leaf.**

PHYLLOXERAN, PHYLLOXERID. Insecta, Homoptera. A sucking **insect** related to the plant lice and scale insects. The many species make up a subfamily which, with the adelgids, constitutes the family Phylloxeridae. They differ from the **aphids** in that all females lay eggs and form the scales in their more complex structure, including the four wings of the winged stages.

The most important phylloxerid is a species which attacks grapevines, working on the leaves and roots. It once threatened to ruin the vineyards of France and has destroyed millions of acres of vines. The use of roots of certain American grapes which are not seriously harmed by the pest has greatly lessened the danger from its attack. Tender varieties are grafted onto the resistant roots. (A.W.L.)

PHYLUM. A principal subdivision of the animal kingdom. **Classification.** (A.W.L.)

PHYSICAL CHEMISTRY. Physical chemistry is that branch of chemistry which deals with the theoretical aspects of chemistry, using as its basis the ultimate particles of matter and their fundamental laws as formulated by physics. Whereas the latter science treats of properties which are common to all matter and energy, physical chemistry is primarily concerned with an interpretation of differences found among the various species of matter. The subject matter of physical chemistry is usually divided into the following topics: Properties of **Gases**; Properties of **Liquids**; Properties and Structure of **Solids**; Theory of **Equilibrium**; Theory of Dilute **Solutions**; Theory of Electrical **Conduction** in Liquids; **Ionization**; Ionic Equilibria; **Thermochemistry** and **Thermodynamics**; **Velocity of Reactions**; **Photochemistry**; **Catalysis.** (R.K.S.)

PHYSICAL CIRCUIT. **Phantom Circuit.**

PHYSICAL DEVELOPMENT. In photography the term physical development is applied to a method of developing the latent image in which the developer contains free silver ions and a reducing agent, such as metol, paraminophenol, etc., in an acid state and deposits silver from the solution on the exposed grains of silver halide. Thus the silver forming the developed image is obtained from the solution and not, as in chemical development, from the reduction of the exposed grains of silver halide.

Physical development has been recommended frequently for miniature work because of the fine grain of the image but has never become popular because in practice it is less reliable than other methods, being more likely to cause general fog and because of the increased exposure required.

It is possible to develop an image after fixation using a physical developer; the exposure, however, must be greatly increased and the process is of theoretical interest only. (C.B.N.)

PHYSICAL MAGNITUDES AND PHYSICAL EQUATIONS. Physics is a quantitative science, dealing primarily with things measurable and expressible in units. There are hundreds of these physical magnitudes, some simple, some requiring elaborate definition. Many obvious relations exist between them; for example, pressure (or any stress) is the ratio of a force to an area. Careful study reveals that most physical magnitudes have their measures so defined that they may be expressed in terms of not more than three elementary or **fundamental** magnitudes, combined in various ways. As to which magnitudes should be regarded as fundamental, custom has fixed the choice upon length, mass, and time; to which many physicists add magnetic permeability and dielectric constant, making five in all. In the **c.g.s. system,** for example, the first three of these magnitudes are respectively represented by the centimeter, the gram, and the second, and all other physical units of the system except the magnetic and electric units are expressible in terms of these. Thus the unit of speed is 1 centimeter per second; of area, 1 square centimeter; of force (the dyne), 1 gram-centimeter per second per second; etc. This analysis may be generalized so as not to depend upon any specified system of units. Thus if length be denoted by L, mass by M, and time by T, the "dimension formula" for speed becomes L/T, for area L^2, for force ML/T^2, etc. The derivation of such relationships, called "dimensional analysis," is a highly important item in theoretical physics.

In order that two physical quantities may be equal, or that one may be added to or subtracted from the other, it is obvious that they must have the same makeup and be expressible by the same combination of fundamental units. It follows that in an equation expressing relationship between physical magnitudes, both members and all terms of each member must have the same dimension formula. For example, the total area of a right circular cone of altitude h and having a base of radius r is $a = \pi r^2 + \pi r\sqrt{r^2 + h^2}$, each term of which has the dimension formula L^2 (since π is abstract). Again, the phase angle ϕ of an **alternating current** of frequency n (per second) in a circuit of resistance R (ohms), inductance L (henrys), and capacitance C (farads) is given by

$$\tan\phi = \frac{4\pi^2 n^2 LC - 1}{2\pi nRC}.$$

Since $\tan\phi$ is an abstract quantity, the fraction on the right must also be abstract. Since the 1 in the numerator is abstract, the other term $4\pi^2 n^2 LC$ and the whole numerator must be also; hence the denominator is abstract. That is n, R, and C should have such dimensions that the component fundamental magnitudes cancel when the product nRC is formed. This is true; for the dimension formula of n is $1/T$, and (in electromagnetic measure) that of R is $\mu L/T$, and of C, $T^2/\mu L$; in which μ represents magnetic permeability. Some physical magnitudes are themselves abstract, and therefore independent of the system of units in use; **specific gravity** and **refractive index** are in this class. (L.D.W.)

PHYSICAL MEASUREMENTS. Physical quantities have practical significance only as they are capable of measurement and of expression as bearing definite numerical ratios to appropriate units. In some cases this comparison can be made directly, as by applying a yardstick to the length of a room. More often the quantity to be measured is incapable of such direct attack, and must be determined by means of known relationships to other quantities which are observable. Thus an electric current can be measured only by appealing to certain of its effects; for example, it can be made to form an electrochemical deposit for an observed time and the mass of the deposit then weighed. Likewise, the observable change in volume of mercury is a convenient "measure" of change in temperature.

Most physical units are expressible in terms of certain

primary standards, which are units of the fundamental magnitudes, length, mass, and time; sometimes in connection with the properties of specified substances. In most physical measurements these primary standards are the **meter**, the **kilogram**, and the mean solar day. Other "derived" units are defined in terms of these or of multiples or aliquot subdivisions of them (**centimeter, gram**; see **C.G.S. System**). Thus the **density of** a substance may be expressed in $g./cm.^3$, the **watt** of power is $10^7 g.cm.^2/sec.^3$. The centigrade degrees is 1/100 of the temperature interval between the freezing and boiling points of water, which is subdivided on the basis of some specified temperature measure such as the pressure or the volume of a gas, the electrical resistance of a wire, etc., and these in turn must be determined in units appropriate to the respective magnitudes. When the measurement of a physical quantity gives its value in terms of the quantities used in defining its fundamental units, the measurement is said to be "absolute." This is the case, for example, with the measurement of electric current by observing the **force** with which a **magnetic field** of known intensity acts upon the conductor carrying the current. (See **Abampere.**)

In all physical measurements, the instruments used must be "calibrated"; that is, the relation of each subdivision on the instrument scale to the unit of the quantity measured must be ascertained. If each subdivision corresponds to exactly one unit, the instrument is said to be "direct reading"; this is usually true, for example, of **ammeters** and **voltmeters**, but seldom of **galvanometers.**

Various instrumental principles have become standard in physics. We have, for example, many instruments utilizing the **vernier**, the **micrometer**, or the **optical lever** principle. There are also certain well-known general observational methods, some of which are designed to minimize errors. In the method of "substitution," a quantity is determined by substituting for it a known quantity which produces the same effect. In the very common "differential method," the quantity required is the difference between two actually measured quantities. The "null" or "balance" method consists in adjusting the apparatus so that the indicator of the measuring instrument reads zero, as the galvanometer used with a **Wheatstone bridge.** In the "cumulative method" a large multiple of the quantity sought is measured, e.g., the thickness of a sheet of paper may be found from that of a thousand sheets. The "coincidence method" is useful in measuring periodic phenomena, as in comparing the periods of two pendulums by observing how often the swings coincide. "Compensation" applies to any method in which an error is made to neutralize itself, as in double weighing (see **Weighing Methods**). Many other schemes, often highly ingenious, are in common use in physical laboratories. (See **Errors of Measurement.**) (L.D.W.)

PHYSICAL METALLURGY. **Metals and Alloys.**

PHYSIOGRAPHIC PROVINCES. **Physiography.**

PHYSIOGRAPHY (GEOMORPHOLOGY). The description and interpretation of the surface features or topographic pattern of the earth. The scientific interpretation of scenery. The science of physiography is one of the major subdivisions of the earth sciences. The term is sometimes loosely used as synonymous with geography, hence the recent tendency to use geomorphology in its place. Since the scenery of any region is fundamentally the present stage of its geologic history, it naturally follows that a discussion of the origin of the topographic or scenic features must include not only an account of the processes of **erosion** and **deposition** which are now active, or have been active in the region, but also the manner in which the agents of erosion have been affected or controlled by the stratigraphy and structure. The relatively modern science of Geomorphology is peculiarly American in its origin and

Map of North America, showing its main political and physical divisions.

development, and the United States has been divided into a number of physiographic provinces whose natural boundaries have little or no relation to the political or state boundaries. (R.M.F.)

PHYSIOLOGY. A division of biological science which deals with the normal functions of the living body. General physiology is a science which treats of the underlying physical and chemical foundations of vital processes. Physiology in the usual sense is concerned with the more evident vital processes themselve, analyzed to some extent in terms of physics and chemistry but without any attempt to reduce them generally to purely physico-chemical fundamentals.

Physiology, especially the physiology of man, deals with many details of the processes which maintain a normal state of vital activity within the body. Among them the maintenance of a normal internal environment is intimately associated with blood chemistry and the circulation. The maintenance and utilization of reserves of material, the action of **enzymes, nervous coordination**, and **chemical coordination** by **hormones** are other important factors. The response of organs to coordinating influences is also involved in this subject. The **all-or-none law** bears upon this topic.

Much of the material of physiology is associated with the organ systems. It is briefly considered under **contractility, digestion, respiration, circulation, excretion**, and **reproduction.** A limited amount of physiological material is also mentioned under the various organ systems associated with these processes. (A.W.L.)

PHYSIOTHERAPY. An aid to the treatment of the sick or injured by means of physical agents. This includes massage, various forms of light, heat, and electricity, ultra-violet light, air, water, and exercise. Physiotherapy is used extensively in restoring function of wasted, stiff, or contracted muscles after injuries, especially fractures of bones, or after **paralysis**, particularly infantile paralysis. (R.S.M.)

PHYSOPODA. **Thysanoptera.**

PHYTOMONADIDA. **Mastigophora.**

PI SECTION. This is a type network in which the elements are arranged in π shape, i.e., a shunt element across the circuit at each end of a series element. (L.R.Q.)

PICA, PIKA. Mammalia, Rodentia. Small **rodents** related to the rabbits. They live chiefly at high altitudes, ranging from 11,000 to 19,000′, and are found only in the northern hemisphere. Two species of the genus *Ochotona* occur in the mountains of western North America and about two dozen in the Old World. All are compactly built, with small ears and a rudimentary tail. In the Old World they are also called tailless hares or mouse-hares. (A.W.L.)

PICHI. Mammalia, Edentata. The pigmy **armadillo,** *Chlamyphorus,* of Argentina. (A.W.L.)

PICIFORMES. An order of birds including the **woodpeckers, toucans,** and related species. They are found in all parts of the world except the Australian region. Most species nest in holes in trees. (A.W.L.)

PICKEREL. Pisces, Teleostei. Fresh-water fishes (**Pisces**) of three species closely related to the pikes and muskellunge. All are North American, living in streams and lakes. They differ from the pike and muskellunge in having both the cheeks and the opercula fully scaled. The little pickerel of the Mississippi Valley and Great Lakes Basin is sometimes called the grass pike, and the true pike is sometimes known as the northern pickerel. All of these species belong to a single genus, *Esox.* (A.W.L.)

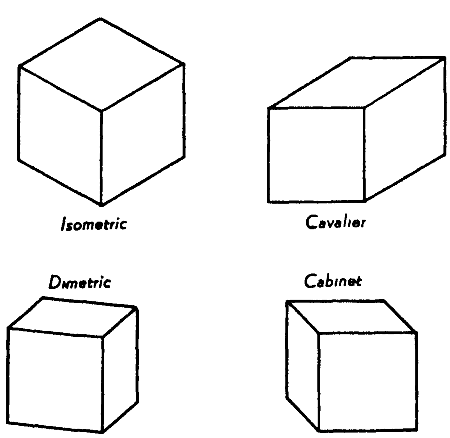
PICKLING. **Scaling.**

PICOLINE. **Pyridine.**

PICRIC ACID. **Phenols.**

PICRITE. A rock which, like **peridotite,** is made up chiefly of **femic** minerals, but contains a little **feldspar,** usually **labradorite.** Sometimes **analcite** is present, in which case the rock is called an analcite-picrite. (E.S.C.S.)

PICTORIAL REPRESENTATION. A method of representation based upon oblique representation, in which the effect of perspective representation is obtained.



In the practical application of pictorial representation, three principal axes are selected, and the actual lengths of the edges of the object are laid off along these axes, resulting in a drawing that is not correct from the standpoint of either orthographic or perspective representation. Since the relative proportions of the object are retained, however, the differences do not detract from the value of the representation. In some forms of representation, however, one or more edges may be drawn to a reduced scale, termed scale reduction, to more closely simulate perspective representation.

The figure shows the appearance of a cube as represented pictorially. Isometric and cavalier drawings correspond to angular and parallel perspective; no scale reduction is used along any axis. Cabinet drawing is similar to cavalier, with scale reduction, usually one-half, along the inclined axis. Dimetric drawing has one vertical and two inclined axes, with one-half scale reduction along the sharply inclined axis. Clinographic representation is used for representing crystals, and employs three reference axes so selected that no face of the crystal will appear as a line. (H.C.H.)

PICTURE PLANE. **Perspective.**

PIDDOCK. Mollusca, Lamellibranchiata. A **bivalve mollusk** that bores in soft rock and floating wood. Especially a European species of the genus *Pholas,* commonly used as bait and in some localities regarded as a delicacy. The family to which these animals belong is near that containing the **shipworms.** Also spelled piddick. (A.W.L.)

PIE CHART. A method of representing relative magnitudes totaling 100% by means of a circular area divided into sectors whose included angles are proportional to the quantities involved. The pie or 100% circle chart is not as effective as other forms of representation, but has gained favor because of its advertising appeal, particularly when colors are used to differentiate between the area sectors. (H.C.H.)

PIER. A pier is a **masonry** structure acting in compression, the purpose of which is to support, in a suitable manner, some superstructure such as a **bridge,** a **trestle,** or a wall. Wharves which project into the water to accommodate vessels which berth alongside are also called piers. Piers of this type allow a great many more ships to be docked in a given length of water frontage. The pier may vary from a simple platform-like structure supported on **piles,** to a costly plant which is roofed and walled and provided with elevators, freight storage rooms, passenger waiting rooms, customs inspection facilities, etc. In bridge practice the pier is usually the intermediate support of a multiple-span bridge, its function being to support the intermediate ends of the spans and to do so with minimum obstruction to the stream. Such piers are often made of reinforced concrete, though, in earlier days, they were made of ashlar stone masonry. The pier is built with its long dimension parallel to the stream so that it will receive a minimum of impact of floating debris, ice, and other waterborne loads and will give the least obstruction to the flow of the stream. Thus piers often have to be set on a skew to the bridge center line giving rise to so-called skew bridges. It must support the dead weight of the bridge, and loads due to wind acting on itself and on the bridge and moving load, traction forces, and live and impact loads. In building construction the wall pier is an enlarged section of the wall similar to a **column** which provides lateral rigidity for the wall and may be used to support beams or trusses. (F.T.M.)

PIEZO- AND PYRO-ELECTRIC PHENOMENA. A number of **dielectric** crystalline substances manifest the curious property that, when subjected to strain in suitable directions, they develop electric polarization. Such substances are said to be piezo-electric, and were first observed by Haüy in 1782 and independently by Curie in 1880. Notable examples are quartz (SiO_2) and

Rochelle salt (sodium potassium tartarate, $NaKC_4H_4O_6 \cdot 4H_2O$).

The directions in which tension or compression develop polarization parallel to the strain are called the piezo-electric axes of the crystal. Thus the axis of a hexagonal quartz crystal indicated by the arrows in Fig. 1 is known as an "X-axis," and a plate cut, as shown, with its faces perpendicular to this direction is an "X-cut"; while one cut with its faces parallel to the lateral faces of the crystal is a "Y-cut."

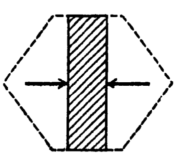


Fig. 1.

The magnitude of the piezo-electric polarization is proportional to the strain and to the corresponding stress, and its direction is reversed when the strain changes from compression to tension. The principal piezo-electric constants of a crystal are the polarizations per unit stress along the piezo-electric axes. While these constants are much greater for Rochelle salt than for quartz, the latter is better adapted to some purposes because of its greater mechanical strength.

Always associated with the piezo-electric property is the inverse property known as electrostriction, namely, the development of mechanical strain as a result of electric polarization. Thus if a piezo-electric plate is placed between metal electrodes and the latter given a difference of potential, the plate becomes either thicker or thinner, depending upon which electrode is positive and which negative.

If a quartz plate is subjected to a rapidly alternating electric field, the inverse piezo-electric property causes it to expand and contract alternately. As an elastic body, the plate has a certain natural frequency of expansion and contraction in the direction of the field, and if the field is made to alternate with the same frequency, the plate responds with a vigorous resonant vibration. This reacts, through the direct piezo-electric property, to augment the electric oscillations. A circuit arranged for this purpose, as in Fig. 2, is known as a piezo-electric or crystal oscillator, the crystal itself, *P*, being the piezo-electric resonator; *T* is the oscillation transformer, and *C* a variable condenser. This device has been much used as a **frequency** control in radio transmitters. Both X-cut and Y-cut quartz plates are subject to changes of frequency with temperature, due to change of elastic modulus; but certain planes in the crystal have been found, oblique to both X and Y, such that plates cut parallel to them are nearly free from the temperature effect.

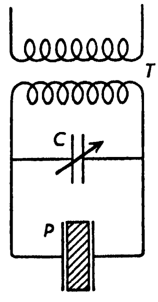

Fig. 2.

The very high piezo-electric response of Rochelle salt makes it adaptable to **microphones** of the crystal type, now extensively used. In these the crystal is subjected to a variable bending or torsional strain, due to the vibrations of the diaphragm.

The heating or cooling of certain crystals develops polarization similar to piezo-electric polarization. In some cases, at least, this may be a secondary result of thermal expansion or contraction, that is, an indirect piezo-electric effect. This phenomenon is known as "pyro-electricity." (See **Crystal.**) (L.D.W.)

PIEZOMETER TUBE. A piezometer tube is a tube which is inserted into a region of fluid flow so as to obtain in the connecting tubing a pressure equal to the static pressure existing in the stream. If the piezometer tube be not carefully located, it will receive some impact or suction by **Pitot** action, and the pressure indicated by it will be in error. For this reason, the piezometer tube location has been the subject of some considerable study. It should open into the stream perpendicular to the thread of the stream, and be made flush with the conduit wall. (F.T.M.)

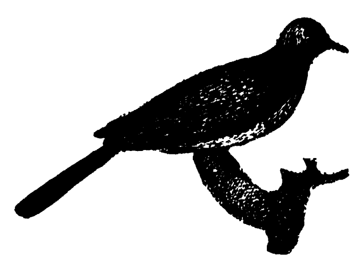
PIG. Mammalia, Artiodactyla. A group of hoofed animals with two functional and two reduced toes on each foot, all with separate metacarpal or metatarsal bones. They are not ruminants (i.e., they do not chew the cud). The true pigs make up the family Suidae and a closely related family Tayassuidae contains the **peccaries.**

Pigs are native to the warmer parts of Europe and Asia, the Oriental region, and Africa. None occur in North or South America, although feral races have developed in some areas. In these continents the peccaries are the only native pig-like animals.

Two of the most peculiar species of pigs are the **babirusa** of Celebes and Boru and the **wart-hogs** of Africa. The former have four tusks in the male sex, all directed upward and recurved. The enormous heads of the wart-hogs, with their wart-like protuberances and stout tusks, make these animals conspicuously ugly. (A.W.L.)

PIGEON. Aves, Columbiformes. The birds (**Aves**) of this order are almost exclusively characterized by the name pigeon or dove, although a few related species of the Old World are known as sand grouse. The extinct dodo also belonged here.

Pigeons and doves have the beak swollen at the tip and covered with soft skin at the base, about the nostrils. In North America the group is represented by the band-



Mourning dove, *Zenaidura macroura carolinensis.* Soft olive brown above, buff-gray below, white tips to outer tail feathers.

tailed, *Columba fasciata,* and red-billed pigeons, *Columba flavirostris,* of the western part of the continent, and by several species of doves of similar distribution. The turtle dove, *Streptopelia,* is the only widely distributed species, although the extinct passenger pigeon, *Eclopistes migratorius,* remains a memory of one of the most abundant and widely distributed birds. Numerous other species are found in all of the faunal regions of the world. They bear the names dove or pigeon, which have no exact scientific distinctness, with the exception of an Australian species called the wongawonga. The **dodo** of Mauritius and the **solitaire** of Rodriguez Island, both now extinct, were giant flightless pigeons. The last of these birds disappeared in the late 17th and in the 18th centuries, respectively. (A.W.L.)

PIGMENTATION IN ANIMALS. The accumulation of colored materials in living things which is partly or wholly responsible for the characteristic **coloration** of different species. Pigments also serve special purposes in the body. In these functions the presence of color may be entirely incidental to the chemical composition of the material.

Pigments are important in visual organs. Here impervious black or dark brown deposits insulate the sensitive nerve endings against all light except that which is transmitted by the lens or cornea. In the eyes of some **arthropods** the pigment is redistributed to admit more light when the surrounding illumination is dim than when it is bright. A similar result is gained in the vertebrate eye by the muscular adjustment of the pig-

mented iris to change the size of the pupil through which light is admitted. Still another pigment, the visual purple (rhodopsin) is found in the rods of the retina of the vertebrate eye. It is bleached by light and resumes its color in darkness; it is associated with the sensitivity of the eye.

Pigments in the superficial layers of the body are also useful in some animals, independently of the relations discussed under coloration. A familiar example is the protective pigment deposited in the human skin as a protection against **ultra-violet light**. The deposition normally follows excessive exposure to sunlight or to other sources of ultra-violet, and the deposits are lessened when exposure is reduced. These deposits are in the form of granules of melanin in the cells of the innermost layer of the **epidermis** and in branching cells called melanoblasts in the underlying dermis. The pigment loses its granular form and becomes diffuse as the epidermal cells move toward the surface. Melanoblasts are possibly active in the formation of the pigment granules. The pigmentation of hair is not thoroughly understood but both granular and diffuse pigments have been reported.

A definite relation also exists between the normal illumination of the body and pigmentation in other animals, but the nature of the relation is not always known and a definite value to the animal need not exist. A familiar example is the dark upper surface and light lower surface of fishes, whether the upper surface is dorsal, as in most species, or lateral, as in the **flatfishes**. Lack of pigment in fishes of subterranean waters is closely associated.

Pigmentation of **insects** has been shown in several cases to respond to light. Lessened illumination may result in deeper colors, and some observers have secured the same result by moderate increase of light. Extreme changes, however, have resulted in decreased pigmentation in some experiments. Humidity and temperature also affect the depth of pigmentation in some insects, and may modify the pattern.

Incidental colors like the pink flush of human skin result from the presence in the body of the respiratory pigments, haemocyanin and haemoglobin, and waste products. Protein wastes deposited in the superficial tissues of insects are one source of color and the bile pigments of vertebrates, formed by the liver in the modification of haemoglobin, are a source of color in some organs.

The entire subject is closely associated with the chemistry of the living organism on the one hand and with coloration and mimicry on the other. (A.W.L.)

PIGMENTS IN PLANTS. The distinctive green color of leaves and many other plant organs results from the presence in such organs of two pigments called chlorophyll *a* and chlorophyll *b* (see **Pyrrole and Related Compounds**). In the higher plants these pigments occur only in the chloroplasts (see **Plastids**). The molecular formula for chlorophyll *a* is $C_{55}H_{72}O_5N_4Mg$; for chlorophyll *b*, $C_{55}H_{70}O_6N_4Mg$. The structural formulae for the molecules of the chlorophylls have also been worked out. The chlorophylls are not water-soluble but can be readily dissolved out of leaf tissues with alcohol, acetone, ether, or other organic solvents. The resulting solutions exhibit the phenomenon of fluorescence; they are deep green when held between an observer and the light, but deep red when viewed in reflected light. By suitable treatments it is possible to obtain pure crystals of chlorophyll from such solutions. Most leaves contain considerably more chlorophyll *a* than chlorophyll *b*, often two to three times as much. In the organs of the higher seed plants, with rare exceptions, chlorophyll is synthesized only upon exposure to light. Leaves of grass which develop under a board, for example, contain no chlorophyll. In the leaves of mosses, ferns, and gymnosperms, however, chlorophyll develops in the dark as well as in the light. The chlorophylls play an indispensable biological role because their presence in plant cells is essential for the occurrence of **photosynthesis**.

Invariably associated with the chlorophylls in the chloroplasts are the yellow pigments carotene and the xanthophylls. These pigments are not, however, restricted in their occurrence to the chloroplasts, but may also be present in non-green parts of the plant where they commonly occur in *chromoplasts*. Collectively these pigments, together with certain others which are closely related chemically, are called the *carotinoids*. Carotene is an orange-yellow pigment with the chemical formula $C_{40}H_{56}$. It is especially abundant in the roots of carrots. This compound is of considerable importance because it is the precursor of vitamin A, one molcule of β-carotene being split into two molecules of vitamin A by a simple hydrolytic reaction. Lycopene, a red carotinoid which is isomeric with carotene, is responsible for the red color of the fruits of tomato, pepper, rose and some other species. The commonest xanthophylls found in leaves are lutein and zeaxanthin although others also occur. Both of the above-mentioned xanthophylls have the formula $C_{40}H_{56}O_2$. Another xanthophyll is *fucoxanthin* which imparts to brown **algae** their distinctive color. None of the carotinoids are water-soluble, but all of them can be extracted from plant tissues with suitable organic solvents.

Most of the red, blue, and purple pigments of plants belong to the group of *anthocyanins*. These pigments are chemically related to the **glucosides** and usually occur dissolved in the cell sap, being water-soluble. In general the anthocyanins are red in an acid solution and change in color through purple to blue as the solution becomes more alkaline. Red pigmentation resulting from the presence of the anthocyanins is found in flowers, fruits, bud scales, young leaves and stems, and sometimes even in mature leaves as in those of the red cabbage. Blue and purple pigmentation due to the presence of anthocyanins occurs principally in flowers and fruits.

Another group of cell sap water-soluble pigments is the *anthoxanthins*. These pigments are also chemically related to the **glucosides**. Anthoxanthins often occur in the plant in a colorless form but under suitable conditions their typical yellow or orange color becomes apparent. Some yellow flowers, such as yellow snapdragons, owe their color to the presence of anthoxanthins, but the color of the majority of kinds of yellow or orange flowers is due to carotinoid pigments.

The autumnal coloration of leaves in temperate regions is one of the most spectacular accompaniments of the march of the seasons. Both carotinoid and anthocyanin pigments play an important role in autumnal leaf coloration which is not, contrary to popular opinion, a result of the action of frost. Brilliant development of the anthocyanin pigments in the fall is, however, favored by dry weather during which cool, but not frosty, nights alternate with clear days. During the late summer and early fall the chlorophyll in the leaves gradually decomposes. In many species this simply results in unmasking the yellow carotinoid pigments already present, accounting for the yellow autumnal pigmentation of such species as birch, sycamore, aspen, and tulip trees. In other species synthesis of anthocyanins occurs more or less concomitantly with the disintegration of the chlorophyll; this accounts for the reds or purplish reds characteristic in the autumnal coloration of such species as many oaks, maples, sumacs, and dogwood.

Except in flowers, white is an uncommon color in the externally visible parts of plants, and results from the complete absence of pigments. In some species white streaks or other markings are of common or regular occurrence in leaves and in the leaves of some species such as roses completely white leaves or even entire branches bearing only white leaves sometimes occur. Such branches cannot be propagated because no photo-

synthesis can take place in the absence of chlorophyll. As long as such branches remain attached to a plant bearing green leaves they can obtain necessary food from the branches bearing normally pigmented leaves. (B.S.M.)

PIGMENTS, PAINTS, VARNISHES. Solid pigments, usually in admixture with a medium of suspension, are widely used (1) in preservative paint coatings, such as those for wood and steel structures and machinery, (2) in decorative paint coatings, either purely artistic as for paintings, enamels, glass, ceramics, or also utilitarian as for interior decoration of walls, floors, furniture, and for automobiles, cars, trucks, (3) in the manufacture of linoleum oilcloth, window shades, book covers, (4) in the manufacture of paper, wall paper, printing inks, writing inks, (5) in plastics such as rubber, celluloid, bakelite, (6) in cosmetics. This variety of uses suggests a wide variety of materials adapted for each purpose, as well as the many different colors involved. The sources are mainly inorganic, but a number of organic preparations are also important. The properties to be considered for each use are (1) opacity, hiding power, covering power, (2) durability, preservative power, (3) beauty and permanence of color.

A convenient classification for the present purpose is that of color.

White Pigments. Any white powdered substance of sufficient permanence in the vehicle to be used and under the conditions to which the finished material is to be subjected, is available. 1. **Calcium** carbonate is one of the cheapest white pigments, and is used as such, mixed with linseed oil, in putty (gray), and with water for wall coatings (white). 2. **Zinc** oxide (zinc white) is used in compounding rubber, and in paints yielding a rather hard film, not colored by hydrogen sulfide in the air. 3. **Barium** sulfate (**barite**) used as a filler in paints, is not excellent when used alone. 4. **Zinc** sulfide (30%) plus barium sulfate (70%), known as lithopone, is prepared by reaction of zinc sulfate plus barium sulfide in water. 5. **Lead** basic carbonate (white lead) is widely used as a white paint pigment yielding a rather soft film readily colored brown (lead sulfide) by hydrogen sulfide in the air. All lead pigments are poisonous. White lead and zinc white are frequently used in admixture. 6. Lead basic sulfate (sublimed white lead), made directly from lead ores by roasting in air, may contain 20% lead oxide and 5% zinc oxide, is cheaper than genuine white lead and is frequently mixed with other pigments. 7. **Titanium** white (titanium dioxide) is remarkable for its whiteness and high hiding power. It finds important use, either pure or in admixture, in enamels for interior work. For exterior use, titanium oxide alone "chalks," and is accordingly best used in admixture with other pigments, for example, zinc oxide. 8. **Silica,** and china clay, on account of their cheapness, are frequently used in admixture with more expensive pigments.

Yellow Pigments. 1. Cheap, permanent yellow pigments are those of hydrated ferric oxide, such as the mineral **limonite,** frequently with clay, known as ochres, yellow, and siennas, yellowish-brown. These pigments are not affected by an oil medium nor do they affect other pigments, and they furnish a considerable range of tints in the yellow, brown, red range. 2. **Lead** monoxide (litharge), brown-yellow, is used in painting steel, as it is slightly basic, thus increasing resistance to corrosion, causes paint oil to dry quickly. 3. **Lead** chromate (chrome yellow) is excellent in hiding power and brilliance and permanence of tint. Different shades are prepared, depending upon conditions of manufacture, e.g., light shades by use of acidified solutions in the precipitation. Like all lead pigments, the chromate is darkened by hydrogen sulfide. 4. **Zinc** chromate is permanent and unattacked by hydrogen sulfide, but not as excellent in tint and hiding power as lead chromate. 5. **Arsenic** trisulfide (orpiment) either as the natural mineral or artificially prepared. Not permanent to light, affects lead pigments, causing darkening (due to sulfide), and is poisonous. 6. **Cadmium** sulfide, very permanent and brilliant, not to be mixed with lead pigments on account of darkening by lead sulfide. 7. Gamboge, a **resin,** is used as a water color pigment, in varnishes, and in lacquers for brass. 8. **Cadmium** lithopones, made by precipitation of cadmium sulfate and **barium** sulfide or **selenide** (or sulfide-selenide) solutions.

Brown Pigments. 1. Cheap, permanent brown pigments are those of hydrated **ferric** oxide and **manganese** dioxide containing clay minerals. Various shades of yellow to brown to red are obtained from a variety of forms found in nature, and darker shades are made by heating these. The yellowish-brown forms are known as siennas, and the darker reddish-brown as umbers. Not affected by the oil medium, do not affect other pigments of good hiding power, cheap, wide variety of shades. 2. Van Dyck brown or Vandyke brown, by heating cork or woody matter to moderate temperatures out of contact with air, and is usually used in admixture with other pigments.

Green Pigments. 1. **Chromic** oxide (chrome green) is permanent under atmospheric conditions and at high temperatures, of excellent tint, of permanent color, can be mixed with other pigments, is unaffected by hydrogen sulfide, alkali, or acids. Other chrome greens (Brunswick green) are made by mixing chrome yellow and Prussian blue. 2. **Copper** greens are copper basic carbonate (**malachite** mineral), copper basic acetate (verdigris), copper basic **arsenite** (Scheele's green), copper acetoarsenite (Paris green, emerald green). These are limited in their satisfactory use due to lack of permanence of color, low hiding power, reaction with sulfide pigments or with moisture, poisonous nature of arsenic compounds. 3. Green lakes, by precipitating certain dyestuffs along with inorganic salts, e.g., of **tin, aluminum.** Used in inks for printing, and for wall finishes.

Red Pigments. 1. **Ferric** oxide (Indian red, Venetian red), either as the mineral **hematite** or prepared by heating ferrous sulfate (alone or with calcium oxide) to the desired temperature. Not affected by oil medium, does not affect other pigments, is of good hiding power, cheap, permanent, used in cosmetics, and in glazes. 2. Trilead tetroxide (red **lead**), orange-red, causes paint oil to dry rapidly, used largely on structural steel alone or as priming coat. 3. **Antimony** trisulfide (antimony vermilion), used in paints (not mixed with lead pigments), and in compounding red rubber. 4. Red lakes, by precipitating certain dyestuffs, e.g., madder, cochineal, aniline dyes, along with inorganic salts, e.g., of tin, aluminum. Used in inks for printing, and for wall finishes.

Blue Pigments. 1. **Iron ferroferricyanide** (Prussian blue, Turnbull's blue), used as a paint pigment, in inks, in laundering, permanent with acids, color destroyed by alkalis. 2. Ultramarine blue (sodium aluminosilicosulfide) used as a paint pigment, discolored by acids, not used where its sulfide content causes color reaction with other pigments, e.g., lead pigments. 3. **Cobalt** blue (cobalt aluminate), by heating to a red heat the precipitate obtained by mixing cobalt salt solution, alum solution, and sodium carbonate solution. Used in oil or water medium and in glazes, not reactive with other pigments, permanent under atmospheric conditions and at high temperatures. 4. **Copper** blue (azurite, copper basic carbonate), color not permanent with sulfides, nor when heated.

Black Pigments. 1. Lamp black (amorphous **carbon**), made by the incomplete combustion of natural gas or petroleum. 2. Bone black or drop black, made by the destructive distillation of bones. Used as a paint pigment, and in stove polishes. 3. Ivory black, made from ivory cuttings as bone black is from bones. Reputed the blackest of pigments, expensive. Used in

high-grade varnishes and enamels. 4. Graphite (crystalline carbon), natural or artificial, inert, permanent. Used in protective paints for metals. 5. Asphalt. Used as a protective varnish on metals, concrete, wood—especially roofing materials.

In the manufacture of paints the (1) pigment is suspended in a (2) medium—drying oil, or water—with or without the addition of a (3) thinner or volatile solvent to the drying oil—turpentine, gasoline, benzene are used as thinners—or a (4) drier. Driers are added to hasten the hardening of the drying oil. **Manganese** borate, red **lead**, litharge, finely divided manganese, **cobalt, nickel, lead**, and metallic soaps, such as linoleates and resinates of manganese, lead, cobalt, are used as driers. Casein increases the adhesiveness of water paints.

Varnishes are similar to paints that contain thinners, in that part (or all) of the medium evaporates. The medium may consist of (1) a drying oil, a thinner, and a drier, with or without pigment. In the use of paints and varnishes a thin film of the material is formed and left exposed on a surface, and the hardening process consists in oxidation of the unsaturated drying oil. (2) **Alcohols, turpentine, benzene,** naphtha, **acetone,** tetrahydronaphthalene, **ethyl acetate,** ethylene **glycol** monoethyl **ether,** in which a **resin,** such as shellac, dammar, copal, sandarac, rosin, synthetic resins of the phenol-formaldehyde type or an **ester,** such as cellulose acetate or cellulose nitrate is incorporated. On exposure, the solvent evaporates, leaving the resin or ester as an adherent film. Some resin films are brittle and not adapted to resist wear, while some ester films are notably permanent and used for such purposes as the coating of automobiles and cloth exposed to the weather.

Paints, varnishes, and lacquers are made for many special purposes. Of special interest may be mentioned (1) shingle stains using creosote oil, or fish oil, (2) luminous paints using radioactive materials such as radium or mesothorium compounds with **barium, strontium,** or **calcium** sulfides or tungstates, (3) linoleum made by mixing specially prepared oxidized linseed oil, rosin, cork dust, and pigments, spreading the mixture on canvas, and allowing to dry. (R.K.S.)

"PIGNOLEA" NUTS. These are the seeds of certain European pines growing in countries bordering the Mediterranean Sea. They are an important food article in European countries; in America they are used mostly as salted nuts and in various candies. (R.M.W.)

PIKE. Pisces, Teleostei. A badly misused name applied in various forms to a number of fresh-water food and game fishes (**Pisces**). They are most abundant in the rivers and lakes of the northern states and Canada. The true pike, *Esox lucius,* is a fish related to the muskellunge. It attains a weight of 40 lbs. and a length of 4′, and is one of the principal game fishes of the north. This species is also called the northern pickerel, but it differs from the closely related pickerels in having the cheeks scaly but the lower half of the opercula bare. Two other species, the wall-eyed pike, *Stizostedion vitreum,* and the sand pike, *Cynoperca canadensis,* are more closely related to the perch than to the true pike. The former is also called the wall-eye, glass-eye, pike-perch, and jack salmon, and in the south is commonly called the salmon. The sand pike is also known as the sauger or gray pike. The wall-eyed pike is an excellent food and game fish, attaining a weight of 25 lbs. The sauger is smaller and less desirable. (A.W.L.)

PIKE-PERCH. Pike.

PILCHARD. Sardine.

PILE. In **foundation** work the pile, often called a bearing pile due to the fact that it carries a direct compressive load, is a post-like member of timber, steel or concrete which is driven into soft ground to support a structure. In case soil conditions are such that an extremely large **footing** or **grillage** is required, piling is used to give sufficient bearing power. Piles are usually necessary for unstable soils and may be used in other types where extremely heavy loads are carried. Formerly, all piling was cut from trees, but, due to the increasing scarcity of timber, especially of the type and size required, reinforced concrete or steel piles are now extensively used.

Many large buildings are constructed on very closely spaced piles driven on 3- or 4-ft. centers. These are surmounted by a monolithic concrete capping which adds to the bearing power by making available whatever bearing power the soil between the piles may possess. Ordinarily, piles are driven deep enough to reach fairly firm soil. Sheet piling differs from bearing piling in that it is used where a continuous wall is required such as in the **cofferdam.** It may consist of vertical wooden planks driven in close contact or specially rolled steel shapes, having interlocking edges, which are driven so that each individual section is firmly united with adjacent sections. Sheet piling is subjected to **lateral** pressures due to earth or water and if driven in water must withstand the impact of floating debris.

Piles are driven by means of a water jet or by a pile driver. The former method, used in sand or gravel, consists of washing the material away from the end of the pile by means of a jet of water. As the material is displaced the pile sinks by its own weight or is driven by light blows from a pile driver. The drop hammer pile driver is made up of a **casting,** which fits into guides on vertical posts, and the machinery and tackle necessary to raise the hammer. The hammer is raised over the end of the pile and then allowed to fall in the guides by gravity. The force exerted by the hammer dropping upon the end of the pile causes it to sink a certain distance. This force is proportional to the weight of the hammer and also to the drop. The single-acting steam-hammer pile driver raises the casting by steam pressure and then allows it to drop by gravity, while in the double-acting type steam pressure raises the casting and increases the force of the blow over that due to gravity. It is preferable to the drop-hammer type since it causes less damage to the pile and can deliver more blows in a given period of time. (F.T.M.)

PILE DRIVER. Pile.

PILES. Hemorrhoids.

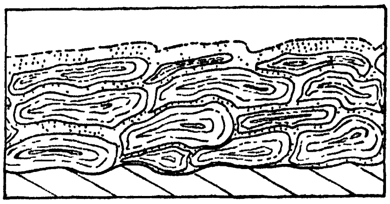
PILIDIUM. A ciliated (**cilia**) larval form of the **nemertine** worms. It forms as a 2-layered saccular structure with a band of cilia around the base and a sensory organ at the apex, resembling in some details the **trochophore** larvae of other animals. The worm develops inside the pilidium and when it breaks out the pilidium perishes. (A.W.L.)

PILL BUG. Crustacea, Isopoda. A small oval terrestrial **crustacean,** commonly found in moist situations at the surface of the ground. They hide in crevices among rocks, under wood, and even invade basements. These forms are also commonly known as sow bugs and wood lice. The pill bugs are properly the species with the power of rolling up into a ball so nearly spherical that it will roll on a slight incline. (A.W.L.)

PILLOW BLOCK. Bearings.

PILLOW LAVA. Effusive volcanic rocks, generally of **basic** composition, which are characterized by pillow-like or bun-like structures formed during the concomitant movement and congelation of the lava. Most pillow lavas are basalts. Frequently the "pillows" have a

skin of rock glass called tachylyte. The evidence of the rapidity of the chilling suggests that pillow lavas owe



Cross-section of pillow lava. (*Field, Outline, Barnes & Noble.*)

their peculiar structure to having flowed into a body of water or as having originated as aquatic lava flows. (R.M.F.)

PILOCARPINE. Alkaloids.

PILOT BALLOON. Meterological Instruments.

PILOT FISH. Pisces, Teleostei. 1. A small marine fish, *Naucrates ductor,* which accompanies sharks and is sometimes supposed to guide and protect them. It is bluish with several dark vertical bars. 2. One of the **whitefishes** found in fresh water from the northern states to Alaska. (A.W.L.)

PILOTAGE (PILOTING). The term pilotage or piloting is used to describe that type of **navigation** in which the positions and motions of a ship are determined by reference to fixed objects on the earth. The landmarks may be natural, such as hills, points of land, small islands, lakes, rivers, etc., or they may be artificial, such as lighthouses, light vessels, **beacons, buoys,** prominent buildings, water towers, railroads, highways, power transmission lines, etc. Two general types of pilotage are recognized by sea navigators: inshore or harbor piloting, and off-shore or coast piloting. Before a ship proceeds up a channel, or into a bay or harbor, the pilot must have a clear mental picture of the locations of all available landmarks, range points, etc. A stranger to the region must obtain this image from a thorough study of **charts,** pilot directions, and similar publications for the region. With the mental picture thoroughly developed, the pilot then guides his ship in much the same manner as an individual finds his way about a city. Aviators use this type of pilotage when operating in the vicinity of a base with which they are thoroughly familiar, or when proceeding by **contact flying.** When a ship is off the coast, with but few recognizable landmarks available, or when a pilot is flying over unfamiliar terrain where prominent landmarks are few and far between, the pilot obtains **lines of position** from the available objects, and then applies geometric constructions to obtain **fixes.**

The **bearing** of an object, taken with the **pelorus** or the **compass,** is the most frequently used line of position in pilotage. If two or more landmarks are available, and are spaced so that their bearings differ by more than 30°, the lines of position will intersect in a fix that is known as a cross-bearing position. A single object will provide only one bearing, but a fix can be obtained if the distance of the object can be measured. In this case the two lines of position will be the bearing line and a circle centered on the object and with radius equal to the distance. Among the various methods for finding the distance we have: the angular height of the object, measured with the **sextant,** if the linear height is known; the use of stadia lines in binoculars; the difference in time of reception of audible and radio signals (see **Radio Beacon**); the time for the echo of a signal from the ship, such as a whistle blast, to return from the shore; etc. None of these methods is as accurate a a bearing line, and they should not be used when other methods for obtaining a fix are available.

One object may be used for obtaining a running fix by taking two bearings of the object, at different times, provided that the distance and direction run between observations is accurately known. At 1015 the navigating officer of a ship, that is proceeding at 18 **knots** on **heading** 060°, sights a lighthouse about 12 miles away that bears 032° off the port bow. He immediately instructs the helmsman to be very careful with his steering, and proceeds to make a careful study of the **current** and tide tables of the region. From the predicted currents he finds that the ship is making good a **course** of 058° with ground speed 17.8 knots. He then starts a graphical construction (Fig. 1) by drawing the 1015

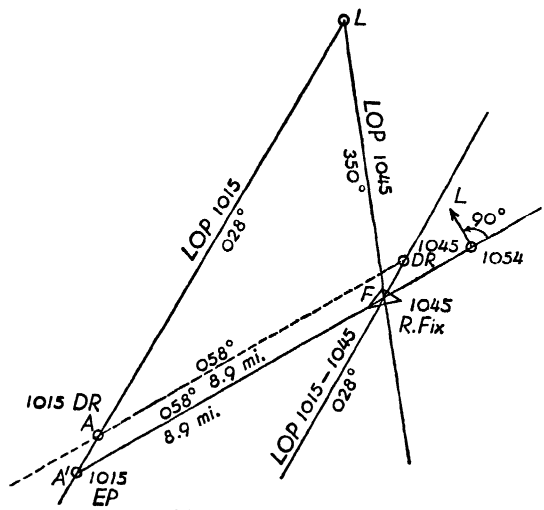


Fig. 1. Scale diagram.

line of position through the lighthouse. This line bears 028° since 060° − 032° = 028°. He then selects a point, *A*, on this line, usually the point closest to his dead-reckoning position, and draws the course line in direction 058°. At 1045 the lighthouse is 070° off the port bow and a 1045 line of position is drawn through the lighthouse on bearing 350°. The 1015 line must now be advanced to 1045 by measuring off the distance made good in 30 minutes (8.9 miles) along the course line and drawing a line parallel to the 1015 line through the estimated position at 1045. The point of intersection of the 1045 line and the advanced 1015 line is the running fix at 1045. A line drawn through this fix in direction 058° will represent the probable course of the ship. This will intersect the 1015 line in the estimated position at that time. When the ship arrives at point *C* the ship will have the lighthouse on the port beam. Measurements indicate that at 1045 the ship bears 170° distant 7.2 miles from the light, and that the light will be on the port beam at 1054 and will be 6.7 miles distant at that time.

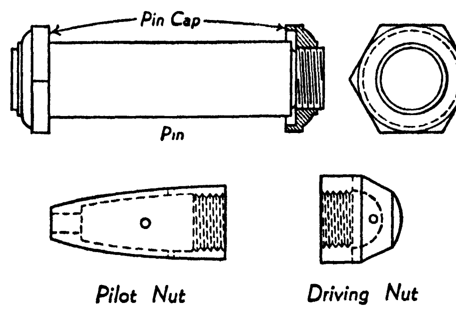
Proper selection of the second bearing will give a fix without plotting the lines. If, in the above case, the pilot had noted the time when the relative bearing of the light was 064° off the port bow (twice the first value), the triangle *A'FL* would be isosceles, with the side *A'F* equal to *FL*. The side *A'F* is the distance run in the interval required to "double the angle on the bow" and the bearing and distance of the light at the time of the second observation is obtained without any plotting. An experienced pilot is familiar with a number of similar short-cuts for locating his positions by taking frequent bearings of available objects. Continual use of these, together with careful steering and a thorough knowledge of the speed of the ship and the set and drift of the

current, will provide the pilot with a series of successive positions of his ship. In many cases, the scattering of the positions will indicate that the predicted currents are in error. By proper allowance for these abnormal conditions the ship may be saved from disaster. Similar methods are available to the air navigator and they may be used to check wind directions and speeds, as well as providing the pilot with accurate positions of his plane. Either visual or **radio bearings** may be used in flight and a series of running fixes obtained (see **Radio Navigation**).

The contour of the sea bottom may be used for determination of position of a ship. If a ship is held on steady heading and frequent soundings are taken, the depths may be plotted on a sheet of tracing paper, using the distance scale of a chart. The position of the ship is found by placing this tracing over the chart, with the line of soundings parallel to the course line, and moving it about until the observed values correspond with the depths shown. At present, a set of accurate contour maps of the ocean floor is in the process of construction. As these charts become available, and are used with a self-recording fathometer, the method of pilotage by depth will become more common and effective. A similar type of air pilotage will be available when the absolute **altimeter** is completely developed and ready for general use. (W.K.G.)

PILTDOWN MAN (Eoanthropus). **Paleontology of Man.**

PIN. The structural pin is a solid steel cylinder, usually heat-treated, which is used to connect steel members when freedom of angular movement at the joint is desired. It is threaded at both ends to receive large pressed or cast-steel pin **nuts**, which are used to secure the pin in its final position in the structure. The pin-connected joint is usually assumed to be frictionless but there is always a certain amount of friction present. The pin may be in direct contact with the member, as in the case of the **eye bar**, or it may pass through plates called pin plates which are attached to the members. It is also used to transfer the loads from the bridge **truss** to the end **bearing**. Pins are subjected to bearing, shearing, and bending **stresses**.



After the members of a pin-connected joint have been assembled in position so that the pin holes line up, the pin is driven through the holes. This driving requires the use of a pilot nut and a driving nut, which are screwed on the ends of the pin. The pilot nut guides the pin through the pin hole and the driving force is applied to the driving nut. These nuts also protect the threads during the driving operation. When the pin is in position the nuts are removed and the pin nuts screwed on. (C.W.C.)

PINACOCYTE. A flattened cell of the outer layer of the body wall of **sponges**. These cells are able to change their shape. (A.W.L.)

PINACONE. **Acetone.**

PINEAL EYE. One of two organs similar to an eye in structure which develop from the roof of the brain. The pineal organ lies behind the parietal organ when both are present, but the evidence of embryology and of their connections with the brain suggests that the two were primitively paired, the pineal organ belonging to the right side, the parietal to the left. In amphibia it is the pineal organ, in reptiles the parietal, which is modified for light reception. The pineal organ undergoes a glandular modification in many vertebrates, including the mammals, leading to the unproved suggestion of an endocrine function. (A.W.L.)

PINEAPPLE. *Ananas sativus.* Bromeliaceae. The pineapple is a native of northern South America. Even in early times it had spread in cultivation to Peru and Mexico; now it is grown throughout tropical lands all over the world. On the short unbranched stem are many thick pale green leaves with sharp-toothed margins. At the top of the stem is borne the **inflorescence**, a cone-like bunch of bluish flowers, each in the **axil** of a **bract**. During ripening of the fruit all parts of the inflorescence, including the axis, bracts, **sepals**, **petals**, and **ovaries**, coalesce and become very fleshy, forming the familiar multiple fruit. The axis continues beyond this fruit as an elongate rosette of stiff-toothed leaves, which are generally marketed with the fruit. Only rarely do seeds form in this fruit, so propagation is accomplished by cuttings or by means of suckers which are formed quite abundantly.

The fruits are cut and sent to northern markets in a green state, coming into the United States mainly from Porto Rico and Cuba. In Hawaii, where the pineapple is an important plant, immense quantities are canned and put on the market.

From the leaves of the pineapple is obtained a very strong but fine white flexible fiber which is unaffected by water and extremely durable. From this fiber a delicate cloth may be woven. (R.M.W.)

PINHOLE "IMAGE." If a small opening is made in one side of a darkened room or box, an inverted picture of objects outside appears upon the wall opposite the opening. Such a picture differs from a true image in that it is not formed by light from a given point of

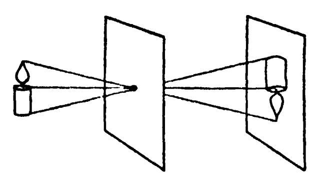


Diagram showing formation of pinhole image.

the source diverging and being reconverged at the corresponding image-point, as by a lens, but is an effect of the rectilinear propagation of light. The only spot on the screen reached by light from a given point of the source is that in direct line with the opening. For this reason, pinhole images are of low intensity. On the other hand, they are free from the distortions to which lens images are subject, and with sufficient exposure, very good photographs can be made by means of them. The pinhole image also affords an excellent means of viewing eclipses of the sun. (L.D.W.)

PINION. **Spur Gearing.**

PINK BOLLWORM. Insecta, Lepidoptera. A widely distributed enemy of cotton which probably originated in India or Africa. The adult is a small gray-brown **moth**, *Pectinophora gossypiella,* and the **caterpillar** is one-half inch long and is pinkish above. The **larvae** work in the flowers and bolls, causing imperfect devel-

opment and destroying seeds and lint. It also attacks other plants, including the hollyhock and okra.

This species is found in the western part of the cotton-growing areas of the United States. Vigorous measures have been taken to eliminate it, for no adequate methods of control have been discovered. (A.W.L.)

PINNA. Ferns.

PINNATE. Leaf.

PINNIPEDIA. A division of the mammals containing the **seals, walruses**, and related forms. Sometimes regarded as an order and sometimes as a suborder of the order **Carnivora.** (A.W.L.)

PINNULE. A small lateral branch of the arm of a feather-star (sea lily, **crinoid**). The arms of these animals are sometimes divided into two or more radiating branches but whether branched or simple they bear small lateral branches which give them a feathery form; these are the pinnules. (A.W.L.)

PINO. The column of smoke and ashes emitted by an explosive **volcano**, usually in the beginning or in the early stage of an eruption. The term is of Italian origin signifying the cauliflower-like shape of the cloud as observed during the eruptions of Vesuvius. (R.M.F.)

PIÑON NUTS. Conifers.

PINWORM. Nemathelminthes, Nematoda. A small roundworm (**Nematoda**) which lives in the alimentary tract of man, chiefly in the large intestine. The female is about ⅜" long and the male somewhat smaller. Eggs are taken into the mouth in water or from the hands, or on raw vegetables. The entire life cycle takes place in the one host.

Pinworms are usually not harmful but they may cause nervous symptoms and are said sometimes to lead to appendicitis. (A.W.L.)

PIPE. Pipe is, categorically, the physical enclosure of a fluid flow. It is usually circular in cross-section. Pipe is made of steel, wrought iron, cast iron, copper, brass, lead, concrete, cement-asbestos, clay, wood or of a number of different plastics. Commercial sizes available, as well as individual physical properties and characteristics, determine the uses and limitations of the various materials. In general, pipe of carbon or alloy steel in sizes from the smallest to the largest is used exclusively where high pressure or high temperature, or both, are encountered. The other materials are selected for the lower pressure applications (approximately 300 lbs. per sq. in. and less) where their particular properties may be advantageous. Recognized codes having legal standing and covering recognized good practice frequently govern the engineering and technical details of pipe material selection where public interest or safety is involved.

Pipe size is commonly designated in terms of either inside (ID) or outside (OD) diameter.

The largest footage and tonnage are produced in the form of steel pipe which is made from flat-rolled material classified as skelp, plates, and strip. There are three basic methods of manufacture: the welding processes, the seamless process, and shop fabrication.

Welding processes include furnace welding (either butt-welded in sizes ⅛" to 4" inclusive or lap-welded in sizes 1¼" to 24"), electric resistance welding (sizes ⅛" to 30") and fusion welding (sizes 4" to 30' or larger).

Furnace welded pipe is not welded in a furnace as the term implies. The full length skelp is heated to welding temperature in a furnace and then, as each piece is withdrawn from the furnace, it is welded continuously. The terms "butt-weld" and "lap-weld" refer to the skelp edge forms and method of joining the edges preparatory to welding. In the first case the edges are cut square or upset and butted. The forming and welding of the heated skelp are accomplished by drawing through a bell-shaped die. In the second case they are scarfed and overlapped and passed through welding rolls. The welding and finishing processes leave little or no visible evidence of welds.

Electric resistance welding employs a series of operations, in the first of which the flat-rolled material is cold shaped into tubular form. Union of the seam is then effected by the application of heat and pressure. The welding heat, produced at or near the seam of the material, is generated by resistance to the flow of an electric current introduced through electrodes or by induction.

In the manufacture of tubular products by fusion welding, flat-rolled material which has had its edges suitably prepared is shaped either hot or cold to tubular form and united by a process of fusing with or without simultaneous deposition of filler metal in the molten or vapor state. No mechanical pressure is required with such welding which may be accomplished by either the electric arc or the gas method, or a combination of both. The term "electric welding" ordinarily embraces both the arc-fusion and electric-resistance methods. Fusion welded pipe is made with a welded seam parallel to the axis (straight seam) or winding around the pipe body in the form of a helix (spiral seam).

The seamless process includes the hot piercing method and the cupping method. In the former process, solid steel ingots, blooms, billets or round bars are hot pierced; then by either hot rolling or hot drawing, or a combination of both, the tubes are brought to the desired size. In the latter process, steel plates are hot cupped and hot drawn to the desired size.

Seamless tubes in the smaller sizes, or those with closer dimensional accuracy, are frequently further processed by cold drawing.

Shop fabrication is accomplished by curving flat plates into cylinders to form "cans" which are side-seam welded, then joined end to end to produce the finished pipe. This process is commonly used for the larger diameter pipe.

Nationally recognized and used engineering specifications have been drawn to cover the quality and the dimensional tolerances of steel pipe employed for common and special uses.

Cast iron pipe is cast by ordinary foundry methods in stationary sand molds (sand cast) or by pouring into spinning molds (centrifugally cast). It is commonly supplied with bell and spigot joints for field caulking which is the ordinary joint seen in cast iron pipe for water works service. Flanges cast integrally with the pipe and special joints are also manufactured.

The dimensions, weights, and form of joints for cast iron pipe have been standardized by several nationally recognized technical organizations to cover use as soil pipe, water pipe, and gas pipe.

Copper and brass pipe of seamless manufacture are available in various metal compositions in sizes 12" and smaller.

Lead pipe in the smaller diameters is available for plumbing and industrial uses.

Concrete pipe, plain or reinforced, and provided with several types of field joints in sizes from about 4" to 84", is used for drains and for water pipe under moderate pressures.

Cement-asbestos pipe is made of a material compounded from cement and asbestos fiber as the name indicates. It is mainly used as water pipe in sizes from 4" to about 30" as well as for various industrial uses for conducting fluids under comparatively low pressures.

Clay pipe in sizes from about 4" to 36" is manufactured from surface clay, fire clay, or shale. It is ordinarily

used for drains and sewers where pressures and strength requirements are negligible.

Wood pipe is made by assembling wood staves and holding them in place by means of a continuous wrapping of steel wire or by individual threaded steel hoops in the same fashion as a wood tank. Continuous wood stave pipe is assembled in the field in such manner that the staves overlap each other with ends of staves staggered along the length of the pipe line. Thus it is distinguished from the ordinary pipe line in which each pipe is an individual unit connected to its neighbor with a field joint.

Plastic pipe has not come into general use but is available in smaller sizes for special purposes. (R. E. BARNARD)

PIPE COATINGS. Inert materials are applied as films either to the inside or outside of pipe and tubing to prevent or slow down the deterioration or destruction of the metal from chemical action or corrosion. The materials commonly used are paints, enamels, cement, rubber, plastics, or layers of metallic substances such as zinc, tin, lead, copper, nickel, chromium, etc.

In general, thin paint coatings are most adaptable to the least corrosive conditions. Bituminous enamels, usually applied hot and in thicknesses of at least 1/16", are far more resistant than thinner coatings. Coal-tar enamel is generally considered best for underground steel water pipe. Cement is used for lining and outside protection. Rubber compounds and synthetic rubber are used most often as linings and the best are vulcanized in place. Plastics are being developed rapidly both as air-drying and as thermosetting types.

Zinc-coated (galvanized) steel pipe is the most widely used pipe with metallic coating. Other metal coatings are used as their resistance and practical economy dictate. (R. E. BARNARD)

PIPE FITTINGS. A piping system, in fulfilling its function of providing a flow path for liquids or vapors, is rarely a straight run of pipe between two points. Flows are joined, parted, started, stopped, and regulated in the piping system. Only occasionally is it possible to take a "crow flight" path between end connections; the common run of pipe must follow configurations of equipment, walls, floors, beams, etc. Fittings and valves, properly incorporated in the pipe system, enable it to meet these varied service conditions.

In general, fittings consist of the pieces required to make turns, junctions, and reductions. The straight size fittings are the 45° and 90° elbows, the tees, crosses, Y's, laterals, and reducers. These fittings may also be had in special reducing sizes. (F.T.M.)

PIPE FRICTION. Piping carrying fluid will have a frictional surface with the fluid. The extent to which friction is developed at this surface is a matter governing either the size of pipe which should be used, or the reduction by friction of pressure or velocity head in the pipe. The size of a pipe is not determined alone by the weight or volume of the fluid being transported. For instance, there is no one pipe size that must be selected to carry 500 cu. ft. of steam per min. At 5000 ft. per min. velocity a pipe of 0.1 sq. ft. cross-sectional area is required; at 10,000 ft. per min. it is 0.05 sq. ft. As soon as the velocity as well as the volume is known, the pipe size is determined according to the familiar relation:

Volume rate of flow = Velocity × Cross-sectional area.

The most difficult quantity to determine in this equation is the velocity. Of course, for short pipes it is easy enough to assume a velocity in accordance with actual practice. This assumption is rarely one giving the most economical pipe size, but as the pipe is short the failure to strike an economic balance is of minor importance. The higher the velocity the smaller the pipe, but, at the same time, the greater the friction loss in the pipe. The most economical pipe size is that for which the annual fixed cost plus the annual cost of friction head is a minimum.

The following symbols are used in the formulae below:

h = Friction head in ft. of the fluid.
f = Coefficient of friction.
L = Length of pipe in ft.
v = Velocity of flow in ft. per sec.
g = 32.2.
d = Inside diameter of pipe in ft.
D = Inside diameter of pipe in inches.
z = Viscosity in centipoises.
S = Specific gravity referred to water as 1.
y = Density in lbs. per cu. ft.
P = Pressure in lbs. per sq. ft.
p = Friction head in lbs. per sq. in.

By assuming that the head lost in friction varies directly as the length of the pipe and as the square of the velocity of flow, and inversely as the hydraulic radius, the formula for feet head lost in friction is obtained:

$$h = \frac{fLv^2}{2gR}.$$

Practically all pipes are circular and $R = d/4$, d being the actual inside diameter of the pipe.

$$h = \frac{4fLv^2}{2gd}.$$

is the common formula for water pipes.

The coefficient for old pipe is to be regarded as highly approximate due to the uncertain nature of the surface of pipe designated merely as "old pipe." The character of the wetted perimeter is liable to change much during the life of the pipe through tuberculation, corrosion, organic growth, scale, silt, etc.

The coefficient f does not remain constant. In order to fit it to the experimental hydraulic data, investigators in this field have found it necssary either to express the equation with fractional exponents on v and d or to express f as a function of v and d. The equations given by Wilson, McAdams, and Setzler are:

For fluid flow in copper, brass, lead pipe

$$f = .00181 + .00662\left(\frac{z}{DvS}\right)^{0.355}.$$

For fluid flow in clean iron and steel pipe

$$f = .0035 + .00594\left(\frac{z}{DvS}\right)^{0.424}.$$

These formulae and constants are based on turbulent flow, as opposed to viscous flow before the critical velocity is reached. All ordinary water velocities are higher than the critical velocity and therefore represent turbulent flow—the more desirable of the two from the standpoint of friction drag.

When a compressible fluid such as air or steam flows in a pipe with average velocity v it can be shown that the pressure loss due to friction is

$$P_1 - P_2 = \frac{4fLyv^2}{2gd},$$

from which can be derived

$$p = \frac{fLyv^2}{6gD}.$$

A formula for f in terms of the dimensionless group $\left(\frac{Dy^v}{z}\right)$ is:

$$f = .0054 + .375\left(\frac{z}{Dyv}\right),$$

z for steam is

$$z = .0083 + 2 \times 10^{-8}t,$$

t being the steam temperature.

The friction loss through steam fittings and valves can only be approximated. (F.T.M.)

PIPE JOINTS. Individual pipe sections must be joined to form a continuous line. There are many types of joints with numerous variations but all may be included in five general classes:

1. Mechanical joints, restrained or unrestrained against movement along the pipe, which rely for tightness on stuffing box principles or on self-sealing V-shaped flexible gaskets held by steel housings.
2. Screw-joints having standard threads on pipe ends and in couplings.
3. Flanged joints bolted together with sealing gasket between the flanges. Flanges may be made integral with pipe or may be welded or otherwise attached. Flange and bolt dimensions have been standardized for various working pressures.
4. Welded joints made by joining plain- or bevelled-end pipe or fittings by means of electric-arc or gas welding.
5. Caulked joints of the bell and spigot type made tight by filling an annular space with lead or other caulking compound and then manually expanding this material within the bell, using hand tools. (R. E. BARNARD)

PIPERIDINE. **Pyridine and Related Compounds.**

PIPING CROW. Aves, Passeriformes. Australian birds (**Aves**) of several species related to the crows and jays but not true crows. They are black and white, whence comes their other name, Australian magpie. Unlike the true crows these birds are quite musical and can be taught to whistle tunes and to speak. They are frequently kept as cage birds. (A.W.L.)

PIPISTRELLE. **Bat.**

PIPIT. Aves, Passeriformes. Small quietly colored birds (**Aves**) of numerous species, related to the wagtails and warblers. They are widely distributed but most species occur in the Old World. In North America the common pipit, *Anthus spinoletta,* nests in the north and at high altitudes in the western mountains, and the one other species, Sprague's pipit, *A. spraguei,* is a bird of the plains. (A.W.L.)

PIRACY (STREAM CAPTURE). A term used by physiographers to designate the manner in which one stream or drainage system grows at the expense of the other. For example, two streams, tributaries to the master stream flowing at the foot of an escarpment, finally tap the head waters of the streams tributary to the master stream on the plateau, diverting the drainage. (R.M.F.)

PIRANHA, PIRAYA. Pisces, Teleostei. *Serrasalmo.* A fish (**Pisces**) of tropical American rivers which is noted for its ferocious attacks on living animals. It has very sharp teeth and is said to be attracted over considerable distances by blood. Although individuals are not large, so many swarm to a feast that a wounded animal in the water is said to be stripped of flesh very quickly. The species is dreaded by man. Similar fishes of African waters are known as dogs of the water. (A.W.L.)

PISCES. **As used in astronomy, this is the name of a constellation (the Fishes). (Map, page 306.) Pisces is a large constellation which is of importance principally because it is the twelfth sign of the zodiac. There are relatively few interesting objects in the constellation although the brightest star (Alpha) is a close double which may be resolved in instruments larger than a four-inch. In spite of the fact that Pisces is the twelfth sign of the zodiac, nevertheless, the vernal equinox is located in this constellation at present. This is because precession has caused the vernal equinox itself to move** back an entire "sign" along the ecliptic since the time when the names were first assigned.

In zoology, Pisces is a class of the phylum **Chordata** made up entirely of aquatic animals which breathe by **gills.** The few species adapted to leave the water either do so for short periods or remain on the wet shores. A few pass longer periods out of water but only in an inert state.

Fishes are characterized by the following structures: 1. The skin is kept moist by glandular secretions and in many species is covered with scales. 2. The appendages are in the form of fins, used in swimming. 3. The **gill slits** persist in the walls of the **pharynx** and serve as the seat of the respiratory gills. 4. The heart has only two principal chambers: an atrium or auricle and a ventricle.

Fishes are widely distributed in the oceans and in fresh waters. Many species are important as food. Billions of pounds are taken each year for this purpose, millions coming from a single species such as the more important salmons and marine species like the herring and cod.

Classification:

Subclass Elasmobranchii. Fishes with **cartilaginous** skeletons.
- Order Plagiostomi. With sharp-pointed (placoid) scales and separate external openings of the gill slits. The **sharks, dogfishes, rays, sawfishes, skates,** etc.
- Order Holocephali. With crushing plates in place of sharp teeth. External openings of the gill slits partly concealed by an **operculum.** The **chimaeras.**

Subclass Teleostomi. Skeleton composed at least in part of bone. Gill slits covered by an operculum.
- Order Crossopterygii. The air bladder is a paired ventral sac connected with the pharynx and used for breathing air. Many remains of extinct species.
- Order Chondrostei. The **paddle-fishes, sturgeons,** and *Polypterus.* The skeleton is composed largely of cartilage.
- Order Holostei. The **gar-pikes** and **bowfin.** The scales are covered with a hard material called ganoin and the skeleton is bony.
- Order Teleostei. An immense order containing most of the existing fishes. All of the familiar forms such as the **catfishes,** the **trouts** and **bass, salmon, herring, flounders,** and many others belong here. The group is so varied in structure that there is a tendency to elevate the many families that it contains to the rank of orders. When this is done the list is augmented by more than a score of orders in addition to those mentioned here.

Subclass Dipnoi. The **lung fishes.** These animals have slender pointed fins, crushing plates in place of teeth, and an air sac which serves as a lung. The existing species are found in Africa, tropical South America, and Australia. Some live in intermittent streams and pass the dry season coiled up in a cell formed in the dried mud of the stream bed, breathing air. (W.K.G., A.W.L.)

PISCICULTURE. The breeding of fishes (**Pisces**), together with other methods of maintaining the supply of these animals in heavily fished waters.

Because of the great importance of fishes as food and the consequent enormous removal each season by commercial fisheries, many species would have been depleted long ago but for artificial propagation and protection. In some cases, notably salmon and trout, it is possible to secure the eggs when they are ripe by gentle pressure on the body of the female. This process is called stripping. The germinal secretion of the male, called milt, is then mixed with the eggs to insure fertilization. The eggs are kept under favorable conditions which insure a large percentage of hatching and the young fish are protected until they are able to shift for themselves before being released in open waters. Hatcheries have been erected in many parts of the country for this work.

Some of the important food and game fishes cannot be handled in this way, but by permitting them to breed normally in protected waters it is possible to avoid much of the tremendous destruction which takes place under natural conditions. Waters are stocked with young fishes of a size which guarantees a much higher percentage of survival than can be expected for newly hatched young.

It is possible also to increase the number of fishes in natural waters at low expense by providing breeding stock from the hatcheries, although no protection can be given to the young in such cases other than the usual legal ban on fishing during the breeding season.

Most states now have rigid laws against taking fish during the breeding season or by destructive methods such as unlimited use of nets and the use of explosives. Unfortunately too many persons are ready to violate fishing laws, but these measures have undoubtedly been of great value.

The United States Bureau of Fisheries and the fish and game commissions and bureaus of conservation of the various states are responsible for most of the work in pisciculture being carried on in the United States. (A.W.L.)

PISOLITE. **Oölite.**

PISTACHIO. *Pistacia vera.* Anacardiaceae. This small tree, with **deciduous pinnate** leaves, is native in southwestern Asia, from which region it has spread in cultivation to the Mediterranean countries. The apetalous flowers are unisexual and borne in panicles and the plants are dioecious. The fruit is a drupe, containing an elongate seed with a greenish kernel, having a very characteristic flavor. The kernels are used in confections and ice cream and also eaten salted.

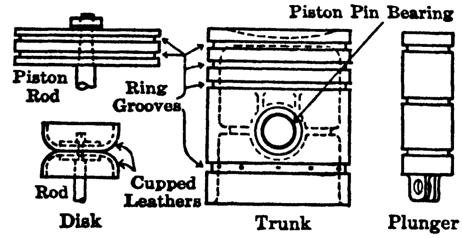
Related to this true pistachio is *Pistacia Lentiscus,* a shrub or small tree of the Mediterranean region with evergreen, pinnately compound leaves. From it is obtained a **resin,** mastic, which is often chewed by the natives of Turkey. It is used in varnishes and, in medicine, as a mild stimulant. Another species is *Pistacia Terebinthus,* a native of eastern Mediterranean countries, which yields China turpentine. (R.M.W.)

PISTIL. **Flower.**

PISTON. A piston forms the movable end of a **cylinder,** the volume of which is to be variable. Variable volume needed for expansion or compression of vapors and gases, or for displacement type pumps, is accomplished by the use of a cylinder in which there is a sliding piston. The space enclosed by the cylinder walls, cylinder head, and piston, forms the volume which can be varied by the motion of the piston. Pistons are extremely valuable, for variable volume mechanisms, of which they form an essential part, are the heart of such important machines as **engines, compressors,** and **pumps.**

Pistons may be classified as single-acting, double-acting, disk, plunger, or trunk type; also, of course, by their material. Most steam engines are double-acting, having the piston joined to the **connecting rod** by a piston rod and crosshead. The piston is disk-like in shape, being relatively thin, and having the piston rod rigidly attached to it. The steam engine piston is often made of cast iron, with grooves for two or three rings on its periphery.

The **steam engine** piston is different from the **internal combustion engine** piston because the latter works at



Piston types.

much higher temperatures, and often at higher pressures than the steam engine. The internal combustion engine is usually single-acting, so that its piston is of the trunk type. The bore of an internal combustion engine cylinder is smaller, on the average, than the steam engine cylinder. A trunk-type piston is one which has the shape of a short cylinder closed at one end and open at the other. The closed end forms the piston face, in contact with the working medium. The remainder of it is the skirt of the piston, and is provided to align the piston properly in the cylinder, to support the wrist pin, and to provide bearing area on the cylinder wall against the side thrust arising from the angularity of the connecting rod. Since the gasoline engine operates at a much higher rotative speed than the steam engine, more attention is given to reducing the weight of reciprocating parts, such as the piston, in order to secure a better running balance. Many such pistons are made of aluminum alloy. The typical gasoline engine piston has a length about equal to its diameter. It carries internal bosses for the wrist or piston pin, and is ribbed near the top to give strength to the thin sections used. Leakage past the piston is sealed off with cast iron or alloy piston rings which are in the form of slices from a thin-walled cylinder. The rings are split and springy so that in use they press firmly against the cylinder wall, closing the gap between piston and wall. Piston ring grooves are machined circumferentially near the piston face. There are usually two or three of these grooves, the purpose of which is to contain the compression rings. Below them is another groove, which may be of the same size, but sometimes is larger, in which is installed an oil scraper ring, whose function is to prevent excessive amounts of oil being pumped by the piston up to the compression space. The wrist pin may oscillate in either the piston bosses, or the connecting rod, or may float in both.

Some pistons have specially shaped heads which are designed to carry out some idea related to the shape of the combustion chamber. Some are dished, some are crowned, some are very irregular in shape, but in each case the shape chosen was one which seemed especially suitable in conjunction with the shape adopted for the end of the cylinder.

Double-acting designs are occasionally found in internal combustion engine practice, and such pistons are hollow disks, through which cooling water is pumped. The water enters and leaves through a hollow piston rod, to which is attached a swinging or telescoping water inlet tube. (F.T.M.)

PISTON RING. Piston.

PIT VIPER. Reptilia, Sauria. A division of poisonous snakes characterized by the presence of a sharply defined pit between each eye and the adjacent nostril. The numerous species occur only in Asia and the Americas. The **copperhead**, water moccasin or **cottonmouth**, and **rattlesnakes** of North America are pit vipers. Rattlesnakes also occur southward into South America, where the more dreaded species of pit vipers are the large **fer-de-lance** and **bushmaster**. The former attains a length of 7′ and the latter 12′. Their fangs are correspondingly long and their poison glands large, hence their bite is extremely dangerous. The bushmaster is also called the surukuku. Other pit vipers of South America are the jararaca and the labaria. In Asia the group is represented by the halys vipers. One small species is known as the carawila.

The poison of the pit vipers acts largely on the blood (haemotarin). The prompt application of a tourniquet between the bite and the heart prevents its being carried freely into the general circulation. The punctures made by the fangs should be cut across in two directions, deeply enough to cause free bleeding to their full depth. Sucking the wounds is effective, but may be dangerous. In any case of snake bite a physician should be secured promptly if possible and an antivenin serum should be administered. (A.W.L.)

PITCH. Musical Sounds; Resins; Bitumens; Anticline; Chain; Gearing; Screw Thread; Riveted Joints.

PITCH, AIRPLANE. Pitching Moment.

PITCH POINT. Spur Gearing.

PITCH, PROPELLER. Propeller; Air, Pitch of.

PITCHBLENDE. Uraninite.

PITCHER PLANTS. Insectivorous Plants.

PITCHING MOMENT. Rotation of an airplane about a lateral axis passing through the center of gravity is known as *pitch*. Nosing-up and diving motions are the result of moments acting around this axis. These moments are produced by propeller thrust, wing lift and drag, parasitic drags, and tail surface forces. For airplane trim these moments must be in equilibrium, whereas for longitudinal stability an increase of angle of attack must produce a diving moment and vice versa. The relation between the moment and the moment coefficient is expressed in the following equation:

$$M = C_m q S c$$

q = Dynamic pressure equivalent to the air speed.

S = Wing area.

c = Wing chord.

(F.T.M.)

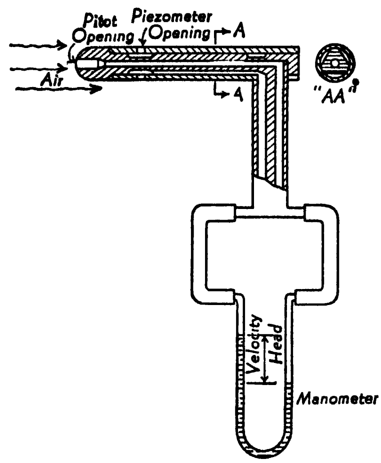
PITCHSTONE. Pitchstone is a volcanic glass of a dull pitchy luster. It contains about 5% of water, which distinguishes it from **obsidian**, of which it seems to be a variety.

Pitchstone is found in a variety of colors, including grays, reds, greens, and browns, or it may be black. (E.S.C.S.)

PITH. Stem.

PITHECANTHROPUS. Paleontology of Man.

PITOT TUBE. This is a tube having an opening turned upstream in a fluid flow. It receives the impact of the current against it, which, could it be completely converted into pressure head, would produce in the Pitot tube a pressure head of $\frac{v^2}{2g}$ superimposed on the existing static pressure of the fluid. When the Pitot tube, which is the impact tube, is used in connection with a **piezometer tube**, the static pressure may be subtracted from the total pressure given by the Pitot tube, leaving a difference which is velocity head. This arrangement is frequently used for measuring the velocity of flow of water or air. For example, a Pitot head for measuring the velocity of air is shown in the illustration. The two



Pitot-static tube. (*Prandtl.*)

leads from this head are carried to either leg of a U-tube manometer. When a current of air flows past the head the liquid is displaced in the manometer by an amount which is proportional to the velocity squared. When this manometer reading is converted into head of the fluid, i.e., air, the velocity is $v = C\sqrt{2gh}$. C is the Pitot coefficient, obtained from a calibration test of the instrument, but is usually assumed to be 1. (F.T.M.)

PITS. Because increase in the thickness of the walls of the **cells** of plants does not take place over the entire surface of the cell, many thin places, called pits, are left in the wall. In cells in any given plant, pits have a very constant appearance, though they do vary greatly from plant to plant. Pits are most abundant in the walls of **tracheids** and **vessels**, and are either entirely absent or of rare occurrence in the walls of **fibers**. The thin places in the walls of two adjoining cells are found always to lie opposite to one another, though they may not have exactly the same size or shape. In many cases the thickened wall of the cell forms an overhanging rim around the pit, which is then called a bordered pit, the surface-view showing a distinct border around the opening. Pits which lack such a margin are called simple pits. In bordered pits the thin membrane has a thickened central portion known as the torus, which is often pressed closely to the overhanging margin, and apparently acts as a valve.

Bordered pits vary greatly in size and shape. Typically both the cavity and the opening of the pit are circular. In much-thickened walls the opening of the pit may become slit-like instead of circular. Often the slits are very numerous and extend far beyond the margin of the actual cavity. Pits may be found irregularly scattered over the entire surface of a cell, or they may occur in regular rows. Frequently they are crowded so closely together as to appear **polygonal** in shape. The function of pits seems to be to facilitate the diffusion of liquids from cell to cell. (R.M.W.)

PITTA. Aves, Passeriformes. *Pitta.* Small, brightly colored birds (**Aves**) of the Old World, also called the ant thrushes, water thrushes, and ground thrushes. They are only superficially like the true thrushes. (A.W.L.)

PITUITARY GLAND (THE HYPOPHYSIS). The pituitary gland is one of the endocrine glands. It is situated at the base of the brain in a depression of the sphenoid bone called the *sella turcica.* Because of its many ***hormones*** which are vitally concerned in fundamental physiological functions, it is sometimes designated as the "master gland." It is about 1 cm. in size, and composed of three parts, the anterior and the posterior lobes and the pars intermedia, each with different functions.

The posterior lobe of the pituitary gland is of neural origin (derived from brain tissue). Its physiology is not completely understood. Posterior pituitary extract or "pituitrin" possesses three distinct actions. One is the stimulation of the uterus (oxytocic effect) so that the uterine muscle contracts. Another is the constriction of blood vessels (pressor effect); and a third is the action on the kidney tubules to increase water reabsorption (antidiuretic effect). These functions form the basis of the therapeutic uses of posterior pituitary extract. The drug is used to induce labor at the end of pregnancy under certain circumstances. During the third stage of labor it is given to promote contraction of the uterus and thus prevent undue hemorrhage; in the days following delivery it is administered routinely to aid in the involution of the uterus. In *diabetes insipidus,* a disease associated with changes in the hypothalamic region of the base of the brain, it is given because of its antidiuretic effect since patients with this condition excrete enormous quantities of urine. After abdominal operations, pituitrin is given to prevent distension due to relaxation of the bowel musculature. Its pressor substance is probably responsible for this effect.

The anterior lobe originates embryonically from the epithelial lining of the pharynx. This lobe may be divided into two main parts, the anterior and intermediate portions. The function of the latter is not known. The anterior portion has many functions, and several of its hormones have been isolated.

Removal of the anterior lobe in young mammals causes cessation of growth, bone changes, failure of development of the permanent teeth, and failure of sexual development. There are also atrophic changes in many of the endocrine glands, showing that the pituitary is the master control of the endocrine system.

The number of hormones produced by the anterior pituitary is not known. At least nine separate types of activity have been attributed to its secretions, but it is probable that in some instances a single chemical substance is responsible for several effects. The following is a list of hormones as they are commonly designated:

1. Growth. Excessive production results in gigantism and **acromegaly;** decreased production is responsible for certain types of dwarfism.

2. Gonadotrophic. Follicle-stimulating and luteinizing hormones are intimately connected with ovarian function and **menstruation.** In the male, the follicle-stimulating hormone induces the development of spermatozoa in the **testicle** while the luteinizing hormone stimulates the production of the male sex hormone, testosterone.

3. Lactogenic. This hormone is necessary for the initiation of the flow of milk and normal lactation following pregnancy.

4. Thyrotropic. Without thyrotropic hormone, the thyroid gland undergoes atrophy; in the presence of excess, the thyroid increases in glandular tissue and function.

5. Adrenotropic. The adrenal cortex hypertrophies if an excessive amount of this hormone is present, and atrophies in its absence.

About the rest of the principles little is known. They are: 6. Diabetogenic. 7. Parathyrotropic. 8. Ketogenic. 9. Pancreatropic. (R.S.M., D.M.H.)

PIVOT BEARING. Bearings.

PLACENTA. 1. A structure which attaches the unborn **embryo** or fetus to the uterine wall of the mother in the true **mammals.** It is formed from a portion of the **chorion,** and the allantoic or umbilical blood vessels provide communication between it and the circulatory system of the embryo. In the simpler placentas the outer surface of the chorion is merely in close contact with the lining of the **uterus** and the structure is called a contact placenta or a semi-placenta. Many mammals, including man, have a burrowing or true placenta. In this form the chorion bears many root-like processes which invade the lining of the uterus and come into direct contact with the blood of the mother. In no type of placenta do the fetal and maternal bloods mingle, although interchange takes place between them through the thin intervening tissues. Many names have been applied to different forms of placentas, both normal and abnormal.

The human placenta is a flat circular mass of tissue, which serves to establish communication between the mother and the child by means of the **umbilical cord.** It is about 6 or 7″ in diameter, about 1″ in thickness, and weighs about 1 lb. During the third stage of labor, after the birth of the child, the placenta and membranes are passed (in the after-birth). If before the child is due, a separation of a portion of the placenta occurs, uterine hemorrhage results and miscarriage usually takes place (premature separation of the placenta). The placenta is normally attached to the uterus away from the **cervix** or the opening of the uterus into the vagina. When the placenta overlaps or covers this opening a condition known as *placenta previa* exists which may result in fatal hemorrhage with death of the child and mother.

2. Among the viviparous **arthropods** the young are attached to the walls of the genital passages for nourishment in some species. The attaching structure is called a placenta. It occurs in **onychophora, scorpions,** and a few **insects (flies).** The salpians also have an attachment of this kind (A.W.L., R.S.M.)

PLAGIOCLASE. Feldspar.

PLAGIONITE. A mineral antimony sulfide of lead, $Pb_5Sb_8S_{17}$. Crystallizes in the monoclinic system. Hardness, 2.5; specific gravity, 5.56±; color, gray to black with metallic luster; opaque. From the Greek, meaning oblique in reference to the obliquity of the crystals. (R.M.F.)

PLAGUE. An infectious disease caused by a rod-shaped bacterium, *Pasturella pestis.* Plague probably originated in Central Asia, but it has been known in Europe for many centuries. Its rise and spread have always been associated with wars. The Crusades were responsible for the Black Death of the 14th century which killed approximately ¼ the population of Europe, or 25,000,000 people. Since the middle of the 19th century, the disease has been rare in the Mediterranean basin, even though a pandemic arising in South China has spread along trade routes into the ports of Asia, North and South America, Australia, and Africa and caused many millions of deaths.

Plague is a rat infection transmitted to man by the bite of fleas which have fed on infected rodents. The **epidemic** and pandemic varieties occur in seaports, and spread is accomplished by the rat population of ships. In the western part of the United States, extending from the Pacific to North Dakota, there is a permanent **endemic plague area.** Here, particularly in sparsely

populated areas, sylvatic plague is always present in wild rodents, ground squirrels, chipmunks, marmots, prairie dogs, wood rats, hares, and rabbits. At intervals, the disease flares up in these animals and appears as explosive outbreaks which kill off great numbers of them. On rare occasions, man becomes infected—as with the epidemic form—through bites from fleas which have fed on these infected rodents.

The incubation time of plague is from 2 to 5 or more days. The bubonic form is characterized by painful enlargement of the lymphatic glands of the groin, axilla, or neck. Suppurating **buboes** containing the causative organism may occur. The onset is sudden and is characterized by chill, headache, backache, high fever and rapid pulse. Extreme prostration and lethargy develop rapidly and vomiting and delirium may occur. The mortality is around 75% and death usually occurs on the third or fourth day. Even in cases which seem to be recovering, sudden heart failure may develop with immediate death.

The pneumonic form is characterized by rapidly spreading **pneumonia.** Here the onset is sudden, prostration may be extreme and the lungs fill up with frothy blood. Death invariably results in 1 to 4 days. This is the only form of plague which is transmitted from man to man without the intermediatory transmission of fleas. The infection is carried by droplets coughed by the patient. The strictest isolation and quarantine must be followed.

Septicemic plague is a fulminating form which develops so rapidly that death occurs before buboes develop. The signs are those of a fulminating pneumonia accompanied by blood-stained watery sputum. It is invariably fatal within a few days.

The treatment of plague consists of the administration of immune **serum** and **sulfadiazine.** The latter has been effective in reducing the mortality considerably. It is of importance that an early diagnosis be made since treatment is more effective in the early stages. Furthermore, the patient is a dangerous source of infection and the strictest isolation precautions must be used when the diagnosis is suspected.

The prevention of plague is a matter of rodent control. Rat-proofing of ships and ridding cargoes of fleas and rats in port have cut down the incidence tremendously. The control of infected rural rodent populations in the West is also of great importance. Individuals likely to be exposed should be immunized with plague **vaccine** which offers partial protection. (D.M.H.)

PLAICE. Pisces, Teleostei. A European **flatfish,** *Pleuronectes platessa,* related to the flounder but of exclusively marine distribution. (A.W.L.)

PLANCK CONSTANT. **Planck's Law.**

PLANCK'S EQUATION. An equation developed by Max Planck in 1900 to represent the **spectral energy distribution** of the radiation from a **black body** at a given temperature, in accordance with his then newly conceived **quantum theory** of radiation. It expresses the emissive power of a black body within the infinitely small wavelength range, λ to $\lambda + d\lambda$, as follows:

$$dE_\lambda = 2\pi c^2 h\lambda^{-5}[e^{ch/k\lambda T} - 1]^{-1}d\lambda.$$

T is the absolute temperature of the black body, c is the **electromagnetic constant,** h is Planck's constant (see **Planck's Law**), and k is Boltzmann's constant (see **Ideal Gas Law**). The value of the coefficient $2\pi c^2h$ is about 3.740×10^{-5} erg cm.^{2}/sec., while the factor ch/k in the exponent is 1.438 cm. deg. An alternative form expresses the radiant energy density, within the same range, of the radiation in thermal equilibrium with a black body as equal to $8\pi ch\lambda^{-5}[e^{ch/k\lambda T} - 1]^{-1}d\lambda$. The law is found to agree accurately with experiment. (See **Wien's laws.**) (L.D.W.)

PLANCK'S LAW. The fundamental law of the **quantum theory,** expressing the essential concept that energy transfers associated with radiation such as **light** or **x-rays** are made up of definite quanta or increments of energy proportional to the frequency of the corresponding radiation. This proportionality is usually expressed by the quantum formula $q = h\nu$, in which q is the value of the quantum in units of energy and ν is the frequency of the radiation.

h, the constant of proportionality, is known as the elementary quantum of action or more commonly, "Planck's constant." Since q is energy and ν is frequency, h has the dimensions of energy $\times$ time, or **action.** Its value has been found to be about 6.624×10^{-27} erg-second. Thus, if the wavelength of a certain monochromatic green light is 5000 angstroms, its frequency is 6×10^{14} per sec., and its energy is made up of quanta each equal to 6.624×10^{-27} erg-sec. $\times$ 6×10^{14}/sec., or 3.97×10^{-12} erg.

Why such a relation should exist between these natural units or quanta of radiant energy and the frequency of the radiation, is still an unsolved problem. (L.D.W.)

PLANE. A plane is a fundamental geometric concept, being one of the basic geometric elements used in the construction of geometric figures in space.

The equation of any plane in **rectangular coordinates** x, y, z is of the first degree (i.e., is a linear equation).

Every linear equation in rectangular coordinates x, y, z is represented by a plane in space.

The normal form of the equation of a plane in rectangular coordinates is

$$x \cos\alpha + y\cos\beta + z\cos\gamma - p = 0,$$

where p is the perpendicular distance from the origin to the plane, and α, β, γ are the direction angles of that perpendicular.

The intercept form of the equation of a plane is

$$\frac{x}{a} + \frac{y}{b} + \frac{z}{c} = 1,$$

where a, b, c are the intercepts of the plane on the axes.

The equation of a plane through 3 given points may be written

$$\begin{vmatrix} x & y & z & 1 \\ x_1 & y_1 & z_1 & 1 \\ x_2 & y_2 & z_2 & 1 \\ x_3 & y_3 & z_3 & 1 \end{vmatrix} = 0.$$

To reduce the general equation $Ax + By + Cz + D = 0$ of a plane to the normal form, divide each coefficient by $\pm\sqrt{A^2 + B^2 + C^2}$.

The coefficients of x, y, z in the equation of a plane are proportional to the **direction cosines** of a line perpendicular to the plane.

The angle θ between two planes $Ax + By + Cz + D = 0$ and $A'x + B'y + C'z + D' = 0$ is given by

$$\cos\theta = \frac{AA' + BB' + CC'}{\sqrt{A^2 + B^2 + C^2} \cdot \sqrt{A'^2 + B'^2 + C'^2}}.$$

These two planes are parallel when and only when $A/A' = B/B' = C/C'$ (i.e., when the corresponding coefficients of x, y, z are proportional).

These two planes are perpendicular when and only when $AA' + BB' + CC' = 0$.

The intercepts of a plane are the distances cut off on each of the coordinate axes; they may be found by putting successively each pair of coordinates equal to 0 and solving the equation of the plane for the other coordinate.

The traces of a plane are the straight lines in which the plane cuts the coordinate planes; they may be found by

putting successively each coordinate equal to o in the equation of the plane.

The perpendicular distance of a point $P_1(x_1, y_1, z_1)$ from a plane whose equation is $x \cos\alpha + y\cos\beta + z\cos\gamma - p = o$ is given by

$$d = x_1 \cos\alpha + y_1 \cos\beta + z_1 \cos\gamma - p;$$

the perpendicular distance from the plane $Ax + By + Cz + D = o$ is given by

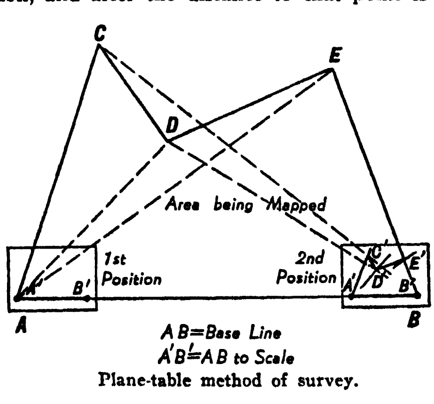
$$d = \frac{Ax_1 + By_1 + Cz_1 + D}{\sqrt{A^2 + B^2 + C^2}}.$$

If $P_1 = o$ and $P_2 = o$ are the equations of two planes, the equation $P_1 + kP_2 = o$ is a system of planes through the intersection line of the two given planes. (See **Woodworking.**) (L.L.S.)

PLANE SAILING. This term is applied to the solution of various problems in the **sailings** in which the earth is considered as a plane surface. The particular subject of plane sailing will be found discussed under the topic **Dead Reckoning.** (W.K.G.)

PLANE SURVEYING. Surveying.

PLANE TABLE. A plane table is a **surveying** instrument which is used for locating and mapping topographical features. A drawing board, accurately made, and arranged so that it may be mounted on a tripod by an adjustable head which allows leveling of the board, is an essential feature of the plane table. Spirit levels are attached to the table in mutually perpendicular directions. The compass, the ruler, and a means for getting a line of sight, such as a telescope or open sights, complete the outfit. A ruler combined with a telescope or with slit sights is called an **alidade.** When the plane table is used for a survey, it is not necessary to take notes of angles or lengths of lines, since they are plotted, at the time of the survey, on the sheet of paper which covers the plane table. Obviously the plane table is not suitable for use in bad weather. When a survey is to be made with this instrument, the table is set up so that some convenient point on the paper is over a selected spot on the ground. The table is leveled and rotated horizontally until it is in **azimuth.** This is accomplished by means of the compass or by sighting back on a known point. It is then clamped in this position and the ruler is brought to the point selected on the paper and swung about it so that the line of sight which parallels the ruler bears on a distant point whose location is desired. A line is drawn in that direction, and after the distance to that point is meas-



Plane-table method of survey.

ured, the length of line is plotted to some scale suitable to include the area being mapped on the surface of the plane table.

It is entirely possible to locate the points of a survey, with the exception of the two points specified in the preceding paragraph without measurement. This method is known as the method of intersections, and requires only one distance to be actually measured. In the method of intersections, the plane table is set over one point, and a line of sight taken on some other selected point, possibly a corner of the area. The distance between those two points is measured, and the other point put in by scale on the plane-table drawing. The alidade is then swung about the initial point, and lines are drawn toward the several other corners which are to be located. The plane table is then set up over the other terminus of the measured base line, and oriented by a compass or by aligning the initially measured line with the initial point by alidade. The alidade is then swung about the second point and lines are drawn again toward the same other corners that are to be located. The intersections will give the location of the points.

Topography may be plotted on a plane table map by either of two methods. If the alidade is telescopic with stadia attachment the general method for topography by stadia may be adapted to plane-table mapping. By this method a small contour interval may be satisfactorily mapped. If the alidade does not have the stadia attachment points, elevation may be secured by the aneroid barometer. When these points are plotted on the map the contours may be secured by interpolation. In either case, sketching contours in the field is preferable to office execution. The use of the aneroid barometer is limited to large contour intervals such as 20 to 100′. (F.T.M., E.W.S.)

PLANER. For wood planers and shapers, see **Woodworking.**

Planers, shapers and slotters are machine tools that employ single-point tools to generate flat surfaces. In each of these the relative motion of the cutting tool and the work is rectilinear, and either the tool or the work feeds in a direction perpendicular to the cutting stroke. In the planer, the work is held on a horizontal table and moves past a stationary tool; in the shaper, the work is stationary and the tool moves over it. The slotter may be called a vertical shaper, since the tool moves in a vertical direction past the stationary work. All three machines finish surfaces in a similar manner, and their selection depends primarily upon the nature of the work.

The planer is generally used for large work. For comparatively small work the shaper is used, unless a large number of like parts are to be finished. In this case the parts are frequently placed on a planer table in rows, and a number of parts are planed at one setting. This operation is referred to as string planing. The slotter is used for machining flat surfaces which are difficult or inconvenient to machine because they are at right angles to the main dimensions of the part. The slotter is also employed for cutting internal keyways, square holes, and die openings.

Planers and shapers are used for machining surfaces to a high degree of accuracy, and in general require less power per cubic inch of metal removed than machine tools employing multi-toothed cutters. Planer and shaper tools are considerably less expensive than milling cutters; the planer may therefore be used in preference to a milling machine if the castings are poor and subject to hard spots.

The conventional form of crank-driven shaper derives its cutting motion from a pivoted lever, which is driven by an adjustable crank. (See **Quick-Return Mechanism.**) The table which carries the work feeds in a direction perpendicular to the tool motion, and may be adjusted for various heights. Universal shapers are equipped with tilting or adjustable tables so that angular work can be handled. Shaper tools are similar to solid or inserted-bit lathe tools; extension tools are used for cutting keyways and square and splined holes.

Shaper work may be held in a vise or clamped to the table.

There are two standard types of planers that are in extensive use in jobbing and production shops. One of these types is the double-housing planer; the other is the open-side planer. The work is bolted or otherwise securely fastened to a table or platen, the under side of which is provided with two accurately machined guides which slide in guide ways on the planer bed. The table moves against one or more cutting tools, which are held by the rail and side heads, at a speed adapted to the material to be cut. The return stroke, during which no cutting takes place, is usually constant, but is from two to four times as fast as the cutting stroke so as to economize on time.

Planer size is determined by the maximum stroke of the table and the width and height of work that will pass through the housings and underneath the cross-rail. A double housing 30″ x 30″ x 8′ planer, for instance, will machine a part 30″ high, 30″ wide and 8′ long. Open-side planers are classified by the cross-rail height and the length of stroke, and will generally handle work that is somewhat wider than its height.

Planer work may be held in a vise bolted to the planer table or the work may be clamped directly to the table. The table has three or more tee slots running lengthwise and numerous holes for inserting stops and clamping blocks. Castings can generally be clamped in place by using straps or clamps on projecting portions of the work. Planer tools are similar to shaper tools, but are usually larger. In many instances, gang planer tools, carrying three or more tool bits closely adjacent, are used. As each chip is comparatively small, a planer equipped with a gang tool will carry a far greater total feed and depth of cut than are possible with a single-point tool.

A slotter is a shaper with a vertical ram which reciprocates in a ram slide which may be swung to any angle from a vertical position up to 5° from the vertical. The ram receives its motion from a rotating crank which drives a slotted rocker arm through a driving block. A movable saddle is mounted on the bed and dovetail guides permit motion in one direction. The table base is mounted on the saddle and guides integral with the saddle permit perpendicular transverse motion. The rotary table is mounted on a swivel bearing in the table base and may be rotated about its center. The rotary table may be rotated for feeding in either direction by power or by the use of the handwheel; and both the table base and the saddle may be hand-adjusted or power fed in either direction. The rotary table has a graduated edge, and the table handwheel has a micrometer dial subdivided so that the smallest divisions represent two minutes of arc. There are indexing notches provided so that the table can be indexed quickly through the major angles and positioned exactly by a small plunger. (H.C.H.)

PLANETARY MOTIONS. The apparent motions of the **planets** on the **celestial sphere** have been observed, recorded and speculated about ever since mankind has existed on the earth. A large part of the pseudo-science of **astrology** is concerned with these motions, or, more particularly, with the various "aspects," or configurations, of the planets. The motions as seen from the earth are complicated by the fact that the earth is moving about the sun in the same direction as the planets, but with a different rate.

Apparent Motions Relative to the Sun. In Fig. 1, we have S representing the sun, E representing the earth (assumed fixed for the purpose of convenience), P'_1, P', P'_2, P'_3, P'_4 indicating various positions of a planet whose **orbit** lies between the earth and the sun (inferior planet), and P_1, P, P_2, P_3, P_4, positions of a planet whose orbit is outside of that of the earth (superior planet). The angle between the sun and the planet (e.g., SEP' or SEP) is defined as the elongation of the planet. For an inferior planet the elongation may have any value from 0 to SEP'_2 *or* SEP'_4 while

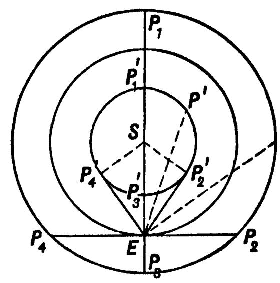


Fig. 1. Motions of planets as seen from earth relative to the sun.

for a superior planet the elongation varies either east or west from 0 to 180°. With elongation 0 we have the planet in the aspect of conjunction.

Inferior planets: It will be noted that the elongation is 0 both at P'_1 and also at P'_3 and hence there are two conjunctions for an inferior planet. To distinguish between them P'_1 is known as superior conjunction and P'_3, inferior conjunction. An inferior planet moves more rapidly in its orbit than does the earth and accordingly from superior conjunction the planet moves out with increasing eastern elongation (evening object) to the point P'_2 (greatest eastern elongation). It then moves in with decreasing elongation, passes the sun and becomes a morning object at inferior conjunction (P'_3) and moves out with increasing western elongation to P'_4 (greatest western elongation) and thence back to superior conjunction again. Hence these planets apparently oscillate back and forth across the direction of the sun. They do not ordinarily pass either between the earth and the sun or directly behind the sun because of the fact that their orbits are not in the plane of the **ecliptic** (see **Transit of Venus**).

Superior Planets: It must be remembered that these planets are moving more slowly in their orbits than is the earth. These planets apparently move from conjunction at P_1 slowly out to the west of the sun (morning objects) to P_2 where the western elongation is 90° and the aspect is western quadrature. From this point the increase in western elongation increases rapidly to 180° at P_3 (aspect opposition) from which point the elongation becomes east (evening object) and decreases rapidly to 90° eastern elongation at P_4 (eastern quadrature). The decrease in eastern elongation then slows down as the planet moves slowly back to conjunction again.

Apparent Motions of the Planets Relative to the Stars. In Fig. 2, we have S representing the position of the sun, E representing the (assumed circular) orbit of the earth, with successive positions marked, P the orbit of a planet with successive positions marked with numbers corresponding in date with the marked positions for the earth, and an outer circle representing directions on the celestial sphere, V being the direction of the vernal **equinox**, A the direction of the autumnal equinox and the direction of increasing **longitude** (or **right ascension**) indicated by arrows.

The successive positions of the planet as seen from the earth relative to the stars, are obtained by drawing lines, representing the lines of sight from successive positions of the earth through corresponding positions of the planet. By examining the successive directions, as indicated by numbers on the outer circle, it will be evident that the general trend of the planetary motion is in the direction of increasing right ascension. Such motion in increasing right ascension is known as direct motion. It will be noticed, however, that in the vicinity of opposition of the planet, the motion reverses for a

period (numbers 6, 7, and 8) and the planet moves in the direction of decreasing right ascension. Such motion, in the direction of decreasing right ascension, is known as retrograde motion.

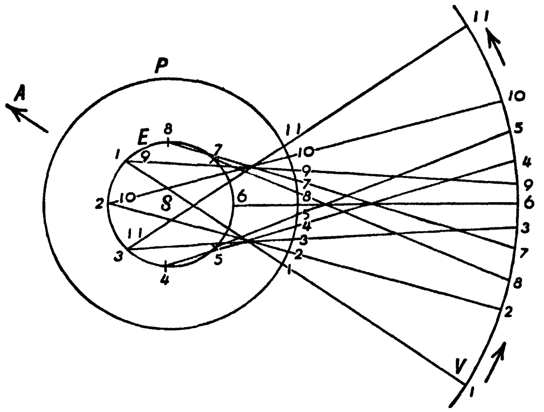

Fig. 2. Motion of planet as seen from the earth relative to the stars.

Since the diagram is plotted in the plane of the ecliptic with the planet also assumed in this plane, the reversal in direction appears only in longitude. However, there will also be changes in direction of motion both in celestial **latitude** and **declination,** giving the appearance on the celestial sphere of loops in the motion of the planet. These loops were observed by the early astronomers and it was to account for those on the assumption of the geocentric universe that the epicycles of the **Ptolemaic system** became necessary.

The general subject of planetary motions referred to the sun alone will be found discussed under the general topic of orbits. (W.K.G.)

PLANETS. The word planet, which comes from a Greek root meaning "wanderer," was used prior to the 15th century to designate those celestial objects (other than **meteors** and **comets**) which were observed to be in motion relative to the stars. Prior to the 15th century, seven objects were listed as planets: **Sun, Moon, Mercury, Venus, Mars, Jupiter,** and **Saturn.** With the advent of the **Copernican** heliocentric hypothesis for the structure of the **universe,** the sun and moon were removed from the list and the earth added. Since the application of the telescope to astronomy three large planets have been added (**Uranus, Neptune,** and **Pluto**) and over 1000 small planets or **asteroids.** The term as it is used at present applies to any opaque object which is shining by reflected sunlight and travels about the sun in an **orbit.**

In spite of the fact that many of the planets are larger than the earth, their distance is so great that they appear to the naked eye as bright stars. The only certain method for distinguishing a planet from a star without the use of a telescope is to watch it carefully for a considerable period, frequently several days are re-

PLANETARY TABLE I. ORBITAL CHARACTERISTICS

quired, and if the object is a true planet, it will move relative to the stars. For a quick method of identification, it may be said that usually a planet does not appear to twinkle as do the stars, but this rule is not infallible. With a telescope a planet may be immediately distinguished from a star (with the exception of the planet Pluto or the asteroids) because of the fact that a planet will show an appreciable disk while the stars appear as points of light no matter how much magnification is used.

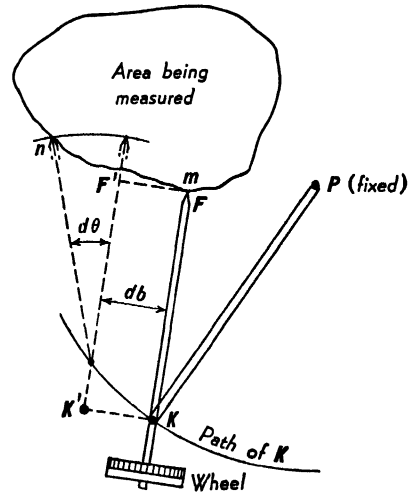
The planets are classified in two general ways. Mercury and Venus are frequently referred to as the inferior planets, while the others are called the superior planets. Another system of classification considers Mercury, Venus, Earth, and Mars as the minor or terrestrial planets, while Jupiter, Saturn, Uranus, Neptune, and Pluto are called the major planets.

In this article we shall limit ourselves to the material contained in the accompanying tables. Elsewhere in this work will be found discussions of planetary **motions**, descriptions of the individual objects, and an outline of the various theories of planetary evolution under the discussion of the **solar system.** The **satellites** will also be considered elsewhere.

In Planetary Table I will be found the characteristics of the individual planets which have to do with distances and motions of the planets themselves. The various terms used for column headings will be found defined elsewhere in this work either under their individual terms or under the general subject of **orbit.**

Planetary Table II contains data relative to the physical conditions of the planets themselves. The mean diameter in seconds of arc, given in the third column, is the average diameter as seen from the earth. Since the distances of the planets from the earth, particularly in the case of Venus and Mars, vary through wide limits, the angular diameter at any particular instant may be very different from the value given. The fourth column gives the average temperature of the objects on the Kelvin scale. The values given are those determined by means of **radiometric** observations. In the case of Mercury the value for the sunlit side is given, in the case of Venus the average of the dark and bright sides is used, and for Mars the value obtained for the warmest portion is taken. Further information regarding planetary temperatures will be found in the articles dealing with the individual objects. The mean densities are calculated from the masses and measured diameters. It should be noted that the measured diameter is that of the planet plus atmosphere and probably in the cases of the outer planets the layer of atmosphere is very thick. Possibly this accounts for the low value of the density in comparison with that of the earth. By surface gravity is meant the **gravitational** attraction on unit mass at the surface of the planet. For example, on Jupiter a mass of 10 grams would have a **weight** of 26.5 grams. All values tabulated for the planet Pluto are uncertain. (W.K.G.)

PLANIMETER. The polar planimeter, which is credited to Amsler, is an instrument for the measurement of irregular plane areas. While the area of a regular plane figure may be found by the application of rules for averaging, methods of subdivision, etc., such methods are tedious compared to the ease and accuracy with which the planimeter measures irregular areas. The general form of the polar planimeter is shown in the accompanying figure. There are two arms pivoted together at the point K. The arm PK is free to rotate about the needle point P, and is held in place at that point by a weight. The other arm KF carries a tracing point at F. This is guided around the border of the area to be measured. The arm KF also carries a wheel whose axis must be parallel to KF. The rim of this wheel is in contact with the paper so that any motion of the arm except that in the direction KF will cause the wheel to rotate. A graduated scale with **vernier** attachment measures the travel of the circumference of the measuring wheel. To use the planimeter, the tracing point is set at some initial



Theory of the Planimeter

point on the circumference of the area, and the reading of the record wheel is next noted. The tracing point is carefully guided around the border of the area clockwise until it has returned to the starting point. A final reading is taken and subtraction of the two readings gives a number which is either the area directly in square inches, or bears a relationship to it as follows:

$$\text{area} = \text{reading} \times \text{a constant}.$$

In some planimeters there is only one constant, but in others the length of the tracing arm may be varied by a micrometer adjustment. This feature is useful when the planimeter is to be used on areas drawn to scale. By employing the proper setting (i.e., the setting constant = scale of area), the area may be obtained directly from the wheel reading.

The explanation of the planimeter rests on a mathematical basis of the integral calculus, since it is primarily an instrument performing a graphical **integration.** It will be shown that the dimensions which are involved in the measurement of area are length of the tracing arm and the movement of the wheel. The length PK has no effect as long as K moves in the arc of a circle. In common use of the planimeter this is true, but large areas sometimes necessitate placing the pole (needle point) inside so that the arm PK describes a complete circle. In this case the area is not read directly from the record wheel. It is the area of the zero circle, plus or minus the wheel reading. The zero circle is that traced by the point F when the plane of the measuring wheel, extended, passes through P. The area of the zero circle, if the graduated scale gives the area directly, is the difference between the readings obtained by traversing the outline of any given area, first with the pole inside and then with the pole outside the area. If the scale does not give the area directly the difference between the readings must be multiplied by a constant to obtain the true value of the zero circle.

The figure above explains the theory of the planimeter. Suppose the tracing point F is moved from m to n along the curve bordering the area. The area swept over by KF can be considered to be made up of a translation dB and of a rotation $d\theta$. The area of translation is the length (L) of the tracing arm KF, multiplied by db. Note also, db is the distance rolled by the wheel. The center K must then be returned to the arc by a motion along the line $K'F'$. This generates no area,

and causes no wheel rotation. The area generated in rotation is $\frac{1}{2}L^2d\theta$. The area generated, then, is:

$$A = L\int db + \tfrac{1}{2}L^2\int d\theta.$$

When the point F has been carried completely around the closed line, the net area swept through by KF is equal to the area enclosed by that line. By returning point F to its original position, the integral of $d\theta$ becomes zero, and area equals $L\int db$. The $\int db$ is the net distance rolled by the wheel, and is read directly therefrom. Thus it is seen that the area measured by planimeter equals the length $FK \times$ the net distance rolled by the wheel. (F.T.M.)

PLANIMETRIC MAP. **Map.**

PLANKTON. The portion of the aquatic flora and **fauna** composed of organisms which merely float and drift and those whose active locomotion is not directional. Most of the organisms of the plankton are small or minute. The terms limnoplankton and haliplankton are sometimes applied to fresh-water and marine organisms, respectively, and other subdivisions have received special names. Floating organisms in the air have been called the aerial plankton, a category which includes no permanently planktonic forms, although some organisms may be carried by air currents in some stages of their development, such as the buoyant seeds of many plants and the pollen of anemophilous species.

The plankton includes many of the smaller invertebrates, such as **protozoans, coelenterates, worms,** and lower **chordates,** many **algae,** and some higher plants. (A.W.L.)

PLANOPHYRITIC. Used by **petrologists** to describe the texture of a **porphoritic igneous** rock in which the **phenocrysts** occur in layers. (R.M.F.)

PLANT ASSOCIATION. **Association, Plant.**

PLANT CUTTER. Aves, Passeriformes. Birds (**Aves**) of several species found only in Temperate South America. They have a short thick beak with finely serrate edges. Related to the chatterers. (A.W.L.)

PLANT LOUSE. **Aphid.**

PLANT SUCCESSION. **Succession, Plant.**

PLANTAIN EATER. Aves, Cuculiformes. An African bird (**Aves**) of an extensive group also called the touracos and louris. They are brightly colored birds and with the exception of the giant plantain eater, which is almost 3′ long, are of moderate size. (A.W.L.)

PLANTAINS. *Plantago* sp. Plantaginaceae. There are some 200 widely distributed species of plantains, many of which are ubiquitous weeds. Some species are stemless plants, the **petioled** leaves forming a rosette which covers a considerable area of ground, from which it excludes other desirable plants. These are the species which cause unsightly patches in lawns.

Plantago major is one of these, with broad ovate leaves on long petioles. *Plantago lanceolata* has **lanceolate** erect leaves. The flowers are borne in elongated **spikes,** the **pistil** maturing before the **stamens.** Plaintains are wind-pollinated plants, although insects occasionally visit them for their pollen. The fruit is a **capsule,** the upper half of which comes off when mature, through the development of a circumferential line of **dehiscence.** The seeds of plantains are often fed to caged birds. In some species the seeds imbibe water and become mucilaginous. One species, *Plantago Psyllium,* native in southern Europe, is sometimes used in medicine under the name Psyllium seed. (R.M.W.)

PLANULA. A larval form of the **coelentrates.** It is covered with a ciliated (**cilia**) ectodermal layer and is filled at first with a solid mass of endoderm, which later splits to form the enteric cavity. A free-swimming stage. (A.W.L.)

PLASMA. **Blood; Ionized Gases; Chalcedony.**

"PLASMOCHIN." (Registered in U. S. Patent Office.) It is also known as pamaquine, and the chemical name is 6-methoxy-8-(1-methyl-4-diethylaminobutylamino)-quinoline. Announced in 1924, this was the first promising synthetic chemical for the treatment of malaria, active against the parasite causing the disease but not directly for the symptoms of the disease itself. (See **"Atabrine."**) (R.K.S.)

PLASMODESMA. Plasmodesmata are minute threads of **protoplasm** passing through minute pits in the walls of adjoining cells. These threads are so minute that special methods of **histological** preparation are usually needed to make them visible. They are larger and more easily seen in the walls of cells of the **endosperm,** and in cells of **gymnosperms** and ferns. It is possible that they may be found connecting the protoplasts of all living cells in plants, but are too minute to be seen. Their function is not known. (R.M.W.)

PLASMODROMA. A subdivision of the 1-celled animals characterized by the presence of a single kind of **nucleus.** The phylum **Protozoa** contains two such subdivisions, the subphyla **Cilophora** and **Plasmodroma.** This subphylum is divided into three classes and many orders. The classification is briefly summarized below:

Class **Mastigophora.** Animals with one or more **flagella.** Many species have chlorophyll and are intermediate between plants and animals.
- Subclass Phytomastigina. Mostly colored species, with chlorophyll.
  - Order **Chrysomonadida.** Minute species of yellow to brown color, rarely bluish or green.
  - Order **Cryptomonadida.** With a cytopharynx. Body flattened.
  - Order **Dinoflagellida.** Body enclosed in a cellulose covering of two parts.
  - Order **Phytomonadida.** Color green. No cytopharynx.
  - Order **Euglenoidida.** Cytopharynx present. Color green. Stored food in the form of **carbohydrates.**
  - Order **Chloromonadida.** Cytopharynx present. Color green. Stored food in the form of oils.
- Subclass Zoomastigina. Without chlorophyll. Usually with a single vesicular nucleus.
  - Order **Pantostomatida.** Animals with both **pseudopodia** and flagella.
  - Order **Protomonadida.** Small animals with one to three flagella.
  - Order **Polymastigida.** Minute forms with two to eight flagella and one to many nuclei. Mostly parasitic in the digestive tract of animals.
  - Order **Hypermastigida.** With more than eight flagella. Parasitic in the intestine of insects.

Class **Sarcodina.** Without a **pellicle** and therefore without constant body form. Pseudopodia are formed for locomotion and to secure food.
- Subclass **Rhizopoda.** Species which form temporary pseudopodia of various forms.
  - Order **Proteomyxa.** Without hard parts. Pseudopodia slender, sometimes branching and anastomosing.
  - Order **Mycetozoa.** The **slime molds,** formerly regarded as plants. Active stage a plasmodium consisting of a large mass of protoplasm with many nuclei.

Order **Amoebaea.** Without hard parts. Pseudopodia thick protuberances.
Order **Testacea.** With an enclosing shell or test containing a single chamber. Chitinous.
Order **Foraminifera.** With an enclosing test of many chambers. Calcareous.
Subclass Actinopoda. With straight slender radiating pseudopodia which are semipermanent.
Order **Heliozoa.** Chiefly fresh-water species. Body usually spherical, without a central capsule enclosing the inner portion.
Order **Radiolaria.** Marine forms. Usually spherical, with the central portion enclosed in a membranous central capsule.
Class **Sporozoa.** Parasitic species without flagella or cilia and with pseudopodia only in the immature stages.
Subclass Telosporidia. Spores without a polar filament. Spore containing more than one sporozoite or without a resistant capsule. The orders are characterized by peculiarities of the reproductive stages.
Order **Coccidia.** Parasitic chiefly in the lining of the digestive tract of vertebrates and higher invertebrates, and in the associated glands.
Order **Haemosporidia.** Part of the life cycle occurs in the blood of vertebrates and part in the alimentary tract of a blood-sucking invertebrate. The **malarial** parasites and others.
Order **Gregarinida.** Parasitic chiefly in arthropods and annelids.
Subclass Cnidosporidia. Spore with a coiled polar filament.
Order **Myxosporidia.** Mostly parasites of fishes.
Order **Actinomyxidia.** Parasitic in aquatic **annelids.**
Order **Microsporidia.** Typically parasitic in cells of **arthropods** and fishes.
Order **Helicosporidia.** A single peculiar species parasitic in insects.
Subclass Acnidosporidia. Spores without polar filament; with a single sporozoite.
Order **Sarcosporidia.** Parasitic in the muscles of mammals and to some extent of birds and reptiles.
Order **Haplosporidia.** Parasitic in invertebrates and lower vertebrates. (A.W.L.)

PLASMOTOMY. A reproductive process of certain one-celled animals. By this process a multinucleate form of species parasitic in fishes (**Plasmodroma,** Myxosporidia) subdivides into two or more parts, each with several nuclei. (A.W.L.)

PLASTER OF PARIS. Calcium Sulfate.

PLASTIC MOLDING. Plastic molding is analogous to die casting in many of its forms. Plastic molding is a pressure process which is performed either in hydraulic presses with ram capacities of 1000 to 3000 lbs. per sq. in., or in special injection molding machines.

In injection molding the material, in granulated form, is placed in a feed hopper and forced past a spreader through a nozzle into a water-cooled die by a reciprocating plunger. The material is heated to a plastic state as it passes through the injection head. Fast production is the primary advantage of injection molding; one machine used operates at four cycles per minute, and will attain a production rate of 480 parts per hour while using a two-cavity mold. Parts with metal cores can be easily produced by this process, so that the final product will have the surface characteristics of the plastic with the rigidity of metal. The insert need not be carefully finished for plastic covering, as is the case when a metal die casting is prepared for plating.

Compression molding is employed for parts that are too large for successful injection molding, or parts of such thickness that excessive shrinkage must be guarded against. The commonest form of compression mold is the flash mold which permits excess material to escape during final closure of the mold. The mold charge is a previously compressed tablet, or preform, made from powdered or granulated material, and the slight excess flows out between the flash surfaces of the die during final closure. The resulting fin or thin edge must be removed after the part leaves the die, and usually constitutes the only finishing operation required on a plastic molded part.

When bulk material must be employed, a positive mold is used. The material must be accurately weighed or measured before loading since no excess is permissible in the mold. The dies are more subject to wear than flash mold dies. Positive molds may be equipped with strippers for removing deep cup-shaped parts. The floating-chase mold is used for parts whose length is great compared to their diameter. This mold consists of two independent plungers in a tubular die. Both plungers act upon the material so that a uniform density in the part may be attained.

Blowing molds use material in sheet or tube form which is expanded to the finished shape by air, water, or steam pressure. Tube molds consist of two die halves, which are loaded with the stock and closed and the stock is clamped in place by two nozzles. Steam under pressure is admitted through the nozzles and expands the stock to fill the mold. The part is then cooled by circulating water through the nozzles. In sheet molds, the sheets are clamped between two die halves, and a hollow needle is inserted through a groove in the dies. The heated dies render the material plastic, and compressed air is admitted through the needle until the material conforms to the mold shape. The needle is then removed and the finished halves of the part are welded by a pressure sufficient to bring the die edges together, which also cuts off the excess stock. (H.C.H.)

PLASTICITY. However defined by physicists and geophysicists, the effects of plasticity are of interest to the geologist (**stratigrapher**) principally in relation to the development of intraformational structures in **sediments** of the silt or clay grade, and are therefore indicative of the peculiar condition under which the sediments were deposited, deformed or reworked previous to **lithification.**

Most metals are characterized by high plasticity or ability to undergo permanent deformation in the solid state without fracture. Above the **recrystallization** temperature metals have almost unlimited plasticity because the deformed crystals are transformed into new unstrained crystals spontaneously. (K.M.F., R.H.H.)

PLASTICS. Plastic materials are of two types, namely, (1) bodies which are rigid at ordinary temperatures and pressures, and, when subjected to increased temperature or pressure, become softened so as to permit bending and forming, e.g., glass, (2) bodies which in the process of working soften sufficiently—generally but not always when they are subjected to increased temperature or pressure—so that they can be made to fill molds of forms, e.g., moist clay, moist Portland cement, rubber. The term plastics is loosely used to denote the classes of organic materials represented by "celluloid," "bakelite," "vinylite," "galalith" and rubber. These are used in a great variety of ways, and several are not confined in their uses to the field of plastics but have extensive use—in the form of resins in a solvent—as lacquers, adhesives, textile fibers, fabric treatment, automobile brake linings, impregnated wood, laminated materials such as glass, wood and paper, and finally in various sheets, tubes, filaments and films. (See **Pigments.**)

Of the synthetic plastics, except rubber, the following groups are representative: 1. Nitrocellulose plastics, ex-

ample Celluloid and its relatives. 2. Phenol-formaldehyde resins, example Bakelite and its relatives. 3. Urea—formaldehyde resins. 4. Cellulose acetate plastics. 5. Ethyl cellulose. 6. Vinyl polymers, example Vinylite. 7. Acrylic polymers, example methyl methacrylate. 8. Polystyrene. 9. Alkyd resins, example glycerol—phthalic acid resins. 10. **Nylon.**

Nitrocellulose plastics are made by taking 70 to 80 parts by weight of nitrocellulose (11% nitrogen), mixing with non-volatile solvents and plasticizers, e.g., castor oil, camphor, butyl phthalate, diethylphthalate, tricresyl phosphate, at 75–90° C., 20 to 30 parts by weight of camphor, and with 0 to 14 parts by weight of dyes, pigments, fillers. A volatile solvent, e.g., ethyl alcohol, is added, the material is shaped, and the volatile solvent evaporated. Residual volatile solvent remains to the extent of 1 to 5 parts by weight. The working range for molding is 85–120° C. The product, commonly "celluloid," is inflammable and therefore hazardous upon heating. The flash point test shows 160–200° C. The process was perfected and manufacture begun in the United States by J. W. and I. S. Hyatt in 1869.

Phenol-formaldehyde plastics and resins are made by mixing **phenol** and **formaldehyde** solution (37–40% HCHO) with **ammonia** as a **catalyzer**. The mixture is heated to 80–90° C. When the mass has formed a resin, the water is boiled off. The product is immediately drawn off and allowed to cool in thin layers, or a solvent, e.g., ethyl alcohol, acetone, is added to stop further reaction by dilution. Another method is to mix phenol and formaldehyde without adding ammonia, and subject the **mixture** to a temperature of 140–160° C. in a digestor. Heating slowly to the higher temperature in a period of about 3 hours is necessary to avoid the rapid reaction. Water is allowed to pass off by opening a valve on the digestor. The thin resinous product is drawn off and allowed to cool. When the properly prepared resin is mixed with modifying agents, such as nitrocellulose, resins, casein, and the desired fillers, at 110 to 140° C. under pressure for one hour, a hard molded product is obtained. Products insoluble in most solvents, and infusible, are for use as plastics, and other products soluble in certain solvents for use in lacquers.

Vinyl plastics and resins are made by polymerization of various individuals and mixtures of vinyl chloride, acetate, butyrate, and alcohol.

The natural resins, such as shellac, rosin, and asphalt, are not uniform in composition, and their uses are limited. In contrast, the synthetic resins are very uniform in individual composition, and their uses accordingly vastly outnumber those of the natural resins. On account of the properties being uniform, these properties, when once ascertained, can be depended upon to function regularly. Some of the properties that are important in connection with the uses but shown in different degrees by various synthetic resins are (1) electrical resistance or dielectric strength, (2) tensile strength, (3) flexing strength, (4) dimensional stability, (5) clarity, (6) ability to withstand high and low temperatures, and (7) ability to resist water, acids, oils, and other chemicals. The accompanying diagram PLASTICS COMPARATOR shows many of these results better than could

MOLDING PLASTICS COMPARATOR

(Thermosetting Materials)

Nos. 1–6 represent highest to lowest in order of merit. Relationships are qualitative and variation in formulation may alter position on chart.

	Shock Resistance (Impact—Izod)	Tensile Strength	Flexural Strength	Cold Flow	Hardness (Rockwell)	Heat Resistance (Utility under Continuous Heat)	Dimensional Change on Aging	Thermal Insulation	Specific Gravity	Flammability	Color Possibilities	Color Stability	Utility Around Inserts	Ease of Molding	Water Resistance (Absorption)	Alkali Resistance	Acid Resistance	Organic Solvent Resistance	Loss Factor 60 cycles/sec. be done with lengthy descriptions. Some specific data are presented in the following table:

Material	Tensile Strength Lbs. per Sq. In.	Softening Temperature ° C.	Electrical Behavior Dielectric Strength Volts per mil (0.001")
Hard vulcanized rubber	1,200–2,000	90	300–1,100
Cellulose nitrate	4,000–10,000	75	250–780
Shellac plastics	900–2,000	80	100–400
Phenol-formaldehyde plastics	5,000–10,000	150–250	200–700
Casein-formaldehyde	....	85	125
Vinyl plastics	7,000–9,000	75	350–400
Cellulose acetate	5,000	50–75	720
Urea-formaldehyde	5,000–6,000	....	300–400
Glass	....	... .	300–1,500
Porcelain	650–2,300	600–1,000	1,000
Portland cement	2,500	550	40–150

The Comparator gives relative property values, and is only a general summary for quick and easy reference. The ratings may not in all instances confirm published data. The materials are rated according to *usage* experience, as well as laboratory data. For example, urea, on the basis of A.S.T.M. water absorption tests, would warrant a better rating. However, on the basis of continuous exposure to high humidity or water, the rating in the Comparator is 4. In detail, the following is a list upon which the choice of values is based:

Shock Resistance. By this term is meant Izod impact strength in ft.-lb. per in. of milled notch.

Cold Flow. These values were based generally upon actual figures which refer to the distortion of the ½-in. cube of the molded material under a specified load at 122° F.

Hardness. These values were based upon figures obtained by the Rockwell hardness test.

Heat Resistance. These values were obtained from data indicating the highest temperatures at which the molded pieces could be subjected continuously and still maintain their utility.

Dimensional Change on Aging. Plasticizer loss; and water absorption. In choosing these values, the temperature was considered as room temperature, and weathering eliminated as a factor. Since no actual data were available, opinion was based on interpretation of the effect of the foregoing variables on dimensional change with normal indoor use.

Thermal Insulation. These values were based upon thermal conductivity measurements.

Specific Gravity. These values were obtained from several sources and represent definite data.

Flammability. These values were obtained from qualitative data evaluating the relative burning rate of the materials.

Appearance and Color Possibilities. The ratings represent opinion, and were based upon the following, in this order of importance: Transparency, brilliance and depth; translucency and color possibilities; surface smoothness and luster.

Color Change. This represents the intrinsic color change of the natural polymer or filler on aging, obtained from qualitative data and opinions.

Water Resistance. These values were based upon the amount of water absorbed by the material when immersed in water at room temperature for a period of 24 hours.

Alkali Resistance. These values were based upon the resistance to weak alkali, such as household soap solution. Water absorption was also considered when determining these values. Opinion as well as fact was used as basis.

Acid Resistance. These values were based upon the resistance to weak acids generally. Opinion as well as fact was used as basis.

Organic Solvent Resistance. These values were based upon the resistance to the common organic solvents; based on generally qualitative information.

Electrical Properties. These values were based upon experimental data.

Synthetic resin plastics are (1) thermosetting, and (2) thermoplastic. Thermosetting types undergo deep-seated chemical change when subjected to heat and pressure, and set to form a hard infusible mass that does not soften appreciably upon reheating. Thermoplastic types to which all natural resins belong do not undergo such chemical change upon similar treatment but do soften and can then be shaped in molds as desired. Upon cooling, these types harden and retain the acquired shape, but obviously are not temperature-resistant. The heating, molding, cooling, solidifying cycle can be repeated if desired.

Various methods of molding can be utilized depending principally upon the shape of the desired product, e.g., compression, extrusion, casting, injection, jet, and transfer. In compression molding, two dies are heated, the plastic placed between the faces of the dies, and then the dies are closed down over the plastic at the required temperature and pressure; in extrusion the plastic is softened by heat and then forced through a die to produce long continuous articles which are cut into the requisite lengths; and in injection the heated softened plastic is forced into a relatively cool mold for shaping.

Reactions involved in the formation of thermosetting shapes (and synthetic rubber) are believed possible only with certain organic functions, such as those having a double or triple bond in the molecule:

>C:C<	>C:O	—C⋮C—	—C⋮N
olefin	aldehyde; ketone	acetylene	nitrile

more markedly if a single atom is completely unsaturated:

>C:C:C<   >C:C:O   >C:C:N—

and still more so if there is conjugated unsaturation adjacent to a single carbon-to-carbon bond:

>C:C—C:C<   O:C—C:O   >C:C—C:N—

That there is a definite periodicity throughout the molecule ("high polymer") is shown by x-ray studies. When the molecule is a thread the primary bonds are chain-like in one direction—that of length; when a thin film the chain-like bonds are cross-bound laterally showing two directions of linkage, namely, length and width; and when solid three directions, namely, length, width and thickness, are interlocked. (R.K.S.)

PLASTIDS. Pigments in plants are often located in special bodies called plastids. There are many kinds of plastids: leucoplasts, those which contain no pigment and which are therefore colorless; chloroplasts, those which contain chlorophyll (by far the commonest kind); and chromoplasts, colored plastids which do not contain chlorophyll.

Leucoplasts occur in parts of stems and roots where light fails to penetrate. They absorb glucose and change it to starch.

Chloroplasts occur in cells exposed to light. They manufacture glucose, a simple sugar, out of water and carbon dioxide; may change the glucose to starch or sucrose for temporary storage and these back again to glucose for respiration or translocation. In the algae the shapes of these bodies are many; in a large number of cases the plastid is a thick cup-shaped body occupying the greater part of the volume of the cell; in other algae the plastids have a central mass from which radiating plates or arms extend outward to the cell wall; spiral, net-shaped and ring-shaped plastids are not uncommon in this group of plants. In some algae and in

nearly all higher plants, the chloroplasts are small subspherical or lens-shaped bodies, varying in number from one to many in a single cell. Always the chloroplasts are found embedded in the **cytoplasm** of the **cell**. In many plants the continuous movement of the cytoplasm in the cell carries the plastids along with it; in others these bodies have a fixed position. In certain algae and in many cells in higher plants, as for example in the palisade layer of leaves, the chloroplasts may change their position so that they will receive the most favorable amount of light. If the light intensity is low they will present their flat surface to it; while if the light intensity is high, the plastid rotates so that it is placed edge-wise to the light. Chloroplasts contain chlorophyll and other **pigments**.

Chromoplasts have no chlorophyll and no known function. (R.M.W.)

PLASTOGAMY. The union of individuals by which the **plasmodium** of the slime molds is formed. The **cytoplasm** becomes confluent but the **nuclei** remain distinct. In some cases the mass formed is large enough to be conspicuous to the naked eye. (A.W.L.)

PLATE DISSIPATION. This is the power loss occurring at the **plate** of an electronic **tube** and is of considerable importance in high-voltage vacuum tubes. The **electrons** in traversing the space between electrodes under the influence of the applied voltage acquire kinetic energy which must be dissipated when the electron is brought to rest upon striking the plate. This power is equal the product of the plate current and plate voltage (it should be noted that this is the voltage at the plate and not necessarily the voltage applied to the circuit since there is usually a drop in the load). (L.R.Q.)

PLATE EFFICIENCY. Conversion Efficiency.

PLATE GIRDER. Girder.

PLATE RESISTANCE. This is one of the vacuum-tube coefficients which is used in analyzing the behavior of the tube in a circuit. Mathematically it is expressed as

$$r_p = \left.\frac{de_p}{di_p}\right] \qquad (E_g \text{ constant})$$

where de_p and di_p represent infinitesimal changes of plate voltage and current and E_g is the grid voltage.

The value of the plate resistance, or, more properly, the dynamic plate resistance, is essentially constant over the normal operating range of the tube but is dependent upon the electrode voltages. From the equation it may be seen that it is the reciprocal of the slope of the plate current-plate voltage characteristic curve of the tube. In developing the equivalent circuit of the vacuum tube the plate resistance is the value used for the internal resistance of the equivalent **generator**. (L.R.Q.)

PLATE, STRUCTURAL. Structural plate is a large, flat body of **steel** which is produced by the working of ingots, billets, or slabs in a rolling mill. There are two types of these plates, one known as sheared plate, the other as universal mill plate. The sheared plate is used for square or rectangular shapes, the universal mill product for long strips, like those needed for plate girders. The sheared plate is rolled in a mill having horizontal rollers through which the plate is passed back and forth while the rollers are successively brought closer to each other. During this process the slab or ingot is rolled to a flat plate. Mills having horizontal rollers only are built to roll extremely large plates, some of which are over 100″ wide. The selvage left during rolling is rough and irregular, and the plates must be sheared to standard marketable sizes or customers' specifications by power shears. Between rolling and shearing operations the plates are straightened, but shearing takes place when the plates are hot, so shrinkage must be allowed for when laying out lines to which the plates are sheared. For this reason, and also for the reason that the shears cannot be manipulated with a great deal of precision, sheared plates must have a large tolerance allowance. However, sheared plates are the only plates available in wide widths.

Universal plate is made on universal mills which have vertical as well as horizontal rolls, the function of the vertical rolls being to edge the plate. Universal plates can be obtained in widths up to 48″. Plates of great length are produced with rolled edges. The allowable tolerances are much smaller, and the purchaser does not need to machine the rolled edge. Structural plate is rolled to several standard thicknesses, beginning at ¼″, and advancing by small increments to 2″.

Another usage of this word describes the structural members with which the tops of walls of buildings are finished off. For example, in the ordinary dwelling built with masonry walls, anchor bolts are built into the masonry at the top of the wall. A substantial wooden timber is bored to receive these bolts and placed on the wall with the bolt projecting through it. The bolts are then capped with nuts which are tightened against washers bearing on the plate. By spacing these anchor bolts at close intervals, the plate is securely anchored to the wall, and forms a base to which rafters or other wooden timbers may be nailed. In wooden wall construction the plate is the horizontal member which is attached to the tops of the studs. (F.T.M.)

PLATEAU. An elevated, relatively flat area or surface of wide extent and underlain by relatively horizontal sedimentary formations. Less correctly used to describe any relatively flat high-level surface of erosion regardless of the structure of the region. (See also **Mesa.**) (R.M.F.)

PLATINOTYPE PROCESS. A process of photographic printing patented by William Willis in 1873. A beautiful process and one of the few producing images of undoubted permanence—it is now obsolete, manufacture of the paper having ceased about 1930. Paper is coated with a ferrous salt (ferrous oxalate), and potassium chloroplatinite. Upon exposure to light the ferrous salt is reduced to the ferric. The faint image is then developed by placing the print in an alkaline oxalate (potassium oxalate), which dissolves the ferric salt and reduces the chloroplatinite to metallic platinum.

$$Fe_2(C_2O_4)_3 + \text{light} \rightarrow 2Fe(C_2O_4) + 2CO_2$$

$$6FeC_2O_4 + 3K_2PtCl_4 \rightarrow 2Fe_2(C_2O_4)_3 + Fe_2Cl_6 + 6KCl + 3Pt.$$

(C.B.N.)

PLATINUM. Symbol: Pt. Atomic number: 78. Atomic weight: 195.23. Density: 21.37. Hardness: 4.3. Melting point: 1773.5° C. (**Isotopes**: page 290.)

Compact platinum is a grayish-white metal, softer than silver, and hardened by the presence of other metals, **iridium** being frequently used to accomplish this result. Platinum in resistant to attack by air or water at any temperature, by **hydrofluoric acid, hydrochloric acid, nitric acid,** dilute **sulfuric acid**; but is attacked by **aqua regia**, forming chloroplatinic (platinichloric) acid (H_2PtCl_6), by ignition with **sodium** hydroxide, nitrate, peroxide, or cyanide. Probably discovered by Scaliger in the 16th century, and named from its similarity to silver in appearance (*platina* (Spanish), small silver).

Platinum is used in alloys for jewelry (white gold contains small percentages of platinum alloyed with gold); pen points (alloyed with **iridium**); parts of sci-

entific apparatus, especially electrical contacts; surgical tools; standard weights and measures; and containers, such as crucibles and dishes. The change of electrical reistance of a pure platinum wire coil upon the passage of a constant current is used to measure high temperatures. A platinum and platinum-**rhodium** thermocouple is also used for the same purpose.

Finely divided platinum is an important catalyzer for the reaction **sulfur** dioxide gas plus oxygen of air at 450° C., forming **sulfur** trioxide, in the manufacture of **sulfuric acid** by the so-called contact process. The platinum catalyzer must be specially prepared for this purpose. A smooth platinum surface as fine wire gauze, is used as a catalyzer for the reaction **ammonia** gas plus oxygen of air at 600° C., forming nitric oxide which is ultimately recovered as **nitric acid**.

Platinum occurs native but containing other elements, especially **osmium, iridium** and similar metals, **gold**, and **iron**. Found in the Ural Mountains of Russia, and less abundantly in South Africa, Canada, and the United States. By treating with aqua regia, platinum and similar metals are dissolved. After filtration, the filtrate is treated with calcium hydroxide and again filtered. From the resulting filtrate crude platinum is recovered by evaporation to dryness, and ignition.

Chlorides: Platinous chloride ($PtCl_2$); platinic chloride ($PtCl_4$), reddish-brown, hygroscopic, crystalline material. By evaporation of platinic chloride solution with hydrochloric acid, chloroplatinic acid ($H_2PtCl_6 \cdot 6H_2O$), reddish-brown crystals, is obtained, which yields upon ignition at 100° C., chloroplatinic acid ($H_2PtCl_6 \cdot 2H_2O$) as commonly marketed, and, upon ignition in **hydrogen chloride** gas, platinic chloride.

Chloroplatinates: Potassium chloroplatinate (K_2PtCl_6), and ammonium chloroplatinate ($(NH_4)_2PtCl_6$) are insoluble in water, and in a mixture of alcohol and ether; sodium chloroplatinate (Na_2PtCl_6) is soluble in the same solvents. This is applied in the separation of potassium in chemical analysis.

Oxides: Platinous oxide (PtO), gray to dark violet; platinic oxide (PtO_2), black.

Sulfides: Platinous sulfide (PtS), black; platinic sulfide (PtS_2), black.

Platinum salts combine with **ammonia**, forming interesting compounds known as platinous and platinic **ammines**. (R.K.S.)

PLATYHELMINTHES. The flatworms, a major division of the animal kingdom containing the most primitive of the triploblastic **Metazoa**. The phylum includes both free-living and parasitic species. Among the latter are the **flukes** and tapeworms, some of which are serious parasites of man.

The phylum is characterized by the following details of structure: 1. The body is bilaterally symmetrical and flattened. 2. The ectoderm is ciliated in free-living forms but forms a **cuticle** in the parasitic species. 3. The mesoderm forms a compact tissue between the various organs, known as a parenchyma. 4. The alimentary tract, when present, has a single opening. 5. The nervous system is a network in which a brain and longitudinal nerve cords are developed. 6. The excretory system consists of large hollow cells with a group of **cilia** extending into the cavity, known as flame cells, connected with tubes.

There are three classes of flatworms:

Class **Turbellaria.** Free-living species. **Planaria.**

Class **Trematoda.** The **flukes.** Parasitic in various parts of the animal body.

Class **Cestoda.** The tapeworms. Parasitic as adults in the alimentary tract of animals. (A.W.L.)

PLATYOSAURUS. Fossil Reptiles.

PLATYPUS. Duckbill.

PLAYA. The flat interior part of an undrained basin on which accumulate fine clastic sediments and chemical precipitates. Playas are formed within desert basins due to intermittent interior drainage, which, during cloudbursts, forms intermittent lakes in which the sediments are deposited. A region remarkable for playas is the Great Basin of the western United States, which covers all of Nevada and Utah. Commercially important mineral salts derived from playa deposits are: **gypsum, sodium** carbonate, the soluble **chlorides**, and **borates.** (R.M.F.)

PLECOPTERA. The **stone flies.** An order of insects with aquatic early stages. The mouth is formed for biting but is usually poorly developed in the adult. They have four wings which fold flat over the back when at rest. Sometimes abundant in the vicinity of water. (A.W.L.)

PLEIADES. The Pleiades is a very famous group of bright stars in the **constellation** of **Taurus.** Probably no one group of stars in the entire sky has received so much notice in classical literature and mythology as has the Pleiades. The Great Pyramid, which was undoubtedly designed for astronomical purposes, is so oriented that in 2170 B.C., when the Pleiades were on the meridian at midnight on the first day of spring, they could be seen through the south passageway. References to this group of stars are to be found in both the Old and New Testaments. One of the seven stars at present is distinctly fainter than the other six and there are many myths regarding this so-called "lost pleiad." In fact, the myths occur in so many different ancient literatures that there is a well-established theory that at one time all seven of the stars were of approximately the same brightness.

The Pleiades is an open **star cluster** with the various members all moving through space together. Long exposure photographs of this group indicate that the space surrounding the stars is filled with a luminous **nebulosity.** (W.K.G.)

PLEISTOCENE. The "great ice age," and first period of the **Quaternary** in the geologic time-scale. The term was proposed by Lyell in 1836. This period, as postulated by the first advance of the continental ice sheets in western Europe and northern North America, is supposed to have begun approximately 2 million years ago. Marine deposits occur in southern California. Both in North America and Europe there was considerable volcanic activity as evidenced by ash beds and basaltic lava flows. The early Pleistocene terrestrial sediments suggest increased humidity in the formerly arid regions. The terrestrial deposits as a whole are classified according to whether they were deposited within or without the glaciated areas. Great areas of **loess** were deposited at the margins of the melting continental glaciers, and the cycles of refrigeration produced not only great ice fields in northern Europe and northern North America, but also caused sympathetic glaciation in the mountainous regions further to the south. The **fossil** plants suggest distinct climatic zones. Both in Europe and North America it has been shown that there were four glacial cycles, or advances and retreats of the continental ice sheets, each with their typical sediments and accompanying floras and faunas. During the Pleistocene there was a great reduction in the number of the larger mammals, except in Asia and Africa. The characteristic types in North America were ***Elephas*** **(elephant)**, as well as the mastodon, *Cervalces* (giant "moose"), a number of ***Equidae*** **(true horses)**, ***Smilodon*** (last of the great saber-tooth tigers), and ***Megalonyx*** (giant ground sloth). In South America occur the peculiar Pampean fauna, descended from the earlier indigeneous Pliocene forms, including large ***Glyptodons, Megatheria*** (giant ground sloths), and ***Hypidium*** (Pampas horse). The

interglacial stages were remarkable for the replacement of northern by southern types of plants and animals,

Map of North America showing the maximum extent of glaciers during the Pleistocene Ice Age. The locations and general directions of movement of the great ice sheets are indicated, and regions of local mountain glaciers are shown in black. (*Modified after U. S. Geological Survey.*)

including the progenitors of modern man. The pleistocene is said by some geologists to end with the beginning of the Recent period. Others suggest that the Recent is merely an interglacial epoch preceding the next epoch of continental glaciation. (R.M.F.)

PLENUM. Pressures slightly above atmospheric are known as plenums. Such pressures usually occur in air or gas systems as the result of the action of **fans** or **blowers**. The plenum is measured in small units of pressure, such as ounces per sq. in., or in inches head of a liquid on a differential manometer. (F.T.M.)

PLEOCHROIC HALOES. The term applied to the colored zones concentric to a **radioactive** mineral, such as **zircon**, included in another mineral, such as **biotite**. (R.M.F.)

PLEOPOD. A form of the **biramous appendage** of **crustaceans**. The pleopods occur on the more anterior abdominal segments and are fringed appendages known usually as swimmerets. (A.W.L.)

PLEROCERCOID. A form of the bladder worm **larva** of tapeworms (**Cestoda**). In contrast with the simpler bladder worms which resemble the scolex of the adult, the plerocercoid contains other parts of the body in addition to a scolex. (A.W.L.)

PLEROCERCUS. A form of the bladder worm **larva** of tapeworms (**Cestoda**) which resembles the scolex of the adult. (A.W.L.)

PLESIOSAUR. **Fossil Reptiles.**

PLEURA. The pleurae are two serous membranes which cover each **lung** and are reflected against the chest wall. The part covering the lung is called the visceral pleura; it is very thin and firmly adherent to the pulmonary tissue beneath. The layer adherent to the wall of the thorax is the parietal pleura. Between the two layers is the pleural cavity, normally a potential space containing a tiny amount of serous fluid, but in certain pathological conditions constituting a true cavity. The function of the pleurae is to effect excursion of the lungs over the walls of the thorax with a minimum of friction. (See diagram under **Respiratory System.**) (D.M.H.)

PLEURISY. Inflammation or infection of the **pleura**, often producing a characteristic type of chest pain. This is a sharp, piercing sensation which appears during the inspiratory phase of breathing as the inflamed pleural surfaces rub together. The friction produced by this approximation of the parietal and visceral pleura can be heard through the stethoscope as a sound simulating the creaking of leather. It is termed a friction rub.

Pleurisy is often accompanied by effusion, the outpouring of a thin fluid which distends the pleural space. The appearance of fluid causes the disappearance of both the rub and the pain. If the expansion of the lung is sufficiently cut down by a massive accumulation of fluid, **dyspnoea** will develop.

Pleurisy alone, or pleurisy with effusion, is most commonly caused by **tuberculosis**. Other causes are **pneumonia**, **rheumatic fever**, and **tumors** involving the pleura. (D.M.H.)

PLEUROBRANCHIAE. **Gills** arising from the sides of the **thorax** in certain **crustaceans**. (A.W.L.)

PLEURODONT. **Dentition.**

PLEURON. **Skeletal System.**

PLEUROPODITE. A basal joint of the **biramous appendages** of certain **crustaceans**. It precedes the usually basal coxopodite and is also called the precoxa. (A.W.L.)

PLEXUS. A network. 1. In many animals the processes of **nerve cells** join to form a plexus or nerve net. This is the characteristic form of nervous system in the **coelenterates** and persists with modifications in the flatworms. The nerves of the radially symmetrical **echinoderms** also take on this form. A plexus underlies the ectoderm of these animals and deeper in the body other nerve fibers form plexuses of limited extent. In the vertebrates nerves branch and rejoin in some parts of the body. The brachial plexus, made up of the spinal nerves which enter the arm, and the solar plexus above the stomach are examples. Almost a hundred such plexuses have been named in the human body. 2. A network of blood vessels. The choroid plexuses of the **brain** are the most commonly mentioned examples of this group. They are the very thin and highly vascular roof plates of the most anterior and the most posterior cavities of the brain, which expand into the interior of the cavities. Other vascular plexuses are found elsewhere in the body. (A.W.L.)

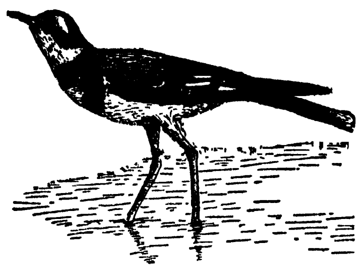
PLIOCENE. The last major subdivision of the **Tertiary** in the geologic time-scale. Term proposed by Charles Lyell in 1832 after the type locality in the Paris Basin. The Pliocene Period began approximately 8,000,000 years ago and lasted for about 6,000,000 years. In the United States the principal marine deposits occur on the Pacific Coast, but the outline of the continental margins was approximately what it is at the present day. There was continued mountain-building during the period, and the interior continental terrestrial deposits were relatively thin and unimportant. There was considerable volcanic activity in the Rocky Mountain

region, with great extrusions of **rhyolitic** lavas in the Yellowstone Park. The fossil plants are of the modern type, and more abundant in Europe than in North America. Also the marine invertebrates are practically identical with the modern forms. Among the mammals were a number of forms quite similar to those of the **Pleistocene** and recent, including all types of carnivores, horses, browsing camels, antelopes, and mastodons. For a description of the mineral resources of this period see the Tertiary. (R.M.F.)

PLIOPITHECUS. Paleontology of Man.

PLOUGH CUT. Dado.

PLOVER. Aves, Charadriiformes. Wading birds (**Aves**) with moderately long legs and a moderate beak. Although usually found near water, many species fre-



Killdeer. *Oxyechus vociferus.* Grayish above, white below, two black bands across the breast.

quent dry ground. The **killdeer** is the most common of the several North American species. The golden plover, *Pluvialis dominica,* is remarkable for its long migrations between arctic breeding grounds and its winter home in Patagonia. The Bartramian sandpiper is sometimes called the upland plover. True plovers constitute the family Charadriidae. (A.W.L.)

PLUG GAUGE. Measurement.

PLUM. Rose Family.

PLUM CURCULIO. Insecta, Coleoptera. A **weevil,** *Conotrachelus nenuphar,* which damages plums and other stone fruits, apples, pears, and quinces in the eastern half of the United States. The insects hibernate in fencerows and rubbish in orchards and pupate in the ground, hence the destruction of their hiding places and thorough cultivation of the soil in late July and early August are useful measures of control. Spraying just after the petals drop and again after 10 days with **lead** arsenate (2 lbs. to 100 gal. of water) is effective. For control of the pest on peaches special methods are necessary which differ in various peach-growing regions. (A.W.L.)

PLUMBAGO. Graphite.

PLUMBUM. Lead.

PLUME MOTH. Insecta, Lepidoptera. A small **moth** whose wings are deeply split to form 2–6 slender fringed lobes. In the family Pterophoridae most species have the front wings split for about ⅓ of their length to form two short lobes and the hind wings deeply divided into three lobes. One genus has the wings entire. Members of the Orneodidae have six slender plumes to each wing. (A.W.L.)

PLUMULE. Seed.

PLUNGE (Geological term). For the use of this term in geology, see **Anticline.**

PLUTEUS. A **larval** form of brittle stars and **sea** urchins (**Echinoidea**). It is bilateral, with a tubular alimentary tract. The body bears several projecting lobes and locomotion is accomplished by **cilia** arranged in a tortuous band. (A.W.L.)

PLUTO. (See tables of planetary data, page 1109.) The planet Pluto, the outermost known member of the **solar system,** was discovered early in 1930 at the Lowell Observatory. The discovery of the planet was announced on March 30, 1930, the anniversary both of Percival Lowell's birth and also of the discovery of **Uranus.** The discovery marked the culmination of a search for a planet outside of the **orbit** of **Neptune** which had been carried on for many years at the observatory of Dr. Percival Lowell at Flagstaff, Arizona. The circumstances which led to the belief that such a planet existed are similar to those which led to the discovery of Neptune. After the **orbit** of Neptune was computed and the motion carried back through the years, it was found that the planet had been observed several times previous to its announcement as a planet, the early observers having recorded it as a star. These early observations were of great value in making an accurate determination of the orbit, and, when all **perturbations** due to known objects had been computed and applied, certain unexplainable differences between observed and computed positions appeared. On the basis of these perturbations Lowell made the necessary laborious computations to determine the positions of a possible planet that might be causing the attractions and predicted Pluto. There is considerable doubt in the minds of many astronomers as to whether Pluto is actually the planet producing the perturbations in the orbit of Neptune or whether the perturbations may not actually be due to accidental errors in the observations of Neptune itself. Whether Pluto is actually the predicted planet itself or not, nevertheless, it is certain that the computations of Dr. Lowell stimulated the search, and that the planet was found as a result of this search.

The name Pluto was selected for the new planet and the first two letters of the name, combined in monogram form ♇, are used as the symbol for the planet. Since these two letters are not only the first two letters of the name of the planet, but also are the initials of Percival Lowell, they are particularly fortunate.

The orbit of Pluto is the most eccentric of all of the orbits of the major planets, and the inclination to the plane of the ecliptic is also the largest. The mean distance of the planet from the sun is slightly less than 40 **astronomical units.** Due to the large value of the eccentricity (0.25) the planet is more than 50 astronomical units from the sun at aphelion and within 30 at perihelion. The latter figure is less than the distance of Neptune from the sun, so at times the planets Pluto and Neptune pass each other. However, the large inclination of the orbit of Pluto makes a collision virtually impossible, the closest approach of the two planets being about 240,000,000 miles.

Comparatively little is known regarding the physical characteristics of this remote member of the sun's family. It appears as a very faint star of about the fifteenth **magnitude,** with a distinctly yellowish color which is in contrast to the greenish appearance of its nearer neighbors in the solar system. In size and mass the planet is apparently much more like the planets Mars and the Earth, than like its closer companions, Uranus and Neptune. (W.E.G.)

PLUTONIC. Plutonic is a general term applied to **igneous rocks** of deep-seated origin as distinguished from volcanic lavas which cool and congeal under the air, or under water. The word is derived from the Roman god Pluto, who ruled the underworld. (R.M.F.)

PLUTONIUM. **Chemical Composition, I. Elements.**

PNEUMATOLYSIS. Pneumatolysis is the process of alteration of existing rocks and mineral deposits, or the formation of new ones, by means of gases or vapors emanating from the magma. (E.S.C.S.)

PNEUMONIA. An acute infection of the lungs most commonly caused by *Diplococcus pneumoniae.* The disease may be caused by almost any organism, including the **Streptococcus, Staphylococcus,** Friedlander's bacillus, plague bacillus, as well as psitticosis and other viruses, and certain fungi.

The pneumococcus, a small encapsulated coccus occurring in pairs, is one of the most widely distributed of the disease-producing **bacteria.** In a harmless form it is a normal inhabitant of the mouth and throat. Virulent forms of the organism also enter through the upper respiratory passageways, being spread by direct contact with infected secretions. Pneumococci have been divided into more than 33 specific types on the basis of differences in immunological characteristics related to the capsular substance. Different types are of varying virulence. The most prevalent types producing pneumonia are 1, 2, 3, 4, 5, 6, 7, 8, and 14.

Pneumonia is classified as lobar, bronchopneumonia and primary atypical pneumonia. The lobar type is produced, characteristically, by pneumococci and occasionally by Friedlander's bacillus, while the other etiological agents usually produce bronchopneumonia. Primary atypical or "virus" pneumonia is a special form of bronchopneumonia which has been observed to occur in epidemic form since the early 1930's.

Lobar pneumonia is an acute infection localized to one or more lobes of the lung. It occurs most often in the winter months, in young healthy individuals. Pathologically it is characterized by massive **inflammation** and exudation into the smallest divisions of the lung, the alveoli. The normally air-filled lobe is thus converted into a heavy, solid, relatively airless structure. The symptoms are dramatic. The onset is with a chill, and often sharp chest pain on breathing (**pleurisy**). Fever, rapid pulse, "rusty" sputum follow. As the disease progresses, difficulty in breathing (**dyspnoea**), **cyanosis,** and prostration may be marked. The course, duration and mortality of the disease have been altered remarkably since the introduction of the **sulfonamides** and penicillin. Either of these, given early, will control the infection so rapidly that the full-blown picture with a solid lung never develops. The complications of pneumonia have also been altered and reduced to rare occurrences by these drugs. They include **empyema, pericarditis, arthritis,** and **meningitis.**

Primary bronchopneumonia due to staphylococci, streptococci and occasionally pneumococci of the higher types is a much less frequent, less sharply defined clinical entity. It occurs chiefly in children and in the aged. Pathologically it involves the walls of the smaller bronchioles, and to a lesser extent the alveoli. It tends to be patchy in distribution and involves the bases of the lungs. The onset is usually gradual, without a chill. The temperature is elevated, but not very high. Cough and thick sputum are characteristic. The disease responds less dramatically to sulfonamides than does lobar pneumonia.

Secondary Bronchopneumonia occurs as a complication of other diseases, particularly **influenza** and **measles.** It also appears as a terminal event in the course of chronic heart and kidney disease.

Primary atypical pneumonia occurs in early fall and winter epidemics in young individuals. It is chiefly an interstitial pneumonia, involving the tissue between the alveoli; **bronchitis** and bronchiolitis are prominent. Its cause has not been proven definitely, but all evidence points to a **virus** or perhaps several viruses. Clinically the disease is characterized by a gradual onset of rather mild symptoms, relatively slow pulse, fever, cough, and little sputum. Chills and chest pain are uncommon. There are usually few signs over the chest although **x-ray** may reveal a widespread involvement of the lungs. The disease does not respond to sulfonamide therapy. The mortality is very low, but in the more severe form, the course may be long with temporary remissions and recurrences. (D.M.H.)

PNEUMOSTOME. 1. The opening leading into the chamber containing the respiratory organs of **scorpions** and **spiders.** 2. A small opening on the right side of a snail between the head and the edge of the mantle. It leads into the mantle cavity of the air-breathing forms. Aquatic forms have a much more extensive opening. (A.W.L.)

PNEUMOTHORAX. The introduction of air into the **pleural cavity,** causing a part or the whole of the **lung** on that side to collapse so that the vesicles of the lung become airless and the lung remains quiet. This occurs following a wound through the chest wall or a rupture of the lung surface through a disease process near the surface, such as tuberculosis.

Artificial pneumothorax is the injection of air into the pleural cavity as a therapeutic measure. It is most frequently used in pulmonary **tuberculosis** to put a diseased lung at rest so that healing may occur. (R.S.M.)

POCHARD. Aves, Anseriformes. A name applied in the Old World to **ducks** of several species related to the scaup ducks, the redhead, and the canvas-back of North America. (A.W.L.)

PODICAL PLATE. Two triangular plates flanking the **anus** in certain **insects.** They lie just behind the tenth abdominal segment and are regarded as the halves of the ventral sclerite of the eleventh segment. They have also been called paraprocts. (A.W.L.)

PODIUM. **Tube Foot.**

PODOBRANCHIA. A form of gill found in some of the **crustaceans.** It is named from its attachment to the basal segments of the thoracic legs. (A.W.L.)

PODSOL. The name of a leached white or gray **soil.** Supposed to be chiefly characteristic of cold moist climates. (R.M.F.)

POEBROTHERIUM. **Oligocene.**

POIKILITIC. **Ophitic.**

POIKILOTHERMY. A condition in which the temperature of the animal body fluctuates according to that of its surroundings. It may be higher or lower, but is always directly conditioned by external temperatures. **Homoiothermy,** in contrast, is the maintenance of a more or less constant body temperature, regardless of the surroundings, and is found only in birds and mammals. Thus a vast majority of animals are poikilothermal.

Poikilothermy has the disadvantage of limiting the **activity** of the animal to temperatures sufficient for the normal rate of metabolic processes. When it is too cold the animal becomes incapable of movement and its other processes are slowed. As a result poikilotherms must hibernate during the winter as a rule and must avoid the colder regions where their period of active life would be too greatly curtailed.

Animals of this kind are commonly called cold-blooded. (A.W.L.)

POINT OF CONTRAFLEXURE. Bending Moment.

POINT OF INFLECTION ON A PLANE CURVE. Concavity and Convexity of a Plane Curve.

POINTES EN FEUILLE DE LAURIER. Paleontology of Man.

POISEUILLE'S LAW. Viscosity.

POISON CLAW. A jointed appendage of the first body segment of **centipedes.** These appendages are not used in locomotion but are sharp-pointed and work together like a pair of jaws. They bear poison glands and are used in capturing and killing prey. (A.W.L.)

POISONS. Compounds of **mercury** (-ic), **lead, copper, zinc, arsenic, antimony, selenium, barium, thallium, fluorine,** are notably poisonous. Soluble metallic **cyanides,** isocyanic acid esters, **cyanogen, hydrogen cyanide,** some **glucosides, alkaloids,** many **nitrogen** and **sulfur** containing organic substances, yellow **phosphorus,** and **chromates** are extremely poisonous. The poisonous nature of many chemicals, some of which are common and necessary, encountered in laboratory and factory, constitutes a serious hazard to life and health. Careful provision for this hazard should be made. Some poisons, notably **phenol, hydrofluoric acid, sodium** hydroxide, **bromine,** yellow **phosphorus, nitric acid** concentrated, **sulfuric acid** concentrated, are also very corrosive to the flesh.

Among the gases which are extremely hazardous are especially **carbon monoxide**—odorless, and present in all gases of *incomplete* combustion of fuels, whether of coal, oil, or motor fuels—**hydrogen sulfide, nitrogen tetroxide, chlorine, bromine, hydrogen cyanide, cyanogen, cyanogen chloride.** Some poisonous gases are used as fumigants of rooms, foods, and in other ways. Gases thus used include hydrogen cyanide, cyanogen chloride, **sulfur** dioxide, **carbon disulfide** vapor—inflammable, ethylene oxide, **formaldehyde.** Their removal when used for fumigation and disinfection, before use of the space or materials, is a matter to be carefully confirmed.

Of liquid poisons, carbon disulfide is one commonly used, also phenol and cresols.

Many solids, either as fine powder or solution, are used as insecticides, germicides, fungicides, weed-killers, rodent-killers. Examples are **copper** sulfate—with calcium hydroxide as Bordeaux mixture—copper **arsenite,** copper-acetoarsenite (Paris green), sodium arsenite, calcium arsenate, lead arsenate, sulfur, calcium sulfide (lime-sulfur), **calcium** hypochlorite, **sodium** hypochlorite, thallous sulfate, mercuric chloride, barium carbonate, sodium fluoride, nicotine, para-dichlorobenzene, pyrethrum, DDT, sodium chlorate—easily ignited in the presence of organic material such as clothing.

In many situations the only substances sufficiently toxic for use against lower organisms are also toxic to man, and the hazard arising from their use cannot be too strongly emphasized.

CODE OF THE STATE OF MASSACHUSETTS FOR MAXIMUM SAFE CONCENTRATIONS OF CERTAIN COMMON TOXIC SUBSTANCES USED IN INDUSTRY

Substance	Maximum Parts per Million of Air
1. Ammonia	100
2. Amyl acetate	400
3. Aniline	5
4. Arsine	1
5. Benzene	75
6. Cadmium	0.1
7. Butyl acetate	400
8. Carbon disulfide	15
9. Carbon monoxide	100
10. Carbon tetrachloride	100
11. Chlorine	1
12. Chlorbenzene	75
13. Chlorodiphenyls	1
14. Chloronaphthalene	5
15. Chromic acid	0.1
16. Dichlorbenzene	75
17. Dichlorethyl ether	15
18. Ether	400
19. Ethylene dichloride	100
20. Formaldehyde	20
21. Gasoline	1000
22. Hydrochloric acid	10
23. Hydrogen cyanide	20
24. Hydrogen fluoride	3
25. Hydrogen sulfide	20
26. Lead	0.15
27. Mercury	0.1
28. Methanol	200
29. Nitrobenzene	5
30. Nitrogen oxides	10
31. Ozone	1
32. Phosgene (carbonyl chloride)	1
33. Phosphine	2
34. Sulfur dioxide	10
35. Tetrachlorethane	10
36. Tetrachlorethylene	200
37. Toluene	200
38. Trichlorethylene	200
39. Turpentine	200
40. Xylene, coal-tar naphtha	200
41. Zinc oxide fume	15

(R.K.S.)

POISSON DISTRIBUTION. The Poisson distribution or probability function is defined by $P_x = e^{-m}\frac{m^x}{x!}$, $x = 0, 1, 2, \cdots, \infty$, where P_x is the **probability** of x successes. It may be derived as the limiting case of the **Bernoulli probability function.** $P_x = {}_sC_x p^x q^{s-x}$ when sp remains constant as $s \to \infty$, and $p \to 0$. However, it may occur without the condition that p be small. The **moments** of the Poisson are **mean** $= m$, **variance** $= m$, $\mu_{3:x} = m$, $\mu_{4:x} = 3m^2 + m$, and $\alpha_{3:x} = \frac{1}{\sqrt{m}}$, $\alpha_{4:x} = 3 + \frac{1}{m}$. As $m \to \infty$, the Poisson probability function approaches the **normal probability function** with mean m and variance m. The Poisson probability function occurs in **industrial statistics,** in certain traffic problems, in the number of mutations when certain fruit flies are bombarded by neutrons, or x-rays, and in many other instances where the **universe** is essentially infinite and the probability of success is restricted to a very small portion of the universe. The probability $\sum_{x=a}^{x=b} P_x$ may be found exactly by a χ^2 distribution, or by **Pearson's Type III function,** or from tables of the Poisson probability function. (L.A.A.)

POISSON'S EQUATION. Laplace's Equation.

POISSON'S RATIO. If a rod of elastic material is stretched with sufficient force it can be elongated. The unit elongation (elongation per unit of length) is the strain, and may be denoted by s. At the same time the lateral dimensions will contract, the unit lateral contraction being c. The ratio c/s, which is constant for a given material within the elastic limit, is known as Poisson's ratio. For materials in which there is no directionality to **elasticity,** the value of Poisson's ratio was demonstrated by that celebrated mathematician to

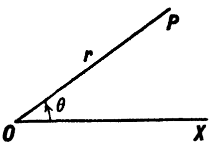
be 0.25. The value of 0.30 is generally used for steels, although recent careful determinations indicate 0.28 is a better average value. For aluminum alloys 0.33 is generally used. For values of Poisson's ratio up to 0.50, stretching results in a net increase in volume. At 0.50 the volume remains constant as in the case of plastic deformation of metals. (R.H.H.)

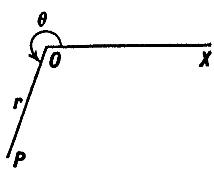
POLAR AIR. Air Masses.

POLAR COMPOUNDS. Valence.

POLAR COORDINATES IN A PLANE. A point in a plane may be determined in position by two numbers called coordinates. One simple method for fixing the position is by means of polar coordinates.

Let O be a fixed reference point, called the pole (or origin), and let OX be a fixed reference line through O, called the polar axis (or initial line).





The position of any point P in the plane is determined by the distance OP and by any one of the directed angles having its initial side along OX and its terminal side along OP.

We agree to consider the directed distance OP as positive when measured along the terminal side of angle XOP, otherwise negative; and to regard the angle XOP as positive when it is generated by counter-clockwise rotation of OP from the initial position OX and negative when the rotation is clockwise.

The polar coordinates of the point P are the directed distance OP and the directed angle XOP. The directed distance OP is called the radius vector of P and is usually denoted by r or ρ; the directed angle XOP is called the vectorial angle of P and is usually denoted by θ. A point whose polar coordinates are r and θ is denoted by the symbol (r,θ).

Every pair of polar coordinates is represented by a single point; but conversely, every point has an infinite number of polar coordinates, since any one of a set of **co-terminal angles** may be used as the vectorial angle and also various combinations of positive and negative coordinates may be used.

Polar coordinate paper is paper ruled into a network of lines by concentric circles and radial lines through the center of the circles, and is useful for plotting points given by polar coordinates.

The distance between the points whose polar coordinates are (r_1, θ_1) and (r_2, θ_2) is given by

$$d^2 = r_1^2 + r_2^2 - 2r_1r_2 \cos(\theta_1 - \theta_2).$$

The relations between **rectangular coordinates** and polar coordinates in a plane are given by the equations

$$x = r\cos\theta, \quad y = r\sin\theta,$$

and

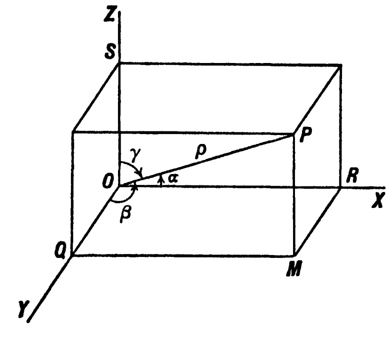
$$r = \pm\sqrt{x^2 + y^2}, \quad \theta = \arctan(y/x),$$

if the pole coincides with the origin and the polar axis coincides with the positive X-axis. (L.S.S.)

POLAR COORDINATES IN SPACE. Let P be any point in space, referred in position to a system of **rectangular coordinate** axes.

The angles α, β, γ which the line OP makes with the X-, Y-, and Z-axes respectively are called the direction angles of the line OP; their cosines are called the direction cosines of OP.

The distance $\rho = OP$ and the three direction angles α, β, γ of OP are sometimes called the polar coordinates of point P.



The relation between the rectangular and polar coordinates of a point in space is given by the formulas $x = \rho\cos\alpha,\ y = \rho\cos\beta,\ z = \rho\cos\gamma,\ \rho^2 = x^2 + y^2 + z^2$. (L.L.S.)

POLAR FRONT. Fronts.

POLAR MOMENT OF INERTIA. Moment of Inertia.

POLARIS. Polaris (α **Ursae Minoris**) is the principal star of the **constellation** and, as a matter of fact, about the only claim to recognition which the "little dipper" has. This star has been the closest star to the pole of rotation of the celestial sphere for the past five millenniums and has been used by navigators throughout written history. The antiquity of the use of this star is attested to by the fact that it is found represented on the earliest known Assyrian tablets. At present, Polaris is slightly over 1° from the pole of rotation and hence revolves about the pole in a small circle about 2° in diameter. Twice, and only twice, during every 24 hours Polaris accurately defines the true north **azimuth.**

At present, the star is universally used by navigators and surveyors for the purpose of determining true azimuth and also astronomic **latitude.** Tables have been computed and are to be found in the **Ephemerides** of the various governments for the purpose of reducing the actual position of the star at any particular instant to the actual position of the pole of rotation. (W.K.G.)

POLARISCOPE. An instrument for ascertaining the properties of **polarized light** or for studying the effects of various agencies upon light of known polarization. It ordinarily consists of a "polarizer" for rendering common light plane-polarized in any desired azimuth, and an "analyzer" for identifying the character of polarized light; between these is usually a mounting for objects whose effect upon the light from the polarizer it may be desired to test. For example, the polarizer may be a **Nicol prism** from which the light emerges vibrating, say, in a horizontal plane; the analyzer may be another, similar Nicol; and between them may be mounted a tube with glass ends in which are placed various liquids to be tested for their rotatory effect. A polariscope of this type for sugar solutions is a **saccharimeter.** Or the object to be tested may be a doubly refracting crystal plate or a metallic reflector, rendering the plane-polarized light elliptically polarized; and the analyzer a Babinet **compensator** or similar device for identifying such light. Some polariscopes use a "half-shade analyzer," for example, a half-wave plate (equal to two quarter-wave plates) covering half the field, the two halves of which look equally bright through a Nicol only when the analyzer is turned into a certain position with reference to the azimuth of the

plane-polarized light entering it. In the simplest polariscopes the polarizer and the analyzer are reflecting plates of opaque glass set at the proper polarizing angle. Many modern polariscopes employ polarizing films, for example "Polaroids," instead of Nicols. (L.D.W.)

POLARITY. In biology, a fundamental differentiation of cells according to functional potentialities. Polarity is commonly and often conspicuously expressed in egg cells by a differentiation from an animal pole at one end to a vegetal pole at the other. The animal pole is the region of greatest **metabolic** activity. Yolk tends to accumulate at the vegetal pole, resulting in extreme cases in a marked concentration of this material in the one part of the cell. Such eggs are called telolecithal.

Polarity is also expressed in other **cells** of the body. Gland cells, for example, have the end toward the free surface of the **epithelium** in which they lie specialized for the accumulation and discharge of the special secretion, while the base of the cell is related to the underlying basement membrane. The phenomenon is also closely associated with the **axial gradients** of the animal body. (See also **Magnetism.**) (A.W.L.)

POLARIZATION. **Cell; Electrochemistry; Polarized Light.**

POLARIZATION PHOTOMETER. In the main forms of **bench photometer**, the illuminations or luminous flux densities from the two sources to be compared are made equal by regulating the relative distances. In photometers of the polarization type, the same object is accomplished by introducing a pair of Nicol prisms into the beam from the brighter source and turning one of these polarizers until the beam is cut down to equality with that from the other source. The ratio in which the flux density has been reduced, and hence the luminous intensity ratio of the two sources, is readily calculated from **Malus' law**, and the polarizer circle may thus be calibrated to give the ratio directly.

The polarization principle may also be applied to **stellar photometry** for the determination of **stellar magnitudes**. In one type of polarization photometer an "artificial star" is produced in the same manner as is described under **wedge photometer** and a pair of Nicol prisms is introduced into the path of light from this star. The method of use of this instrument is similar to that described for the wedge photometer, the difference being that the angles at which the Nicol prisms are set instead of wedge settings are converted into stellar magnitude difference. In the Pickering type of polarization photometer two telescopic objectives are combined in one tube, so that the images formed by each fall side by side. In front of each objective a plane mirror is placed; one being adjusted so that an image of Polaris is formed in the field of view, and the other adjustable so that the image of any star, close to the meridian, may be brought into the field of view close to the image of Polaris. In the light path from Polaris the pair of Nicol prisms is placed, and the angles at which they are set relative to each other may be calibrated to give the magnitude difference between Polaris and the star under examination. There are many modifications of this same general principle which have been devised by observers for their particular problems. (L.D.W., W.K.G.)

POLARIZED LIGHT. Whenever ordinary light is reflected from a glass plate, a varnished table-top, or other polished **dielectric** surface, we find upon suitable examination that a much larger part of the reflected beam is vibrating at right angles to the plane of reflection than in that plane; whereas originally it gave no evidence of any preferential direction of vibration. A little experimenting shows that at a certain angle of incidence (the "polarizing angle," different for different dielectrics), the component vibrating in the plane of reflection is practically extinguished, all vibration being confined to the plane at right angles to this. The light is then plane-polarized. The effect is more conveniently produced by a **Nicol prism** or by one of the recently invented polarizing films, such as "Polaroid," which polarize by transmission with less loss of light.

When the light passes through two such polarizers in succession, as in a **polariscope,** the fraction of it finally emerging depends upon the angle between the transmission planes of the polarizers, and varies all the way from nearly 100% to zero (see **Malus' law**). The same effect may be produced by two reflections at glass plates turned to reflect in different planes but at the same (polarizing) angle. It seems probable that when the polarizing films above mentioned have been further perfected and cheapened, this intensity-reducing effect will be turned to account in reducing automobile headlight glare.

Metallic reflectors do not produce plane-polarization, but when plane-polarized light falls on a polished metal, its vibration is in general changed from a rectilinear to an elliptic one, and the light is said to be elliptically polarized. (See **Compensator.**)

When plane-polarized light traverses a crystal exhibiting **double refraction,** such as calcite, at right angles to its axis, it is transformed into elliptically polarized, or even circularly polarized, light.

If plane-polarized light is passed through quartz along its axis, or in any direction through one of the many optically active liquids such as turpentine or sugar solution, it undergoes optical rotation, i.e., its vibration plane is twisted around through an angle which steadily increases with the distance traversed in the substance. Different substances have very different rotatory power, and some rotate one way and some the other. The **saccharimeter** is especially adapted to the study of this effect in liquids. Somewhat similar is the **magneto-optical rotation** produced under suitable conditions by a magnetic field. (L.D.W.)

POLARIZING ANGLE. **Polarized Light; Brewster's Law.**

POLECAT. Mammalia, Carnivora. Long-bodied animals with short legs, related to the weasels and minks. They are known for their disagreeable odor, a characteristic which is responsible for the occasional erroneous application of the name to skunks.

The European polecat, also known as the foumart or foul marten and as the fitchet, fitcher, or fitcheu, is the source of the fur known on the market as fitch. Three other species occur in Europe and Asia, and one, the black-footed polecat, commonly called the black-footed **ferret,** is found in the plains region of North America. The **Cape polecat** of South Africa is more closely related to the skunks than to the true polecats. (A.W.L.)

POLES AND POLARS OF CONICS. For the ellipse $b^2x^2 + a^2y^2 = a^2b^2$, the equation of the **tangent** at the point (x_1, y_1) is $b^2x_1x + a^2y_1y = a^2b^2$. But if (x_1, y_1) is not a point on the ellipse, the preceding equation represents a straight line called the polar of the point $P_1(x_1, y_1)$ with respect to the ellipse, and P_1 is called the pole of the polar line. If the pole P_1 is outside of the ellipse (Fig. 1), the polar of P_1 may be obtained by drawing the two tangents from P_1 to the ellipse, and drawing the chord of contact. If the point P_1 is inside the ellipse (Fig. 2), the polar of P_1 may be obtained by drawing two chords through P_1, drawing the pair of tangents to the ellipse at the ends of each chord, and joining their intersections.

The poles and polars of the other **conic sections** are defined in a similar way.

An important property of poles and polars of conics is: If a point P_2 lies on the polar line of P_1, then P_1 lies on the polar line of P_2. (L.L.S.)

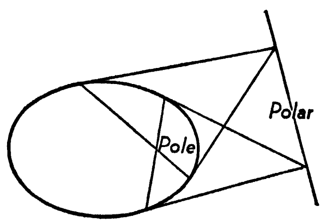

Fig. 2

POLIAN VESICLE. Water Vascular System.

POLIOMYELITIS (Infantile Paralysis). A common acute **virus** disease which tends to occur in epidemic form during the late summer months. Poliomyelitis often involves the **brain** and **spinal cord** and may result in a flaccid **paralysis** of various groups of muscles. The disease is caused by a filtrable virus which can be readily isolated from the stools of infected individuals, and identified by animal inoculation. In monkeys and chimpanzees a disease similar to human poliomyelitis can be produced; a few strains will also cause the disease in certain rodents.

The **epidemiology** of poliomyelitis is not completely understood. It is thought that the virus can enter the body probably through several portals including the **mucous membrane** of the oral cavity and the **pharynx**, the lower gastrointestinal tract, and possibly the skin. Once in the body, the virus localizes in (1) the intestinal tract and (2) the brain and spinal cord. There is proof that the gastrointestinal tract serves as one of the major portals of exit for the virus. Patients may continue to excrete active virus in their stools for 6 weeks or longer after the onset of the acute disease, even though they are clinically well. Healthy **carriers** who have never had any symptoms of the disease are also known to exist. These facts lend support to the theory that the disease is spread by direct human contact or by contamination of food either directly, or through an intermediary agent such as the fly, which is known to carry the virus in epidemic areas.

The **pathology** of poliomyelitis is primarily an **inflammation** and destruction of the cells in the gray matter of the spinal cord—the ganglion or motor cells of the anterior horn. The clinical picture is extremely variable. The average incubation period is 10 days. In most instances the illness is mild, of short duration, and not accompanied by muscular weakness. The onset is sudden, with fever, malaise, headache, sometimes sore throat, and often vomiting. Pain in the back and stiffness of the neck and back due to muscular spasm are common. In the abortive type of poliomyelitis, these symptoms disappear after 3–4 days, and the child is well. In the paralytic type, which is much less common, the picture goes on to one of pain and weakness of the muscles and sometimes complete paralysis of the arms and legs and respiratory or other muscles, depending on which parts of the central nervous system are affected. If the respiratory muscles are involved, death from asphyxiation may occur. In the bulbar type of the disease which involves the cranial nerves and has a high mortality, the voice has a nasal twang, the eye muscles may be paralyzed, and there is difficulty in swallowing; mucus and saliva accumulate, and coughing and choking are common.

The treatment of mild abortive poliomyelitis is symptomatic. In the paralytic form of the disease, the application of hot moist packs to the involved muscles relieves pain and relaxes muscles which are in spasm. Physostigmine and prostigmine are drugs which also seem to be effective in relieving muscular spasm. Early massage, passive and then active exercise of the affected muscles, are now recognized to be beneficial in achieving restoration of function of partially paralyzed limbs. If there is complete destruction of the nerve cells in the spinal cord which supply a group of muscles, nothing will restore the function of these muscles. If the respiratory muscles are involved, the respirator, or iron lung, may be used to give continuous artificial respiration. It may be necessary for a patient to remain in the respirator for weeks or months, until restoration of the function of his respiratory muscles occurs. (D.M.H.)

POLISHING. A surface-finishing process whereby scratches and tool marks are removed by using a polishing wheel made of leather or paper, to the face of which abrasive grains are cemented. (H.C.H.)

POLLACK. Pisces, Teleostei. A marine fish (**Pisces**) related to the haddock and cod. One species, *Gadus pollachius*, found in European waters, is also called the whiting-pollack, and another which is taken on both sides of the Atlantic is sometimes called the coal fish. (A.W.L.)

POLLAN. Pisces, Teleostei. A species of **whitefish** found in Irish lakes, *Coregonus pollan*. (A.W.L.)

POLLEN TUBE. Flower.

POLLINATION. Pollination is the act of transference of pollen grains to the **stigmatic** surface of a flower, where the pollen grain will germinate, forming a slender pollen tube, the development of which leads to the process of **fertilization**.

That the ancients should know anything of the act of pollination is scarcely to be expected, yet they had at least an inkling as to the necessity of the process, since they knew that male flowers of dates must be brought to the female flowers if a crop of fruit was to follow. Picture engravings on Egyptian monuments show this quite clearly. Later the need for caprification in **figs** was recognized.

But scientific understanding of the significance of the process and the ways in which it was accomplished was delayed until the studies of Joseph Kölreuter in the second half of the eighteenth century and of Christian Sprengel, who followed soon after. From the keen observations of these two men came the first real knowledge of pollination. Later Charles Darwin (1809–1882) made careful observations on pollination, observing the existence of two or more flower types in a single species and pointing out the way in which they might effectively cause cross-pollination, which he believed to be of great importance in maintaining the vigor of a race. He also attentively studied the process of pollination in **orchids**, observing many of the elaborate developments found in these flowers to insure successful cross-pollination. In the United States, Asa Gray (1810–1888) extended observations to American plants, including many native orchids. In Brazil Fritz Müller (1822–1897) made many interesting additions to the knowledge of the mechanisms and agencies involved in pollination. While these names are those of men whose observations

were extensive, many others have also studied the various ways in which flowers are modified seemingly by foresight as to the needs of the process.

Flowers may be self-pollinated or cross-pollinated. In self-pollinated flowers, pollen from the **anthers** is transferred directly to the **stigma** of the same flower, while in cross-pollination pollen is carried to the stigmas of other flowers not on the same plant. Pollen transfer to other flowers on the same plant accomplishes self-fertilization and is called close pollination. That pollen may easily be deposited on stigmas of the same flower does not mean necessarily that self-fertilization shall occur, for in many cases pollen under such a condition fails to develop or develops so slowly that foreign pollen from other flowers soon grows beyond it and brings about fertilization. When pollen from the same flower or plant fails to bring about fertilization, the plant is said to be self-sterile; many varieties of cultivated fruit are of this sort. This explains why it is necessary to plant other varieties of apple among trees of the MacIntosh variety; many apple varieties are self-sterile.

Self-pollination must be a fact in certain flowers of the type known as cleistogamous—flowers which never open to allow pollen to be shed into the air or transferred by any means from flower to flower. In such flowers, which are found in many plants, as in several species of violet, the pollen grains may germinate while still in the anther, the pollen tubes growing out to the stigma, and then on to bring about fertilization. In other cleistogamous flowers the pollen is shed from the anthers and falls directly onto the stigma, and there develops. Self-pollination also occurs, though not of necessity, in many perfect flowers. In many cases the stigma is directly beneath the ripened anthers, so that pollen shaken from the anther is likely to fall onto the stigma. In some plants the stigma is always beneath the mature anther, while in other plants movement occurs so that as the part grows older the stigma bends over to a position beneath the anther. In such a case, if cross-pollination has not already occurred, self-pollination may be effected. In other flowers it is the stamen which exhibits movements, curving or bending in such manner that pollination shall be accomplished. In still other plants the filaments gradually elongate so that the anthers are carried upward to the stigma.

Cross-pollination is insured by several means. In many plants, the stamens mature and shed their pollen long before the stigmas are receptive, while in other plants, the stigmas are mature before the pollen of the same flower has ripened. Either case necessarily insures cross-pollination. Equally certain is the occurrence of cross-pollination in those plants which bear unisexual flowers on different plants, or if on the same plant male flowers mature some time before the female, as is the case of the Alder, where the inconspicuous pistillate (see **Pistil**) flowers are mature two to four days before the pendulous **catkins** of staminate (see **Stamen**) flowers begin shedding their pollen.

Another method which tends to effect cross-pollination is the occurrence of flowers of two, or three, or even four different kinds. The purple swamp loosestrife, *Lythrum Salicaria,* shows one such case. Some of the flowers of its spike have anthers borne on long filaments and contain pollen grains of relatively large size; other flowers have stamens with short filaments and contain small pollen grains; while a third flower type is intermediate in habit, the filaments being between the others in length and the pollen grains of intermediate size. In flowers like these, if insect-pollinated, every likelihood is that pollen of one flower type will be carried to stigmas which show the same gradations in length, so that pollen from stamens with long filaments will be deposited on such parts of the insect's body as will be touched by long-styled pistils; and since these long-styled pistils are not found in flowers having long filaments, cross-pollination will probably occur. Flowers having such differences in style length are called heterostylous flowers.

Many plants, notably those in the **Carrot** and **Composite Families,** often bring about cross-pollination in another way. The flowers grow in compact groups, either **umbels** or heads. As the floral organs, stamens and pistils, mature, they grow out in a way that brings about contact between nearby flowers, the stigmas of one flower touching the anthers of another. That this does often occur is seen in the **Composite Family,** where in many instances the styles curl back at maturity so that the stigmatic surface is brought directly against the pollen masses. Many plants in this family are self-sterile.

While the transference of pollen from anther to stigma usually occurs, many cases are known in which development of the **ovules** occurs without the presence of any pollen. Development of the ovule in such cases is said to be by parthenogenesis. In some of these it may be that the vegetative cells around the embryo sac play a significant part in the process.

The agents which are instrumental in carrying pollen from one flower to another are principally air-currents and insects. Plants pollinated by air-currents, or wind, are said to be anemophilous; those by insects are entomophilous. In addition to these two main agencies there are several minor ones; in a few plants, water is the agent carrying pollen from flower to flower. A few flowers are considered to be pollinated by snails, others by birds and some even by bats. Man himself may effect pollination by selecting plants of special value to him and transferring pollen from one to the other, taking special precautions to prevent the presence of foreign unwanted pollen; this is artificial pollination to produce special strains of plants. Commonly it is accomplished by gathering mature pollen from unopened anthers of any desired flowers. With a small camel's hair brush, or special pollinating scalpel, this pollen is then placed on the stigmas of another selected flower; the second flower is emasculated, that is, the stamens are removed before maturing, to prevent any possible self-pollination. Flowers to be pollinated are usually kept enclosed in bags to prevent the presence of any unwanted pollen until fertilization has been effected. If accurate results are required all instruments and the hands of the operator are sterilized by immersion in alcohol between successive pollinations.

As a rule wind-pollinated flowers are inconspicuous, and of small size: color, odor, and nectar, all associated with insect-pollinated flowers, are largely lacking. Pollen is produced in immense quantities, since much will be lost. The pollen grains are dry and dust-like, and so float buoyantly in the air. In many plants of this group the stigmas are much-branched, feathery objects, offering a considerable area of sticky surface to catch any pollen that falls on it. To further the ready discharge of pollen, which ordinarily occurs only when the atmosphere is dry, the flowers are often borne in pendulous catkins, or on slender flexible **pedicels,** or have stamens the anthers of which are versatile, that is, attached at the middle and easily moved by any slight disturbance. Examples of wind-pollinated plants are found in the **Gymnosperms,** all of which are so pollinated, in most grasses, in many hardwood trees, such as birches, alders, **oaks,** and beeches, and in the common **cat-tail** of the marshes.

Water-pollinated plants are not numerous. That a plant grows in water is not an indication that its flowers shall be pollinated by water. Indeed, only a very few water-plants are so pollinated. In some cases, as in the marine **eel-grass,** *Zostera marina,* pollination occurs under water, the heavy pollen grains being carried by the water and by chance reaching the stigmatic surface. The fresh-water plant, *Naias,* is similarly pollinated under water, its pollen grains having a specific gravity of 1. In other water plants, pollination occurs at the surface

of the water. Examples of this type are found in the fresh-water eel-grass, *Vallisneria spiralis,* and in the marine *Ruppia maritima.* When the staminate flowers of eel-grass are mature, they break from their rather short stem and, being buoyant because of air-chambers, float to the surface of the water. There the spathes surrounding the flowers open, exposing the stamens within. These float about on the surface of the water, driven by air currents, as well as borne by water currents. The pistillate flower is solitary at the end of a long spiral stalk; when this flower is mature the stalk straightens so that the flower floats on the surface of the water, its three stigmas spreading wide and over-reaching the three-parted perianth. Chance drifting of the staminate flowers brings them near the stigmas which may then be pollinated by contact with the anthers. After pollination and subsequent fertilization, the stalk of the pistillate flower coils into a tight spiral, drawing the developing ovary deep into the water, where it matures.

Plants with flowers pollinated by animals are extremely numerous, and with many variations seemingly calculated to assure cross-pollination. A few tropical plants are said to be pollinated by bats. The flowers have very fleshy petals, open during the evening hours, and are apparently sought by bats, which eat the petals, or perhaps seek any insects which may occur in the flowers. Quite possibly, in going from flower to flower, bats do bring about a transfer of pollen. Pollination by such animals is undoubtedly restricted to a very small number of plants.

Similarly birds, especially hummings-birds and honey-suckers, are held to be the agents pollinating several tropical plants. In these the question arises as to whether the birds are seeking the numerous insects which are to be found in the flowers or after the nectar which is found in the flowers. The flowers visited by birds are rather large, brilliantly colored, often scarlet. Unquestionably humming-birds do seek nectar in flowers, both in the tropics and in temperate regions. Pollination may well result from their visits.

A few flowers are said to be pollinated by snails or slugs. Plants so pollinated have dense masses of flowers borne on a fleshy stock. This mass of sterile tissue attracts these animals, which crawl over it in the search for food, and so are said to carry pollen from flower to flower. Many observers doubt that such animals ever bring about pollination.

All, however, recognize that insects are very important in the pollination of many flowers. In many cases the flowers show remarkable adaptations fitting them to be pollinated by certain insects. The insects which effect pollination are for the most part bees, flies, beetles, and moths and butterflies.

As certain features characterize wind-pollinated flowers, so also insect-pollinated flowers exhibit several common features. In them the pollen grains are usually somewhat adhesive, often sticking together into considerable masses. The surface of each grain is variously sculptured, with knobs, spines, or other protuberances definitely increasing the ability of the grain to stick to the insect body. As in wind-pollinated flowers, so here the pollen would be seriously impaired by water, from which it must be protected during periods when pollination would not occur. Many are the ways in which protection is obtained. In some plants the entire flower bends down at night, while in many others the petals close together over the stamens; often a passing cloud is sufficient stimulus to cause closing, which takes place with surprising speed. In many plants the flowers are located beneath the leaves, as in the common Jewel-weed or Touch-me-not, *Impatiens biflora;* in the common Iris, each stamen is located beneath the broad-petaloid stigma. Often the anther itself is so constructed as to afford considerable protection, the pollen frequently being shed through narrow slits which close tightly during periods of excessive moisture; or small pores may allow the pollen to escape when advantageous but protect it from water otherwise.

A most obvious characteristic of insect-pollinated flowers is color, which may be found in a single flower with large conspicuous petals, or may result from the massing together of many small flowers, as in the **Composite Family.** While it is generally assumed that bright color is an aid to pollination because it attracts insects, it should be recognized that insect vision is not necessarily like that of human beings. Often the color of a flower changes with age, many becoming gradually deeper toned, as in the common Lady's Slipper, while others as gradually fade out. Flowers opening at night are almost all white or very light-colored.

The odors of flowers are also assumed to attract insects. Every fragrant flower has an odor which is quite distinctive. The odors of flowers are of many types, from the foul rankness of the Skunk Cabbage and Carrion Flower to the delightful perfume of Verbena, Gardenia, the Roses, and many Lilies. In many cases the odor of the flower is very delicate, being scarcely detectible to many people; in others it is of such penetrating strength as to become objectionable. Often the odor is evident only during certain periods, some flowers being scentless by day but fragrant during the night, while others emit their odors only in broad daylight. All these differences in odors seem designed to attract special insects which will accomplish pollination. The foul odor of carrion calls carrion-flies, and the sweet fragrance of night-blooming flowers attracts moths. After pollination the odor of the flower generally ceases, attraction of insects being no longer of any value.

Many insects undoubtedly visit flowers for the purpose of obtaining nectar, a sweet watery secretion formed in special glands called nectaries. These nectaries are variously located in the flower, usually deep down at the base of the corolla, so that any insect obtaining it must either have a mouth part of sufficient length to reach the nectar or be strong enough to push its way into the flower, passing any obstructions which may serve to protect the nectar from less fortunate insects. Obstructions are found of several sorts. A very common means of excluding such crawling insects as ants, which in all probability would not be efficient pollinators, is by the presence of a barricade of hairs, especially in the throats of flowers having a tubular corolla. Long-tongued bees are able to push through these hairs enough to reach the nectar, while at the same time they are thoroughly powdered with pollen which may be removed later in another flower. The existence of a sticky secretion over the outside of the flower or on the stem of the plant is an effective barrier to many crawling insects, as is also a waxy coating. Especially noteworthy are those flowers in which the nectar is located at the base of a long narrow tube or spur; often the nectar is present in quantities large enough to form a considerable volume. In such cases there is usually an insect with mouth parts just long enough to reach through the tube into the nectar supply, which is sucked up greedily. This becomes the more remarkable when one considers that in some flowers the nectar is at the bottom of a tube which may be 3 or 4″ long, and in the case of one tropical Orchid a nectar-secreting sac over a foot long exists; in such cases insects, usually moths or butterflies, with correpondingly long sucking tubes are found. Often short-tongued insects succeed in obtaining the nectar illegitimately by biting a hole in the wall of the nectar-containing part of the flower, and obtaining the nectar thereby. It is interesting to note, in connection with this problem of nectar-secreting flowers and insects, that the introduction of clover into Australia was not a success until honey-bees were also introduced. The native Australian bees were too short-tongued to reach the nectar and so pollination was not effected. As a consequence the clover crop soon died out, no seed

being formed to perpetuate it. With the introduction of suitable bees the plant seeded abundantly.

It is interesting to note that in addition to the existence of colors, odors, and nectar, the structure of the flower and its position on the plant seem designed to facilitate the work of the insect in transferring the pollen. Many flowers are broad and flat, affording convenient support to the insect as it crawls about over the flower. Others, especially those which are visited by long-tongued moths, are borne in such a position as seems most suited to permit the insect to insert its tongue and obtain the nectar. The pollen is collected in quantities by many species of bees, who use it as a food for the developing young.

Several plants have developed a most striking relationship with insects. While the majority of flowers are not visited indiscriminately by all insects but only by certain species or genera, in these special cases the restriction is extreme, both the flower and the insect seeming to be modified especially to serve one another. One such case is seen in the edible **fig**, pollinated only by a small insect, *Blastophaga grossorum*, which lays its eggs in the ovaries of certain flowers of the fig. Another example of this insect-flower association occurs in a species of Yucca. The creamy-white flowers of this plant are borne in large panicles. They open during the evening and are visited by a small moth, *Pronuba Fuccasella*, which seeks the abundant pollen of the flower. Of this pollen the moth makes a tiny ball which it carries away to another Yucca flower. In the ovary of this flower the female moth lays her eggs, while on the stigmatic surface it deposits its ball of pollen. The developing ovules serve as food for the growing larvae of the insect. However, many ovules grow to maturity to form viable seeds, which perpetuate the plant and so continue the food supply of the moth, which seems to be the sole agent capable of transferring the sticky pollen of the Yucca from plant to plant. Many other cases are known where pollination of the flower depends on the visit of certain insects, which do not, however, themselves depend on the flower for existence. On the other hand, many elaborate devices, such as the keel mechanism in papilionaceous flowers, which ought to assure insect pollination, fail to do so. Garden peas are normally self-pollinated. (R.M.W.)

POLLUCITE. The mineral pollucite is rather rare. It contains caesium, aluminum, silicon, and oxygen, its chemical composition being approximately $H_2O \cdot 2Cs_2O \cdot 2Al_2O_3 \cdot 9SiO_2$. It is **isometric**, usually in cubic crystals or crystalline masses; conchoidal fracture; brittle; hardness, 6.5, specific gravity, 2.9; luster, vitreous on fresh surfaces; colorless and transparent. Found on the Island of Elba and in the **pegmatites** of Maine. Pollucite and petalite were found in the **granites** of Elba and at first named pollux and castorite for the two famous brothers of Roman mythology, Castor and Pollux. Pollucite is derived from the Latin genitive *Pollucis*. (E.S.C.S.)

POLLUX. Pollux (β **Geminorum**) is the brighter of the "heavenly twins." The two stars are always considered together in ancient writings and in astrology, and, as a matter of fact, are not mentioned individually in literature, but always as the **constellation** of Gemini. This constellation is of very ancient lineage and is referred to throughout all classical literature. They were always considered of good omen by all peoples and always referred to as twins. **Astrologically,** the constellation was most favorably regarded, portending genius, goodness, and liberality. (W.K.G.)

POLONIUM. Symbol: RaF (or Po). A radioactive element of the uranium-radium series. (See **Radioactive Changes.**) (R.K.S.)

POLYBASITE. A mineral antimony sulfide of silver in which copper substitutes for silver to approximately 30 atomic %. Crystallizes in the monoclinic system. Hardness, 2–3; specific gravity, 6.1 ±; color, black with metallic luster; nearly opaque. From the Greek, meaning many, suggesting the many metallic basis. (R.M.F.)

POLYCHAETA. **Chaetopoda.**

POLYCHORIC CORRELATION. This is a method, rather complicated, of determining the **coefficient of correlation** in an $r \times s$ **contingency table.** (L.A.A.)

POLYCLADIDA. **Turbellaria.**

POLYCONIC PROJECTION. This form of **map projection** is essentially a series of simple **conical projections** of zones on the earth, so stretched as to form a continuous map. While the projection is in reality mathematical rather than geometrical, it may be described in words by considering a series of cones to be constructed which are tangent to the earth at certain selected parallels of **latitude**. Some **meridian** is selected as the central **longitude** for the map. Zones of latitude on the earth, each centered on one of the standard parallels and extending half-way on either side toward the adjacent standard parallels, are projected on the particular cone for the zone. All zones, on the cones, are then cut along the meridian differing by 180° from the central longitude, and developed on a plane.

The resulting map will not be continuous. All parallels will be represented as circles, but the centers of the circles will be different for successive zones. Hence the boundaries of adjacent zones will be tangent along the central meridian, but separate with increase of longitude in both directions from the center. To make the map continuous the zones are stretched, along a north-south direction, until the bounding parallels of adjacent zones are congruent with a curve bisecting the area of discontinuity between the zones. When this is done the meridians in adjacent zones will be discontinuous, and an east-west stretching must be made to bring the meridians into continuous curves. The resulting **graticule** does not appear to be very different from that of the simple conic, but examination shows that the parallels are not circles and the meridians not converging straight lines.

The advantage of the polyconic projection for maps is that there is virtually no distortion of relative size and shape along the central meridian. The same scale of distance can be used for a considerable distance either side of this line. The polyconic projection is frequently used for maps of river valleys and coast lines when these extend in approximately a north-south direction. For navigational purposes the **Lambert projection** has completely superseded the polyconic. (W.K.G.)

POLYCYTHEMIA. An abnormal increase in the red cells of the blood so that their total number is in excess of the normal 5 million per cu. mm. *Polycythemia vera* occurs as a primary, slowly progressive disease which is eventually fatal. Patients show reddish **cyanosis**, enlarged spleen and liver, and they suffer from malaise, digestive symptoms, and often painful **thromboses** of the superficial veins. Their red counts range from 7 to 11 million.

Secondary polycythemia, as a result of circulatory stasis, occurs with chronic heart disease (particularly of the congenital type), and chronic pulmonary disease, such as **emphysema**. It is also present in mild degree in individuals who live at high altitudes, the increased numbers of cells compensating for the low oxygen tension. (D.M.H.)

POLYEMBRYONY. The development of more than one individual from a single fertilized egg cell. In this process the egg breaks up during its early development into several to many component parts, each of which becomes a complete animal. It takes place in the

phylum **Bryozoa** in connection with the formation of colonies and has been reported in some of the parasitic insects (**Hymenoptera**). Since the host animal defends itself against the efforts of the female parasite to deposit her eggs in its body, the development of many young from each egg successfully placed is an obvious advantage. The process is akin to an asexual reproduction. (A.W.L.)

POLYMASTIGIDA. Mastigophora.

POLYMERIZATION. Association and Polymerization.

POLYMORPHISM. The occurrence of individuals of distinctly different structure or appearance within a species. In many cases two such forms occur and the species is said to be dimorphic rather than polymorphic.

Polymorphism depends upon many different conditions in various groups of animals. The various forms may be adapted for different places in a life cycle, for special parts in a colonial or social organization, or for special stages in a **metamorphosis**. They may also result from the incidence of different environmental conditions due to seasons or to unusual climatic conditions.

The alternation of **polyp** and **medusa** in a reproductive cycle in some species of **coelenterates** is a conspicuous example, as also is the appearance of such varied polyps as the gasterozooids and dactylozooids in colonial species. A differentiation of individuals according to special duties is evident in the castes of social insects. Many insects also vary according to the season or according to geographical range, as in the case of the wet and dry season forms of various tropical butterflies. Seasonal form, geographical race, variety, and subspecies are terms applied to forms of this kind. The influence of unusual conditions sometimes affects an occasional individual, producing an aberration. In chemistry, the term polymorphism is applied to compounds which exhibit **allotrophy**. Thus a substance that can occur in two crystalline forms like calcium carbonate is said to be dimorphous, one that can exist in three crystalline forms like thallous nitrate is said to be trimorphous, etc. The term polymorphous, as stated above, is general for them all. (A.W.L.)

POLYNOMIAL EQUATIONS. A polynomial equation of degree n in one variable or unknown is an equation of the form

$$a_0x^n + a_1x^{n-1} + a_2x^{n-2} + \cdots + a_{n-1}x + a_n = 0 \; (a_0 \neq 0),$$

where n is a positive integer and the coefficients a_0, a_1, $\cdots$, a_n are independent of x. It is also frequently called a rational integral equation.

Polynomial equations are classified into various types according to degree, as: **linear equations, quadratic equations, cubic equations, quartic** (or biquadratic) **equations**, quintic equations, etc.

Every **linear equation** and every **quadratic equation** in one unknown can be solved in terms of algebraic expressions involving the coefficients. **Cubic equations** (of third degree) and **quartic equations** (of fourth degree) can also be solved by explicit formulae for the roots in terms of algebraic expressions involving the coefficients. It has been proved, by Abel, however, that a polynomial equation in one unknown of degree higher than 4 cannot be solved in the general case algebraically, that is, for the roots in terms of algebraic expressions involving the coefficients.

In special cases, polynomial equations may be solved by the method of **factoring**.

Approximate values of the real **roots** of polynomial equations may be found by a **graphical solution**, by constructing the **graph** of the corresponding function and finding the **abscissas** of the **intersections** of the graph with the X-**axis**.

If a **polynomial function** $P(x)$ contains $x - r$ as a factor exactly k times and no more, so that $(x - r)^k$ is an exact divisor of $P(x)$ but $(x - r)^{k+1}$ is not, then r is called a multiple root of the equation $P(x) = 0$, or we say that r is a root of multiplicity k or a root of order k. A root of order one is called a simple root.

The so-called "fundamental theorem of algebra" is: Every polynomial equation in one unknown has at least one root (which may be real or complex).

It follows from this that every polynomial equation of degree n in one unknown has n and only n roots, provided a multiple root of order k is counted as k roots.

If r is a simple root of a polynomial equation $P(x) = 0$, (i.e., if $x - r$ is a factor of $P(x)$ once and only once) it is not a root of the equation $P'(x) = 0$, where $P'(x)$ denotes the **derivative** of $P(x)$. If r is a multiple root of order $m > 1$ of $P(x) = 0$, it is a root of order $m - 1$ of $P'(x) = 0$.

If a root of a polynomial equation is known, the corresponding factor may be divided out of the polynomial, leaving a new equation of lower degree, called the depressed equation.

The location of the real roots of a polynomial equation may be investigated by means of **Descartes' rule.** This rule gives more or less definite information about the nature of the roots of a polynomial equation.

The location of the real roots of a polynomial equation may be determined by the following theorem: If $P(x)$ is a polynomial with real coefficients, and if $P(a)$ and $P(b)$ have opposite signs, the equation $P(x) = 0$ has at least one and in fact an odd number of real roots between a and b; if $P(a)$ and $P(b)$ have like signs, the equation $P(x) = 0$ either has no roots between a and b, or it has an even number of roots between a and b.

In locating the real roots of the equation, the following result is also of use: If in substituting in a polynomial $P(x)$ a positive value r by **synthetic division,** all the partial sums are positive, then r is greater than any real root of the equation $P(x) = 0$.

In the process of finding the rational and irrational roots of a numerical polynomial equation, certain **transformations of the equations** are useful.

The determination of the rational roots of a polynominal equation is generally based on the following theorem:

If a polynomial equation, with the coefficient of the highest power of the variable unity, and all the other coefficients integers, has any rational roots, those roots must be integers, and must be divisors of the constant term, if the constant term is not 0.

To find the rational roots of a polynomial equation with first coefficient unity and all other coefficients integers, it is only necessary to test whether the integral factors of the constant term satisfy the equation, usually using synthetic division.

If the coefficient of the highest power of the variable is not 1 or if the coefficients are not integers, we may divide all terms by the coefficient of the highest degree term, and then remove any fractions in the other coefficients by transforming the equation by multiplying the roots by the appropriate factor, and thus reduce the equation to the form of the preceding method.

If a quadratic surd $a + \sqrt{b}$, where a and b are rational but $\sqrt{b}$ is irrational, is a root of a polynomial equation $P(x) = 0$ with rational coefficients, the conjugate surd $a - \sqrt{b}$ is also a root of the equation.

For the calculation of the approximate values of the irrational roots of a polynomial equation, there are available **Horner's method, Newton's method,** interpolation methods, and combinations of these. These methods will give the approximate values of the roots to any desired degree of accuracy.

If a complex number $a + bi$ is a root of a polynomial equation $P(x) = 0$ of degree $n \geqq 2$ with real coefficients,

the conjugate complex number $a - bi$ is also a root of the equation $P(x) = 0$.

In other words, complex roots of polynomial equations occur in conjugate pairs.

Approximate values of the roots of a polynomial equation may also be calculated by use of Graeffe's root-squaring method; this method is particularly useful in finding the complex roots of high-degree equations.

The relation between the roots and coefficients of any polynomial equation are given as follows: If $r_1, r_2, \cdots, r_n$ are the roots of the equation

$$x^n + a_1x^{n-1} + a_2x^{n-2} + \cdots + a_{n-1}x + a_n = 0$$

then

$$\begin{aligned} -a_1 &= r_1 + r_2 + \cdots + r_n, \\ a_2 &= r_1r_2 + r_1r_3 + \cdots + r_{n-1}r_n, \\ -a_3 &= r_1r_2r_3 + r_1r_2r_4 + \cdots + r_{n-2}r_{n-1}r_n, \\ &\cdots\cdots\cdots\cdots \\ (-1)^n a_n &= r_1r_2 \cdots r_n. \end{aligned}$$

(L.L.S.)

POLYNOMIAL FUNCTION. A rational integral function (or polynomial function) is a **rational function** in which the variable never appears in the denominator of a fraction. It can be expressed in the form

$$P(x) = a_0x^n + a_1x^{n-1} + \cdots + a_{n-1}x + a_n,$$

where x is the variable, n is a positive integer, and the coefficients $a_0, a_1, \cdots, a_n$ are constants (independent of x); in this case, the function is said to be of the n^{th} degree.

Polynomial functions are classified into types according to the degree, into **linear functions, quadratic functions, cubic functions, quartic** (or biquadratic) **functions**, etc. (L.L.S.)

POLYNOMIALS. A polynomial in general is an algebraic **expression** consisting of two or more terms connected by plus or minus signs.

A polynomial in one variable is an expression of the form

$$a_0x^n + a_1x^{n-1} + a_2x^{n-2} + \cdots + a_{n-1}x + a_n,$$

where the coefficients $a_0, a_1, \cdots, a_n$ are **constants** (independent of x), x is the **variable** and n is a positive integer, which is called the degree of the polynomial. The degree of the polynomial is the highest power of the variable that occurs in the expression. A polynomial in a variable x is frequently denoted by a symbol as $P(x)$.

A polynomial in several variables $x, y, z, \cdots$ is an algebraic expression of the form of an algebraic sum of terms of the type $cx^my^nz^p \cdots$, where c is a constant coefficient and each of the **exponents** $m, n, p, \cdots$ is either a positive integer or zero. The degree of such a polynomial term in the variables $x, y, z, \cdots$ is the sum $m + n + p + \cdots$ of the exponents of these variables. The degree of the polynomial is the degree of its term of highest degree. (L.L.S.)

POLYOPISTHOCOTYLINEA. **Trematoda.**

POLYP. In zoology, a polyp is one of the two types of individuals found in many species of **coelenterates.** The two are the polyp or hydroid and the **medusa.** Polyps are approximately cylindrical, elongated on the axis of the body. One end is usually attached and the other bears the mouth, surrounded by a circlet of tentacles. The wall is relatively thin, due to the thinness of the mesogloea. In the class **Hydrozoa,** polyps are often very simple, like the common little fresh-water species of the genus *Hydra.* Actinozoan polyps, including the **corals** and **sea anemones,** are much more complex, due to the development of a tubular stomodaeum leading inward from the mouth and a series of radial partitions called mesenteries. Many of the mesenteries project into the enteric cavity but some extend from the body wall to the central stomodaeum.

In medicine, a polyp is a smooth-coated tumor projecting from a mucous surface. It is attached to the surface by a narrow elongated **pedicle.** Polyps are commonly found in the nose, bladder, rectum and large intestine. They may also occur elsewhere in the body. (A.W.L., R.S.M.)

POLYPEPTIDES. **Aminoacids, Polypeptides, and Proteins.**

POLYPHYLETIC. A group of organisms derived from more than one ancestral stock is said to be polyphyletic. (R.M.W.)

POLYPHYLY. An evolutionary hypothesis which assumes that animals have originated by several lines of descent from as many ancestral forms, rather than from a single primordial form by gradual divergence. Special creation is the extreme of polyphyly but the hypothesis is not in discord with organic **evolution.** Although a great majority of organic forms seem traceable to a common ancestry there are a few peculiarities among the simpler living things which may indicate origin from independent lines. Among them are the cell structure of the **bacteria,** which lack a centralized **nucleus,** and the peculiar **metabolism** of some of the autotrophic species, such as iron and sulfur bacteria. Since modern evolution assumes the origin of life in the beginning from inorganic matter, there is no inherent obstacle to the assumption that living matter in that simple state may have been established independently in more than one place on the surface of the earth. (A.W.L.)

POLYPLACOPHORA. **Amphinura.**

POLYSACCHARIDES. **Carbohydrates.**

POLYTROPIC PROCESSES. The expansion or compression of a constant weight of gas may assume a variety of forms, depending on the extent to which heat is added to or rejected from the gas during the process, and also on the work done. There are, theoretically, an infinite number of ways possible in which a gas may expand from an initial pressure p_1, and volume v_1 to a final volume v_2. All these expansions may be grouped generically as polytropic expansions, and all could be represented graphically on the PV plane by the family of curves $pv^n = C$. They are all, in theory, perfectly reversible. n may have any positive value, 0 to ∞, and having been selected numerically it defines the type of expansion. From the infinite number of possible polytropic expansions, it is worth while to isolate four which deserve special attention. When one of the four physical characteristics, to wit, **pressure, temperature, entropy,** or volume, remains constant, expansions of more than ordinary interest are denoted, since they are frequently employed in a practical way, in situations which can be subjected to thermodynamic analysis. The value of the exponent n of the polytropic family for each of these is:

Isobaric	$n = 0$,
Isothermal	$n = 1$,
Isentropic	$n = \gamma$ (γ = ratio of specific heat at constant pressure to that at constant volume)
Isometric	$n = \infty$.

These thermodynamic processes, as they occur in useful machines, are not often of the exact polytropic form desired. For example, an isentropic process which is exemplified, at least theoretically, by expansion of the burned gases after the explosive combustion in the

gasoline engine, is modified slightly by the interchange of heat between gases and cylinder wall, whereas a true isentropic has no heat either added or rejected in this way. The particular polytropic curve which would suit these conditions of expansion would depart somewhat from the adiabatic form.

During a polytropic process conditions of the working medium are constantly varying, and analysis may be aimed at determining one of the following: the work done, the heat added, the variation of temperature, and the change of entropy. Some information may be obtained merely by comparing the value of the exponent n with certain other data. For example, if n lies between 0 and 1, the temperature rises during an expansion and falls during a compression; when n is greater than 1, the temperature falls during expansion and rises during compression. Also, when n is less than γ, heat must be added to obtain an expansion, whereas when it is greater than γ, heat must be expelled. From the above it will be noted that there is a certain range of polytropic expansion in which, although heat is added, the temperature falls. This may seem to some to be paradoxical, but it is readily explained. During these expansions work is being done by the gas at a rate greater than that at which heat is being added, with the result that the deficiency must be made up from within the gas. The only way that this may be accomplished is for the gas to cool and give up some of its internal energy.

The equations for work done and for heat added in the case of the general polytropic expansions are:

$$W = \frac{p_1v_1 - p_2v_2}{n - 1}.$$

$$Q = (p_1v_1 - p_2v_2)\left(\frac{1}{n - 1} - \frac{1}{\gamma - 1}\right).$$

Both of these are expressed in foot-pounds. Sometimes a substitution of a definite value of n in one or the other of these equations leads to an indeterminate; for example, with the isothermal,

$$W = \frac{p_1v_1 - p_2v_2}{1 - 1}.$$

But since the equation of the isothermal for an ideal gas is

$$pv = C,$$

$$p_1v_1 = p_2v_2,$$

and the work equation becomes indeterminate:

$$W = \frac{0}{0}.$$

By approaching the isothermal from a different angle, however, the equation

$$W = pv \log_e \frac{v_2}{v_1}$$

may be deduced for work done. (F.T.M.)

POLYZOA. Bryozoa.

POMACE FLY. Drosophila.

POME. Fruit.

POMEGRANATE. *Punica Granatum.* Punicaceae. The pomegranate is a shrub or small tree which is native to southeastern Europe and southwestern Asia. It has been cultivated since early times, and is now grown extensively in tropical and subtropical regions in both hemispheres. The plant has opposite entire leaves which are elliptical to oblong in shape. The flowers are borne either singly or in small clusters in the axils of the leaves. They are perfect and have a bright red **corolla** of 5–8 **petals,** and many **stamens.** The **fruit** is a many-seeded berry. The outer coat of each seed is the edible portion. It is soft and fleshy and red in color. Pomegranates are used in making jellies and jams. (R.M.W.)

PONS. Brain.

PONTOON. Cottontail.

PONTOON BRIDGE. Bridge.

PONY. Mammalia, Perissodactyla. A **horse** of various small, hardy and agile breeds indigenous to certain islands of the Old World. The Shetland pony is most familiar, from its use for children in the United States. Other breeds occur in the Orkneys and Iceland, northern Europe and Great Britain. (A.W.L.)

PONY TRUSS. Bridge.

POOR-WILL. Aves, Caprimulgiformes. A small North American **goatsucker,** *Phalaenoptilus nuttali.* The species lives in the western half of the United States and Canada. (A.W.L.)

POPPET VALVE. Otto Engine, Valve Gear.

POPPY. *Papaver somniferum.* Papaveraceae. The poppy from which opium is obtained is an annual herb having a smooth branching stem 2–3′ tall, large, dull, green, smooth leaves and solitary single flowers, varying from white to purple in color and rather showy. The flower consists of two **sepals,** which soon fall off when the flower opens, four **petals,** many **stamens** and a single **pistil** with a 1-celled **ovary.** The fruit is a **capsule,** 1–2″ in diameter, containing many small seeds, which escape through a ring of pores which form around the top of the capsule, beneath the persistent **stigma.**

To obtain opium, the unripe capsules are incised with a knife. From these cuts the milky juice oozes and dries to form a plastic gummy substance, which is scraped off and molded into a ball. This crude opium contains fragments of the plant tissues and considerable dirt. About 10% of the opium is the alkaloid morphine. When first prepared opium is brownish and easily molded. It gradually dies to a hard brittle substance, easily ground to a powder. Besides morphine it contains many other alkaloids.

The opium poppy was known and used by the ancients. It is a native plant in southwestern Asia, but has spread in cultivation over much of Asia as well as parts of Europe and elsewhere. In the Orient opium is much used in smoking, a habit-forming pastime which quickly ruins its follower. To produce opium profitably much cheap labor is necessary, therefore the principal producing countries are in Asia.

Opium and its derivative, morphine, are extremely valuable medicinally, being used to relieve pain and to induce sleep.

Poppy seeds, which contain no harmful substances, are frequently used in bread and cakes. From them is expressed an expensive oil used in cooking and in making artist's paints. (R.M.W.)

POPULATION. A population or universe consists of all the items from which the **sample** is drawn. The population may either be infinite or finite in size; it may consist of qualitative or quantitative variates, and in general does not refer to people. The population may be the yield per acre of a variety of wheat, the weight of a particular animal, or the shape of the head in a

human being at a specified age. The population may be mathematically specified by a **probability function.** (L.A.A.)

POPULATION PARAMETER. A population parameter is a value in the **population,** such as the mean of the population and the **variance** of the population. In the **Bernoulli probability function** the parameter is p; in the **normal probability function** there are 2 parameters, the mean m, and the **standard deviation** σ. (L.A.A.)

PORBEAGLE. Pisces, Plagiostomi. A **shark,** *Lamna cornubica,* found in the warmer parts of the Atlantic, occasionally farther north and in the Pacific. Its length is 8–10′. Also called the mackerel shark, although this name belongs to another larger species. (A.W.L.)

PORCELAIN. **Ceramics.**

PORCELAIN ENAMEL. A vitreous coating applied to **cast iron** and **steel** sanitary ware, cooking utensils, stove and refrigerator panels, etc. A frit of finely powdered borosilicate glass is applied to the surface by either spraying or dipping. The part is then fired at temperatures near 1500–1600° F. to form an adherent coating. A ground coat and one or more cover coats are generally applied. Coatings on cast iron are generally heavier than on steel and are fired at lower temperatures. Porcelain enamel coatings have excellent corrosion resistance and would have even wider application except for their brittleness. Thinner coatings having improved adherence to the base metal are coming into use. (R.H.H.)

PORCELLANITE. Metamorphosed **marls** and **shales** which look like porcelain. (R.M.F.)

PORCUPINE. Mammalia, Rodentia. An animal with many modified hairs resembling quills in form. These hairs are sharp-tipped rigid spines with finely barbed tips which penetrate flesh very readily and serve as an almost impregnable defense.

North America has two species of porcupines, one ranging over the eastern half of the continent as far south as Virginia and the other, *Erethizon epixanthum,* in the far west, from Alaska to Mexico. The common eastern species, *E. dorsatum,* is also called the hedgehog. Both species are partial to the leaves, twigs and bark of evergreen trees as food.

The tree porcupines differ in having long prehensile tails. They are found in Mexico and South America. Still other species live in Eurasia, Africa, and the Oriental Region. (A.W.L.)

PORGY. Pisces, Teleostei. A fish (**Pisces**) of the family Sparidae, in particular a valuable food fish found along the Atlantic coast from Cape Cod to South Carolina. This species is also called the scup or scuppaug. Among the other species of the family are the red snapper and sheepshead, both among our best marine food fishes. The name is also spelled porgie and porgee. (A.W.L.)

PORIFERA. The sponges. A **phylum** of animals of low organization, related to some of the 1-celled **protozoans** and much more primitive than any other multicellular group. Because of their loosely integrated structure the sponges are regarded as one of three major types of animal organization, designated by the term Parazoa. This group lies between the Protozoa, also a single phylum, and the **Metazoa,** containing all of the other multicellular phyla.

Sponges develop only two germ layers, the ectoderm and endoderm, but many different cells lie in the mesogloea between the two. The body wall is perforated by many canals leading to a central cavity, the **paragaster.** Some part of these passages is lined with collared **flagellate** cells which produce currents of water flowing inward through the pores and out of a larger opening of the paragaster called the osculum. The body wall contains several kinds of specialized cells. The scleroblasts form hard supporting structures of various forms and materials, called spicules. **Phagocytes** ingest, digest, and transport food. **Porocytes** become perforated to form canals. The outer surface is covered with flattened cells called pinacocytes.

Three kinds of sponges are recognized, according to the plan of the canal system: 1. Ascon sponges have canals leading entirely through the body wall and collared cells (choanocytes) in the lining of the paragaster. 2. Sycon sponges have radial canals lined with choanocytes and opening into the paragaster. Between them inhalant canals lead inward from the outside but do not reach the paragaster. The two types of canals are connected by minute pores called prosopyles through which water must pass to reach the interior. 3. In the rhagon or leucon sponges the canal systems are more intricately branched and the choanocytes are located in small chambers.

Commercial sponges are the skeletal remains of species whose bodies are supported by fibers of a peculiar material, spongin. The organic matter is removed by maceration and washing.

The phylum is divided into three classes:

Class Calcarea. Sponges whose bodies contain calcareous spicules only. The **choanocytes** are large and all three types of canal systems are represented.

Class Hexactinellida. **Spicules** 6-rayed and siliceous. Choanocytes small. Canal system of a simple rhagon type. The glass sponges.

Class Demospongiae. Spicules siliceous but not 6-rayed or an association of siliceous (**silicon**) material and spongin. Rhagon type of canal system. The sponges of commerce are included here. The subfamily Spongillinae includes the only species of sponges found in fresh water. (See also **Invertebrate Paloeontology.**) (A.W.L.)

POROCYTE. A kind of cell found in sponges. They become perforated to form minute pores through which water passes to enter the body of the sponge. (A.W.L.)

POROUS PLUG EXPERIMENT. **Joule-Thomson Effect.**

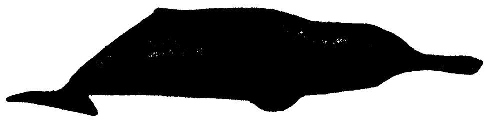
PORPHYRINS. **Pyrrole and Related Compounds.**

PORPHYRITE. A term applied to **hypabyssal igneous** rocks, such as **dikes, sills** and **laccoliths** of andesitic composition and pronounced porphyritic texture. (R.M.F.)

PORPHYROBLAST. A term proposed by Becke, in 1900, for pseudo-**porphyritic** crystals formed by thermodynamic **metamorphism.** (R.M.F.)

PORPHYRY. Porphyry is a textural term applied to **igneous rocks** in which one or more of the mineral constituents present exists as well crystallized individuals in a ground mass that is relatively of much finer grain. The derivation of the word presents an interesting study. The **gasteropods** of the genus Murex were much used for obtaining a purple dye; the Greek name for both the animal and the dye is the same. A certain Egyptian rock which was once much used for building and ornamental purposes displays very prominent crystals in a purplish groundmass and so the same Greek word was applied to it, then later came to mean all rocks of this general appearance. Modern use now restricts the term porphyry to the description of texture alone as in the case of the Egyptian rock. (E.S.C.S.)

PORPOISE. Mammalia, Odontoceti. Small animals related to the toothed **whales.** They reach a length of about 5'. The muzzle is bluntly rounded and most species have a dorsal fin. Porpoises are found chiefly in the northern oceans although one species ranges from Japan to southern Africa and enters the rivers of China and India. (A.W.L.)



Porpoise. (*American Museum of Natural History.*)

PORPOISING. An undulatory movement of a seaplane consisting of a combination of a vertical oscillation and an oscillation about its transverse axis, which occurs at certain stages of planing. (F.T.M.)

PORT. The word port refers to the opening or means of entry into a certain region. In engineering, the port is that connecting passage or opening by means of which a fluid flow is admitted to such a region as that furnished by a cylinder. The gasoline engine (**Otto engine**), the **Diesel engine,** and the **steam engine,** as well as the **air compressor,** have openings arranged in the cylinder so that the contents may enter and leave properly. In the steam engine, the single port may sometimes serve for both admission and exhaust of the steam. This port leads from the valve chest into the end of the cylinder. The valve will alternately connect the cylinder with either the high-pressure steam or the exhaust region, and the steam flows first in through the port, then out. Some steam engines are double-ported, having separate ports for admission and release of steam. This is an aid to reducing a loss known as **initial condensation.** The **internal combustion engine** usually has two ports, one the inlet, the other the exhaust, since the internal combustion type valve is not suitable for single valve practice. In the gasoline engine, the typical port is a circular opening cored into the cylinder block, terminating at one end in the valve seat, and at the other in the manifold. Usually the valve stem passes through this port for a short distance. If an exhaust port, it must be well water-jacketed or flanged, so that heat may be conducted away rapidly enough to prevent damage to the metal. Smoothness of stream flow through the ports and minimum friction loss are desirable in obtaining the maximum possible inflow to the cylinder, or exhaust from it. The size of a port is fixed by the cylinder bore and piston speed, and the ports should bear a relationship to piston area which has been found to be satisfactory in actual practice. (F.T.M.)

PORTAL. Bridge.

PORTLAND CEMENT. Cement, Portland.

PORTUGUESE MAN-OF-WAR. Coelenterata, Hydrozoa. A beautiful but dangerous colonial **hydrozoan,** *Physalia.* It consists of a large hollow float, the pneumatophore, from which many delicate filaments hang into the water. These filaments are tentacles of a form of individual called a dactylozooid. The stinging cells in them kill the prey and their muscular contractions draw it up within reach of the gastrozooids which digest it. The poison of these animals is virulent and the colony is large enough to be dangerous even to human beings. (A.W.L.)

POSITION ANGLE. The term position angle is used in astronomy to denote the angle between the great circle joining any two celestial objects, and the **hour circle** through one of the objects. In measuring **double stars** the position angle is the angle between the great circle joining the two stars and the **hour circle** through the brighter of the pair, the angle being measured from the north to the east through 360°. (W.K.G.)

POSITIVE RAYS. Canal Rays.

POSITIVE-RAY ANALYSIS. Mass Spectrograph.

POSITRON. An elementary charged particle, sometimes called the "positive electron" because its mass is apparently of the electronic order and its charge is positive. Positrons were first observed by C. D. Anderson by means of their ionization tracks in the air of a **cloud chamber.** They were thought to arise from the impacts of **cosmic rays** of very high energy upon atoms. Anderson later showed that particles of the same type are emitted when gamma rays of very high frequency are intercepted by a plate of metal. For this purpose the gamma-ray quanta must have energies exceeding a million electron-volts. Blackett and Occhialini have set forth the remarkable theory that in such an encounter the quantum itself, originally neutral, is transformed into a positron and an electron, part of its energy being converted into the masses of these particles (see **Energy** and **Relativity**), and the rest appearing as their kinetic energy. (See **Nuclear Particles.**) (L.D.W.)

POT HOLE. Under favorable conditions where streams flow over the bedrock, swirling eddies will wash sand, gravel or pebbles around and around in the same place with the result that cylindrical holes called pot holes, are worn, often to a considerable depth. These pot holes may be from a few inches to several feet in diameter and rarely as much as 40–50' deep. Similar features found on the sea shore, the result of wave action, are called sea-mills. Pot holes also have been formed by water from crevasses and ice cliffs and glaciers. (R.M.F.)

POTAMOGALE. Mammalia, Insectivora. *Potamogale.* An amphibious animal of western Africa. It has a slender body and short legs like the mink and otter, and is further characterized by the compressed tail and valves to close the nostrils. (A.W.L.)

POTASH. Term applied to **potassium** compounds. Potash, potassium carbonate; caustic potash, potassium hydroxide. Percentage of potash expressed in analyses of chemicals is for potassium oxide (K_2O). (R.K.S.)

POTASSIUM. Symbol: K (kalium). Atomic number: 19. Atomic weight: 39.096. Density: 0.87. Hardness: 0.5. Melting point: 62.3° C. Boiling point: 760° C. Isotopes: 39 (93.4%), 40 (0.01%), 41 (6.6%).

Potassium is a silver-white metal, can be readily molded, and cut by a knife, oxidizes instantly on exposure to air, and reacts violently with water, yielding potassium hydroxide and **hydrogen** gas, which burns spontaneously in air with a violet flame due to volatilized potassium element, is preserved under kerosene, burns in air at a red heat with a violet flame. Discovered by Davy in 1807.

Potassium occurs as potassium chloride or sulfate in certain salt deposits (**carnallite,** potassium magnesium chloride ($KCl \cdot MgCl_2 \cdot 6H_2O$); **kainite,** potassium magnesium chloride sulfate ($K_2SO_4 \cdot MgSO_4 \cdot MgCl_2 \cdot 6H_2O$)), mainly in Stassfurt, Germany, Alsace-Lorraine, Spain, Poland, California, New Mexico; in common rocks (average of the solid shell of the earth, 2.6%) and the minerals, **feldspar, greensand, alunite, leucite;** present in vegetation (average 1.7%) remaining in the ash when burned.

Potassium metal is obtained by **electrolysis** of fused potassium hydroxide or chloride fluoride mixture in a specially designed cell.

Acetate: Potassium acetate ($KC_2H_3O_2$), white solid, soluble, formed by reaction of potassium carbonate and **acetic acid**, and then evaporating.

Alum: Potash alums are those alums, such as **aluminum** potassium sulfate ($Al_2(SO_4)_3 \cdot K_2SO_4 \cdot 24H_2O$), chromium potassium alum ($Cr_2(SO_4)_3 \cdot K_2SO_4 \cdot 24H_2O$) where potassium sulfate is crystallized with the heavy metal sulfate.

Bromate: Potassium bromate ($KBrO_3$), white solid, soluble, melting point 434° C., upon heating oxygen is evolved and the residue is potassium bromide; formed by electrolysis of potassium bromide solution under proper conditions. Used as a source of bromate and bromic acid.

Bromide: Potassium bromide (KBr), white solid, soluble, formed by reaction of potassium hydroxide and **bromine**, and then evaporating and heating to decompose bromate. Use (1) in photography, in engraving and lithographing, (2) in medicine as a sedative.

Carbonate: Potassium carbonate, potash, pearl ash (K_2CO_3), white solid, soluble, formed (1) in the ash when plant materials are burned, (2) by reaction of potassium hydroxide solution and the requisite amount of **carbon dioxide**. Used (1) in making special glasses, (2) in the making of soft soap, (3) in the preparation of other potassium salts (a) in solution, (b) upon fusion; potassium hydrogen carbonate, potassium bicarbonate, potassium acid carbonate ($KHCO_3$), white solid, soluble.

Chlorate: Potassium chlorate, chlorate of potash ($KClO_3$), white solid, soluble, melting point about 350° C., powerful oxidizing agent, and consequently a fire hazard with dry organic materials, such as clothes, and with **sulfur**; upon heating oxygen is liberated and the residue is potassium chloride; formed by electrolysis of potassium chloride solution under proper conditions. Used (1) in matches, (2) in pyrotechnics, (3) as disinfectant, (4) as a source of oxygen upon heating. (Hazardous! Use of potassium perchlorate is recommended instead.)

Chloride: Potassium chloride, chloride of potash, muriate of potash (KCl), white solid, soluble, melting point 790° C., boiling point 1500° C. Common constituent of potassium salt minerals. Volatilized when potassium-bearing silicates, such as **feldspar, leucite**, are heated with **calcium** chloride to a high temperature, as in a cement kiln. Used (1) as an important potassium fertilizer, (2) as a source of other potassium compounds.

Chloroplatinate: Potassium chloroplatinate (K_2PtCl_6), yellow solid, insoluble, formed by reaction of soluble potassium salt solution and chloroplatinic acid. Used in the quantitative determination of potassium.

Chromate: Potassium chromate (K_2CrO_4), yellow solid, soluble, formed by reaction of potassium carbonate and **chromite** at a high temperature in a current of air, and then extracting with water and evaporating the solution. Used (1) as a source of chromate, (2) in leather tanning, (3) in textile dyeing, (4) in inks.

Cobaltinitrite: Dipotassium sodium cobaltinitrite ($K_2NaCo(NO_2)_6 \cdot H_2O$), golden yellow precipitate, formed by reaction of **sodium** cobaltinitrite solution in **acetic acid** with soluble potassium salt solution. Used in the detection of potassium.

Cyanate: Potassium cyanate (KCNO), white solid, soluble, formed along with lead metal by reaction of potassium cyanide and **lead** monoxide solids upon heating. Source of cyanate.

Cyanide: Potassium cyanide, cyanide of potash (KCN), white solid, soluble, very poisonous, formed by reaction of calcium **cyanamide** and potassium chloride at high temperature. Used as a source of cyanide and for hydrocyanic acid, but usually replaced by the cheaper sodium cyanide.

Dichromate: Potassium dichromate, chromate of potash ($K_2Cr_2O_7$), red solid, soluble, powerful oxidizing agent, formed by acidifying potassium chromate solution and then evaporating. Used (1) in matches and pyrotechnics, (2) in leather tanning and in the textile industry, (3) as a source of chromate.

Ferricyanide: Potassium ferricyanide, red prussiate of potash ($K_3Fe(CN)_6$), red solid, soluble, formed by reaction of potassium **ferrocyanide** solution and **chlorine**, and then evaporating.

Ferrocyanide: Potassium ferrocyanide, yellow prussiate of potash ($K_4Fe(CN)_6$), yellow solid, soluble, formed by treating "spent oxide" of coal gas works with **calcium** hydroxide to extract ferrous cyanide as soluble calcium ferrocyanide and then treating with potassium carbonate, filtering and evaporating the filtrate. Used (1) as a source of ferrocyanide, but usually replaced by the cheaper sodium ferrocyanide, (2) in blue print paper, (3) in tanning, (4) in tempering steel.

Fluoride: Potassium fluoride (KF), white solid, soluble, formed by reaction of potassium carbonate and **hydrofluoric acid**, and then evaporating. Used in the etching of glass; potassium hydrogen fluoride, potassium bifluoride, potassium acid fluoride (KHF_2), white solid, soluble, formed by reaction of potassium carbonate and excess hydrofluoric acid, and then evaporating.

Glycerophosphate: Potassium glycerophosphate ($(KO)_2PO(C_3H_7O_3)$), pale yellow liquid, formed by warming **glycerol** and **metaphosphoric acid**, and then neutralizing with potassium carbonate. Used in medicine.

Hydroxide: Potassium hydroxide, caustic potash, potassium hydrate (KOH), white solid, soluble, melting point 380° C., formed (1) by reaction of potassium carbonate and **calcium** hydroxide in water, and then separation of the solution and evaporation, (2) by electrolysis of potassium chloride under the proper conditions, and evaporation. Used in the preparation of potassium salts (1) in solution, (2) upon fusion.

Hypophosphite: Potassium hypophosphite (KH_2PO_2), white solid, soluble, formed (1) by reaction of **hypophosphorous** acid and potassium carbonate solution, and then evaporating, (2) by reaction of potassium hydroxide solution and **phosphorus** on heating (poisonous phosphine gas evolved).

Iodate: Potassium iodate (KIO_3), white solid, soluble, melting point 560° C., formed (1) by electrolysis of potassium iodide under proper conditions, (2) by reaction of **iodine** and potassium hydroxide solution, and the fractional crystallization of iodate from iodide. Used as a source of iodate and iodic acid.

Manganate: Potassium manganate (K_2MnO_4), green solid, soluble, permanent in alkali, formed by heating to high temperature **manganese** dioxide and potassium carbonate, and then extracting with water, and evaporating the solution. The first step in the preparation of potassium manganate and permanganate from pyrolusite.

Nitrate: Potassium nitrate, saltpeter, niter (KNO_3), white solid, soluble, melting point 333° C., formed by fractional crystallization of **sodium** nitrate and potassium chloride solutions. Used (1) in matches, explosives, pyrotechnics, (2) in the pickling of meat.

Nitrite: Potassium nitrite (KNO_2), yellowish-white solid, soluble, formed (1) by reaction of nitric oxide plus **nitrogen** tetroxide and potassium carbonate or hydroxide, and then evaporating, (2) by heating potassium nitrate and **lead** to a high temperature and then extracting the soluble portion (lead monoxide insoluble) with water, and evaporating. Used as a reagent (**diazotizing**) in organic chemistry.

Oxalate: Potassium oxalate ($K_2C_2O_4$), white solid, soluble, formed by reaction of potassium carbonate or hydroxide and **oxalic acid**, and then evaporating. Used as a source of oxalate; potassium hydrogen oxalate, potassium binoxalate, potassium acid oxalate (KHC_2O_4), white solid, soluble; potassium tetroxalate ($KHC_2O_4 \cdot H_2C_2O_4 \cdot 2H_2O$), white solid, moderately soluble.

Oxides: Potassium oxide, potassium monoxide (K_2O), white solid, reactive with water to form potassium hydroxide, formed by reaction of potassium and **oxygen**

at reduced pressure, and removal of excess metal by distillation in vacuum; potassium peroxide, potassium tetroxide (K_2O_4), yellow solid, soluble in water with evolution of oxygen, formed by heating potassium at 200° C. in a current of oxygen.

Perchlorate: Potassium perchlorate ($KClO_4$), white solid, very slightly soluble, melting point 610° C., but above 400° C. decomposes with evolution of oxygen gas and formation of potassium chloride residue; formed (1) by electrolysis of potassium chlorate under proper conditions, (2) by heating potassium chlorate at 480° C. and then fractional crystallization. Used (1) as a convenient and safe (preferred to use of potassium chlorate) method of preparing oxygen by heating, (2) in the determination of potassium in soluble salt solution.

Periodate: Potassium periodate (KIO_4), white solid, very slightly soluble, melting point 582° C., formed by electrolysis of potassium iodate under proper conditions.

Permanganate: Potassium permanganate, permanganate of potash ($KMnO_4$), purple solid, soluble, formed by oxidation of acidified potassium manganate solution with **chlorine,** and then evaporating. Used (1) as disinfectant and bactericide, (2) in medicine, (3) as an important oxidizing agent in many chemical reactions.

Persulfate: Potassium persulfate ($K_2S_2O_8$), white solid, slightly soluble, formed by **electrolysis** of potassium sulfate under proper conditions. Used (1) as a bleaching and oxidizing agent, (2) as an antiseptic.

Phosphates: Tripotassium phosphate (K_3PO_4); dipotassium hydrogen phosphate (K_2HPO_4); potassium dihydrogen phosphate (KH_2PO_4); potassium pyrophosphate ($K_4P_2O_7 \cdot 3H_2O$); potassium metaphosphate (KPO_3); white solids, similar in properties and formation to the corresponding and more common **sodium** phosphates.

Phosphites: Dipotassium hydrogen phosphite (K_2HPO_3); potassium dihydrogen phosphite (KH_2PO_3); white solids, similar in properties and formation to the corresponding **sodium** phosphites.

Silicate: Potassium silicate (K_2SiO_3), colorless (when pure) glass, soluble, melting point 976° C., formed by reaction of **silicon** oxide and potassium carbonate at high temperature, similar in properties and uses to the more common sodium silicate.

Sulfates: Potassium sulfate, sulfate of potash (K_2SO_4), white solid, soluble. Common constituent of potassium salt minerals. Used (1) as an important potassium fertilizer, (2) in the preparation of potassium or potash **alums;** potassium hydrogen sulfate ($KHSO_4$), white solid, soluble; potassium pyrosulfate ($K_2S_2O_7$), white solid, soluble, formed by heating potassium hydrogen sulfate to complete loss of water.

Sulfides: Potassium sulfide (K_2S), yellowish to reddish solid, soluble, formed by heating potassium sulfate and **carbon** to a high temperature; potassium hydrogen sulfide, potassium bisulfide, potassium acid sulfide (KHS), formed in solution by reaction of **sodium** hydroxide or carbonate solution and excess **hydrogen sulfide.**

Sulfite: Potassium sulfite ($K_2SO_3 \cdot 2H_2O$); potassium hydrogen sulfite ($KHSO_3$); white solids, similar in properties and formation to the corresponding **sodium** sulfites.

Tartrates: Potassium tartrate ($K_2C_4H_4O_6 \frac{1}{2}H_2O$), white solid, soluble, formed by reaction of potassium carbonate solution and **tartaric acid,** and then evaporating; potassium hydrogen tartrate, potassium bitartrate, potassium acid tartrate, "cream of tartar" ($KHC_4H_4O_6$), white solid, slightly soluble. Obtained from "argols," a by-product of wine fermentation (argols consist of 50–85% potassium hydrogen carbonate and 6–12% calcium tartrate). Used (1) in **baking powder** as a source of acid, (2) as a source of tartrate, potassium sodium tartrate, Rochelle salt ($NaKC_4H_4O_6 \cdot 4H_2O$), white solid, soluble, and **Fehling's solution.** Used (1) in medicine, (2) as a source of tartrate.

Thiocarbonate: Potassium thiocarbonate (K_2CS_3), yellow solid, soluble, formed by reaction of potassium sulfide and **carbon disulfide.**

Thiocyanate: Potassium thiocyanate, potassium sulfocyanide, potassium rhodanate (KCNS), white solid, soluble, melting point about 170° C., formed by fusing potassium cyanide and **sulfur,** and then crystallizing. Used as a source of thiocyanate.

All potassium-containing substances impart a characteristic violet color to the bunsen flame, but small amounts are easily masked by the presence of sodium and its yellow flame. (R.K.S.)

POTATO FAMILY. Solanaceae. This is a relatively small family of some 1700 species, in about 80 genera. The members include herbs, shrubs, and a few trees, most of the last being found in the tropics. The family has many important food and medicinal plants. All of its members contain poisonous **alkaloids,** as solanin, capsaicin, **belladonna,** nicotine, and **atropine.**

Members of this family have leaves which are usually alternate and variously shaped, often lobed or dissected or **pinnately** compound. The variability frequently occurs in the leaves of a single plant. The flowers occur either singly or in **cymes,** and are regular with an inferior 5-lobed **calyx,** a 5-lobed **corolla** of various shapes; often large and conspicuously colored, five **stamens** and a **pistil** composed of two united **carpels,** a long **style** and a single terminal **stigma.** The **ovary** contains many **ovules.** The fruit is either a **berry** (potato and tomato) or a **capsule** (tobacco).

The most important member of this family is the Potato, *Solanum tuberosum,* commonly called the Irish potato, common potato, White Potato, or English potato, to distinguish it from the sweet potato. The plant is a branched herb, the branches tending to spread out more or less, and growing 2–4′ in height. The green stems are annual, but the tubers, which are modified stems, give to the plant a perennial nature. The leaves are pinnately compound and rather irregular. The flowers are 1–1½″ in diameter, white, often with blue or purple tones or stripes, and with a tubular corolla. The fruit is a globular berry containing many small seeds embedded in a green pulp. Common names given these potato berries are potato balls, potato apples or seed balls. When mature, they are either green or brown; often they contain few seeds, but since they are rarely used in propagating the potato, this is of little consequence. They are used experimentally in the production of new varieties. Once a desirable variety is found, it is perpetuated vegetatively by means of the tubers. These tubers are formed at the tips of modified underground branches, or **rhizomes,** which radiate outward from the basal portion of the stem and to the casual observer resemble roots. The length of these stolons varies from a few inches to a foot or more, depending somewhat on the variety. Rhizome formation and tuber development start soon after the tops appear above ground, and are advanced by darkness and low temperatures. The tubers continue to grow throughout the growing life of the plant. A mature tuber has the structure of a stem, but very much modified. Externally, one may recognize nodes and internodes, the nodes being determined by the eyes, depressions in the surface of the potato, each depression or eye containing a tiny bud. Internally the tuber is largely **parenchymatous** tissue with the cells filled with starch-grains. Near the surface of the potato, cross sections show a faint dark line which is the **vascular** tissue, very much reduced. Potato tubers vary greatly in shape, as well as in size; the better varieties are oblong or oval, with smooth skin and rather shallow eyes. In color, tubers range from brown through yellow to red, according to variety. The length of time required to mature a marketable tuber also varies greatly, some early varieties reaching a desirable size in about

two months, while late varieties require five or six months.

The tubers are the principal means of propagation. For this purpose a tuber is cut into irregular pieces, each of which contains two or three eyes. To prevent disease the cut pieces are treated with sulfur and allowed to dry slightly, after which they are planted. Sprouting starts at once, indeed frequently occurs while the potato is still in the storage bin. If the bin is dark the sprouts formed will be long, slender and white. Sprouts formed in light are short, stout and dark green.

In addition to being an important article of food to inhabitants of the temperate regions of the world, the potato has many other uses. **Starch** is made from them, cull or small potatoes being much used for this purpose. To make starch the raw potatoes are cleaned, soaked in water for several hours, then washed thoroughly and reduced to a pulp. This pulp is strained to remove any fibrous material. The strained liquor is allowed to stand, the starch settling to the bottom. This starch layer is drawn off and purified by running slowly down an inclined table where the starch grains once more settle to the bottom. They are then collected and dried thoroughly, then broken up into marketable size.

Another use for potatoes is as a source from which to make **alcohol**. Finally, potatoes are much used as food for domestic animals, especially swine, being fed either raw or cooked or, at times, dried.

The potato is a native plant of cool upland regions of South America, where it has been long cultivated by the natives, who use the tubers for food. From America is was carried to the southern part of Europe, where at first it was grown largely as a curiosity. From Europe the plant was brought back to America and introduced into what is now the United States, thus explaining its name of English or Irish Potato. It is now extensively grown in regions having a cool climate, Maine being particularly noted for its potato crop.

In all green parts of the potato a poisonous alkaloid, solanin, occurs. This substance may also occur in the tubers, particularly if the latter are exposed to light long enough to become green in color.

Another important food plant of this family is the tomato, *Lycopersicum esculentum,* and related species. This is a native of South America, in which continent the tomato is still found wild. The tomato is a coarse branching perennial herb which is usually grown as an annual. It is an important food which in recent years has become immensely popular. Large quantities are consumed raw or canned. Tomato juice is an important article of diet. From the seeds an oil may be obtained, which is used in making soaps.

The tomato was carried to Europe by the early Spanish explorers and became an important food plant in southern European countries. In England and also in the United States it was widely grown before 1830 as a garden ornamental known as "Love Apple," which however was not eaten, but was held by many to be rankly poisonous. The Italians seem to be the first to have braved the danger of tasting the delicious fruit of this "poisonous" plant.

A third member of the family providing food to man is the egg plant, *Solanum Melongena,* a coarse, somewhat woody, branching herb native to India. The plant has a rough stem, 2 or 3′ tall, large sinuate-lobed ovate leaves and purplish oflwers. The fruit is a berry, very large in some varieties. It is eaten either baked or sliced and fried.

Serving rather as a condiment than a food, but still used as a food stuff in some of its varieties, is the **pepper,** *Capsicum annuum,* another native plant of tropical America. Peppers are either annual or biennial plants, with branching stems 1–3′ tall, smooth shining leaves and white flowers. There are many varieties, which bear fruits of a variety of sizes and shapes, as well as degrees of pungency. Some varieties are known as sweet peppers, and are used in salads or stuffed and baked; others are hot peppers. The pungent taste is due to an acrid compound, capsaicin, which in hot peppers occurs throughout the fruit, but in sweet peppers is largely restricted to the immediate region of the seeds; since only the fleshy **pericarp** is eaten, the seed being removed, this pungent substance is lost.

Peppers are used in many ways other than as food. Small hot peppers are a frequent component of mixed pickles, and also are used in salads. The whole fruit of some varieties is ground up to a powder, and becomes Cayenne pepper, an extremely pungent condiment. Small smooth fruits of var. *conoides* are preserved whole in brine or vinegar, and known as Tabasco sauce or Tabasco peppers. Red peppers are used medicinally. Many varieties of pepper are grown as ornamental plants, the brilliant fruit offering a startling contrast to the dark green leaves.

More widely grown for its ornamental properties is the Petunia, introduced from South America.

Many members of the Potato Family are important drug plants. Here belong *Atropa Belladonna,* yielding **atropine,** and *Datura Stramonium,* the Thorn Apple, called also Jimson Weed or Jamestown Weed. The latter is a tall, rather coarse, branching annual having broad leaves with sinuate margins and large trumpet-shaped white flowers, borne singly in the axils of the leaves (a related species, *D. Tatula,* has purple flowers). The fruit is a prickly capsule. In all parts of the plant, but especially in the seed, are found several drugs. The most abundant is **hyoscyamine,** with small amounts of atropine and scopolamin present. The powdered leaves and seeds are used medicinally, chiefly in treating asthma.

Less important medicinally are several plants such as *Hyoscyamus niger, Solanum Dulcamara,* the Bittersweet, and *Solanum niger,* the garden Nightshade, all held to be poisonous plants if eaten in sufficient quantity by man or domestic animals.

Another member of this family, ranking along with the potato in importance, is the tobacco plant, *Nicotiana Tabacum,* also a native plant of tropical America. It is an annual plant growing 3–6′ or more in height, and stout. The leaves are alternate, simple and rather large and, like the stem, covered with sticky hairs. The rather large flowers are borne in terminal racemes and have a funnel-shaped corolla which is yellow, white, pink or purple in different species and varieties. The fruit is a capsule containing many small seeds. The entire plant contains a poisonous alkaloid, nicotine.

While tobacco plants are sometimes grown as ornamentals, the principal use is made of the large leaves, which are smoked or chewed. Different demands have led to the development of several types of tobacco. One of these is the type used for cigar wrappers in which the leaves are large, thin and have a fine texture with a relatively small amount of vascular tissue. This type of leaf is often obtained by growing the plants in the shade of sheets of cloth. Another type of tobacco has the leaves thicker and with many veins giving a rather coarse structure. The leaves of these coarser sorts are used in making pipe tobacco, chewing tobacco, cigar filler, cigarettes, etc. In all tobaccos considerable differences are produced by cultivation and the nature of the soil on which the plants are grown.

In preparing tobacco for use, the leaves are removed from the plant and dried, either by natural air currents in open ventilated sheds, a process requiring 6–8 weeks, or by artificial heat, which is naturally much quicker. The leaves are then packed tightly in wooden containers and left for several months. During this time fermentation occurs, and important changes take place which lead to the formation of the pleasing aromas of prepared tobaccos. During fermentation the leaves may be repacked several times. The cured leaves are either rolled into cigars or blended, ground up, and used in

smoking tobaccos and cigarettes. Mixed with various substances and pressed into cakes it becomes chewing tobacco. Ground fine it becomes snuff.

Tobacco is now extensively grown, not only in tropical regions but also in temperate climates. Its users are very numerous, including a large proportion of the human race. The United States alone grows considerably over a billion lbs. each year. (R.M.W., B.S.M.)

POTENTIAL. This term is used to denote a number of different quantities used in physics, all characterized by their connection with potential energy (hence the name). The most familiar is **electric potential.** One of the simplest is gravitational potential or mass potential. The mass potential at any point is measured by the energy necessary to carry a unit mass from that point to a region of space infinitely removed from all matter. Its value is the integral of $G\frac{dm}{r}$, in which G is the **gravitation constant,** dm is any mass element, and r is its distance from the point in question; the integration being extended throughout all existing matter. So far as we know, it always has the same sign; that is, gravitation is always an attraction, and the energy must therefore always be added to the unit mass in the process described; whereas electric potential may be either positive or negative. The magnetic potential at any point is measured by the energy necessary to carry a unit north pole from infinity to that point; or mathematically, it is the line integral of the magnetic intensity between that point and infinity. The "Newtonian potential function" is a mathematical expression occurring as a factor in all these potentials. (See **Laplace's Equation.**)

A characteristic of the mass potential, the electric potential, and the magnetic potential, is that in each case the first derivative of the potential with respect to any direction, as x, at any point in space, is equal in magnitude to the component of the field intensity in that direction at the point in question.

The foregoing potentials all involve inverse-square forces; if the field obeys the inverse-first-power law, the potential involves the logarithm of the distance, and is called the "logarithmic potential."

By analogy, we have also a so-called "thermodynamic potential," which, in reference to a substance in any state, represents the energy which has been required to bring unit mass of the substance to the state in question from some arbitrarily defined, initial state. (L.D.W.)

POTENTIAL DROP, LAW OF. Electric Circuits; Electric Currents.

POTENTIAL ENERGY. Whenever **energy** takes a form not directly associated with motion, it is called potential energy. Energy is apparently able to go into a state of "hibernation" and to remain dormant, sometimes for long periods. We are taught, for example, that there are somehow locked up in coal or petroleum deposits vast stores of energy traceable to the solar radiation of past geological ages. The evidence of such energy is the work which can be derived from burning the fuel in a suitable engine; or more directly, the **heat** produced by its combustion, which we recognize as a form of **kinetic energy.** But a closer analysis shows that, since combustion is a union of carbon and other elements of the fuel with oxygen, and since the process effected by the sun's rays in the growth of carboniferous plants was largely the separation of oxygen from those elements in carbon dioxide and other compounds, there is really no more reason for localizing the energy in the fuel deposit than in the oxygen of the air. A weight lifted from the earth is able to do work in descending, and we say that it has potential energy. But lifting a weight is merely the work of separating two mutually attracting masses, one of which is the earth; so that the energy may as well be said to belong to the earth as to the lifted weight. These illustrations suffice to show that the "location" of potential energy is quite ambiguous.

A notable characteristic of potential energy is its tendency to transform itself into kinetic energy at every opportunity, and to continue the process until a state of stable equilibrium is reached. This is the well-known **least energy principle.** In many physical processes, such as the swinging of a pendulum or the oscillation of electricity in a conductor, the transformation takes place back and forth from potential to kinetic and vice versa; but in each cycle the total potential energy becomes a little less and the total kinetic energy a little greater (including the heat generated in friction). Ultimately all the energy except a certain minimum corresponding to stable equilibrium takes the form of radiation and is lost. It has thus suffered "degradation" and final "dissipation." (L.D.W.)

POTENTIAL FLOW. The steady flow of an incompressible fluid through a certain region may be created by pressures upon the boundary surfaces of a previously stationary fluid. Study of streamline flows in the x, y plane (two-dimensional flow) is greatly facilitated by the "potential function" describing the flow. Calling the potential function φ,

$$\varphi = f(x, y).$$

Then the component of fluid velocity in the x direction is $u = \frac{\partial\varphi}{\partial x}$ and in the y direction, $v = \frac{\partial\varphi}{\partial y}$ For the function to be analyzed (i.e., to meet the requirement of incompressibility and continuity),

$$\frac{\partial^2\varphi}{\partial x^2} + \frac{\partial^2\varphi}{\partial^2 y^2} = 0.$$

The streamlines have paths described by the stream function ψ, which is also $f(x, y)$. The component velocities in terms of the stream function are:

$$u = \frac{\partial\psi}{\partial y}; \quad v = -\frac{\partial\psi}{\partial x}.$$

The relation between φ and ψ is:

$$d\psi = \frac{\partial\varphi}{\partial y}\,dx + \frac{\partial\varphi}{\partial x}\,dy.$$

The advantage of analysis by potentials is that an analysis of complex flows may be made by adding the potential functions of simple flows which, when superimposed, form the complex flow. Thus the flow around a static cylinder in a rectilinear air stream may be reproduced by superimposing a doublet on a rectilinear stream. while the flow around a rotating cylinder is found by the further addition of a circulation. The potentials are additive, thus:

For the rectilinear stream	$\varphi = Vx = Vr\cos\theta$
For the doublet	$\varphi = \frac{R^2Vx}{x^2+y^2} = \frac{R^2V\cos\theta}{r}$
For the circulation	$\varphi = \frac{\Gamma\tan^{-1}\frac{y}{x}}{2\pi} = \frac{\Gamma\theta}{2\pi}$
For the complex flow	$\varphi = V\cos\theta\left(r - \frac{R^2}{r}\right) + \frac{\Gamma\theta}{2\pi}$

R = radius of cylinder, V = rectilinear velocity, Γ = **circulation** strength, θ and r are polar coordinates. At any point, r, θ in this flow the normal velocity is $\frac{\partial\varphi}{\partial r}$ and the tangential flow is $\frac{\partial\varphi}{r\partial\theta}$. (F.T.M.)

POTENTIAL HEAD. **Fluid Flow.**

POTENTIAL TEMPERATURE. An air parcel at any given altitude and pressure has a certain temperature which can be determined with proper instruments. If this parcel is lowered or raised dry-adiabatically from its existing pressure to a pressure of 1000 millibars, which is a standard reference pressure, it will assume upon arrival at that level temperature which is designated as its potential temperature. Potential temperature is used to compare the temperature of air parcels at different levels by referring them all to one level. Temperature and pressure of a parcel at its existing level and its potential temperature are related as indicated by the equation,

$$\theta = T\left(\frac{1000}{p}\right)^{.288}.$$

where θ = Potential temperature.
T = Actual temperature.
p = Actual pressure. (P.E.K.)

POTENTIAL TRANSFORMER. **Transformer.**

POTENTIOMETER. An instrument used for the measurement or comparison of small potential differences or electromotive forces, based upon the "law of potential drop" (see **Electric Circuits**). One of the simplest potentiometer circuits is shown in the accompanying diagram. Current from a battery B is sent

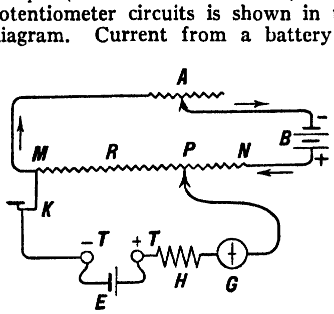


Diagram of potentiometer circuit.

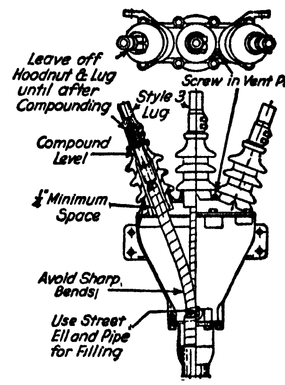
through a resistance MN and is adjustable by means of a rheostat A. From one extremity M of this resistance is taken off a branch circuit containing the potentiometer terminals $+T$, $-T$, between which E, one of the electromotive forces to be compared, is connected. This circuit rejoins the main circuit at a point P which is adjustable so that the partial resistance MP or R can be varied, while MN as a whole remains constant. The $+$ and $-$ leads from E must be connected as shown, and the electromotive force of B must exceed E. The position of P is now adjusted until the galvanometer G shows no current, indicating that the potential drop from P to M just balances the electromotive force E. If two different electromotive forces E_1, E_2, are thus connected and balanced in succession, and if the corresponding values of the resistance MP are R_1, R_2, then since the current through MN is unaltered, the law of potential drop gives

$$\frac{E_1}{E_2} = \frac{R_1}{R_2}.$$

In particular, one of the electromotive forces may be a **standard** cell of accurately known voltage; the other is thereby determined. In such case the standard cell should be safeguarded by a high resistance H, which is gradually reduced as the zero-current adjustment is approached; and the key K should be closed only for an instant. In some potentiometers the whole equipment, including galvanometer and standard cell, is contained in one compact case. (L.D.W.)

POTHEAD. In electrical distribution networks it is often convenient to run the conductors in a subterranean multi-conductor cable. Where such a cable is brought to the surface and either connected to some equipment or brought up a pole for connection to an overhead



Three-conductor cable pothead.

line, some means for terminating the cable insulation and connecting the conductors to the overhead wires must be provided. This is relatively simple in low-voltage cables, but most cables operate at a voltage which requires a special terminal. This equipment, known as the pothead, is usually unnecessary below 2300 volts. At the cable terminal the separate conductors are fanned out in the pothead, which not only affords the necessary insulation between conductors where they leave the cable, but also seals the end of the cable against the entry of moisture. (F.T.M.)

POTOROO. Mammalia, Marsupialia. *Potorous.* Any of several species of small animals related to the kangaroos and known also as rat kangaroos. They are found in Australia and Tasmania. (A.W.L.)

POTTER WASP. Insecta, Hymenoptera. A small **wasp** whose nest is built of mud in the form of a globular pot with a narrow neck. The several species belong to the genus *Eumenes.* All are solitary. (A.W.L.)

POTTERY. **Ceramics.**

POTTO. Mammalia, Primates. A name for the African slow **lemurs,** animals which resemble the lorises of Asia in many ways. They are remarkable for the rudimentary index finger, which is a stub without a nail or joints, and for the very short tail. The two species are Bosman's potto and the awantibo, *Perodicticus calabarensis.* (A.W.L.)

POUCHED MOLE. Mammalia, Marsupialia. A rare pouched mammal of the Australian deserts, *Notoryctes typhlops,* highly specialized for burrowing. Like the true moles it has enormous claws and rudimentary eyes. (A.W.L.)

POUCHED MOUSE. **Dasyure.**

POULTRY. A term applied to the domestic breeds of birds, exclusive of cage birds and such ornamental species as the peacocks. The forms embraced by the term are the **chickens, turkeys, ducks, geese,** and **Guinea fowls.** Although pheasants are bred extensively in captivity they are classed as game birds rather than poultry, as are other species which are often raised for the stocking of preserves.

The economic value of poultry varies with the species and with the breed. Most eggs used as food are those of chickens but the flesh of all species is valued. Geese

produce the best feathers and down, with ducks a close second. (A.W.L.)

POUT. Pisces, Teleostei. A European fish (**Pisces**), *Gadus luscus,* related to the cod. Also called the bib. (A.W.L.)

POWDER METHOD OF CRYSTAL ANALYSIS. Crystal Structure.

POWDER METALLURGY. Powder metallurgy embraces the production of finely divided metal powders and their union through the use of pressure and heat into useful articles. The temperatures required are below the fusion point of the principal constituent, and bonding depends on interdiffusion of the metal particles in the solid state. It is necessary to provide intimate contact between particles, hence reducing atmospheres are provided in the sintering process to prevent formation of oxide films. Readily oxidized powders such as aluminum require special technique.

Powder metallurgy is taking its place alongside of melting and **casting** and the various processes involving **plastic deformation** of metals as a means of fabrication. While it is inherently costly to produce metal powders, compact them under high pressure in a specially constructed die, sinter in a controlled atmosphere furnace, and in some cases restrike in a finishing die, there are many compensating factors which make such processes economical and for many purposes indispensable.

Among these factors is the great saving in machining in the production of gears, for example, by powder metallurgy as compared with machining them from bar stock or forgings, or even from a rough casting. Die **casting** compares favorably with powder metallurgy in this respect, but in both cases the production must be great enough to justify the high cost of die making. An example of a powder metallurgy product whose success is due to ease of fabrication to high dimensional accuracy is the oil pump gear used in most automobiles. Two involute gears operating in a closed housing provide positive oil pressure. These gears are made from iron powder and require removal of less than 1% of the metal for finishing.

Probably the most important applications of powder metallurgy are those in which a product is made which cannot be duplicated by other methods. There are many examples of this kind. The melting point of tungsten, 6100° F., is much too high for ordinary melting and casting methods and the only way in which filaments for electric lights can be made is to draw them from rods of compacted and sintered tungsten powder. The **cemented carbide** cutting tools are another important product of refractory nature which is readily made by powder metallurgy.

Self-lubricating bronze bearings having controlled porosity are products which can be made only by powder metallurgy. The pores are impregnated with oil, and flow to the bearing surface is maintained by capillary action. Graphite is incorporated with the metal powder in one type of oilless bearing. A material made from powdered copper and graphite is used for electric-current collector brushes, and tungsten-copper or tungsten-silver combinations are used for electric contact points. In contrast to these high-conductivity materials, a high-resistance element is produced from a mixture of copper and porcelain powders, combining a metal with a non-metallic substance. (R.H.H.)

POWER. The time rate of the performance of work or of the transfer of **energy**. It may be expressed in units of work per unit time (e.g., foot-pounds per minute or **ergs** per second), or more arbitrarily, as in **horse power** or in **watts**. For most modern purposes, especially where electrically distributed energy is concerned, power is commonly expressed in watts or kilowatts. Since the product of the power by the time during which it is operative is the work done, the product of a power unit by a time unit, such as the watt-hour or the horse-power-year, is a unit of work or energy. Electrically delivered energy is thus commonly measured in kilowatt-hours, each of which is equal to 3.6×10^{13} ergs or 3.6×10^{6} joules. The average power of large hydro-electric installations subject to wide seasonal variations is often rated in kilowatt-hours per year. For electric circuits having appreciable reactance (see **Alternating Currents**), the power in watts is equal to the product of the voltage, the current in amperes, and a **power factor** dependent upon the reactance.

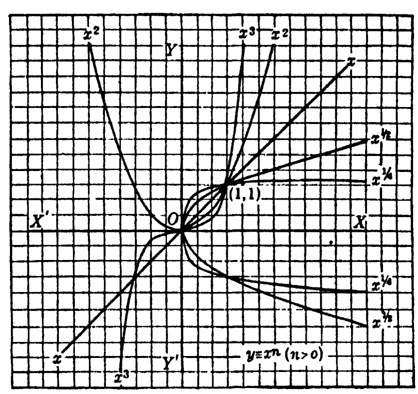
The measurement of mechanically delivered power is usually effected by some form of power **dynamometer** or "ergometer." This commonly takes the form of a friction brake and a speed indicator, as in the **Prony brake.** Since the power may be considered as the product of the force (of friction) by the linear speed, or the product of the torque by the angular speed, it is necessary only to measure these quantities and to deduce the power therefrom. (L.D.W.)

POWER, AIRPLANE ENGINE. Airplane Engine Performance Characteristics.

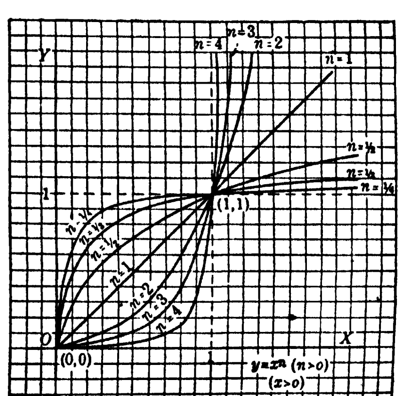
POWER FACTOR. Alternating-Current Circuits.

POWER FUNCTION. A power function is an algebraic **function** of the form ax^n, where a and n are **constants** (independent of x) and x is the **variable.** It has a variable base x and a constant **exponent** n. The exponent may be a positive integer, or it may be a fraction or negative number, or even irrational.

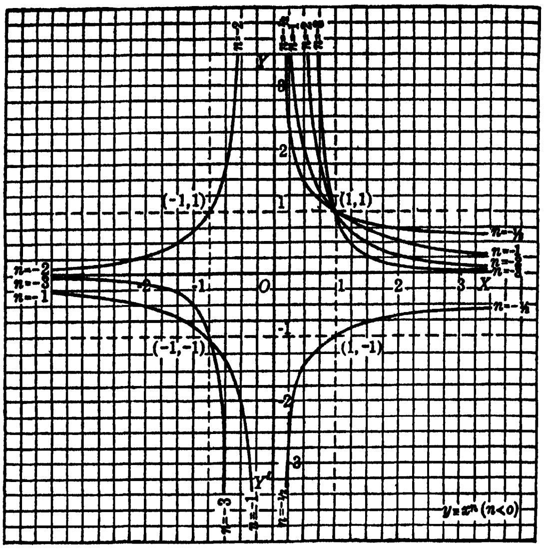
The graphs of the power function are shown in the accompanying figures. (L.L.S.)



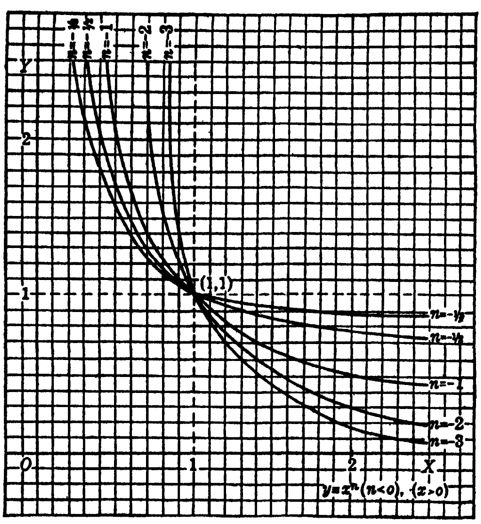
Power function.



Power function.



Power function.



Power function.

POWER OF A TEST. The power of a test is the **probability** in using this test of rejecting the hypothesis being tested when some alternative hypothesis is true in the **Neyman-Pearson theory of testing** a statistical hypothesis. Naturally statistical tests with high power are preferred. (L.A.A.)

POWER PLANT. A power plant is a machine or an assembly of machines and equipment, the purpose of which is to convert energy from a dormant or useless state to a useful one. This usually takes the form of the conversion of the latent chemical energy of a fuel into mechanical or electrical energy, a conversion that is accomplished with difficulty, and then only at the expense of the loss of a major portion of the energy while it is in the form of heat.

Power is the rate at which mechanical or electrical energy is produced. We may regard a power plant as a factory for the production of a given commodity, energy, from fuel as a raw material, the rate of manufacturing being the power capacity of the plant as measured in hp. or kilowatts.

The possible sources of energy are as follows:

1. Fuels.
2. Streams of water.
3. Ocean tides and waves.
4. Winds.
5. Solar rays.
6. Terrestrial heat.

The **fuels** are most abundant and easily utilized. **Coal** continues the principal fuel for power generation. Coal, oil, gas, and wood all contain **hydrogen** and **carbon** which in rapid chemical union with oxygen from the air liberate heat energy. All fuels have been fired under boilers and gas and oil, in addition, are sources of power in internal combustion engines. The greater portion of the power generated in the United States is produced from fuels.

The hydraulic plant has as its source of energy the kinetic energy of a stream or the potential energy of impounded water. Hydraulic plants are increasing in size and numbers, but it is obvious that a point will be reached beyond which the energy of a stream will not be exploitable in competition with the steam plant.

Power from the winds has served man for many centuries, but the total amount of energy generated in this manner is small. While the expense of installation and the uncertainty of operation have prevented serious consideration of the windmill for other than such intermittent services as pumping, there has been considerable experimentation relative to the generation of electrical energy by moderate-sized wheels for charging storage batteries.

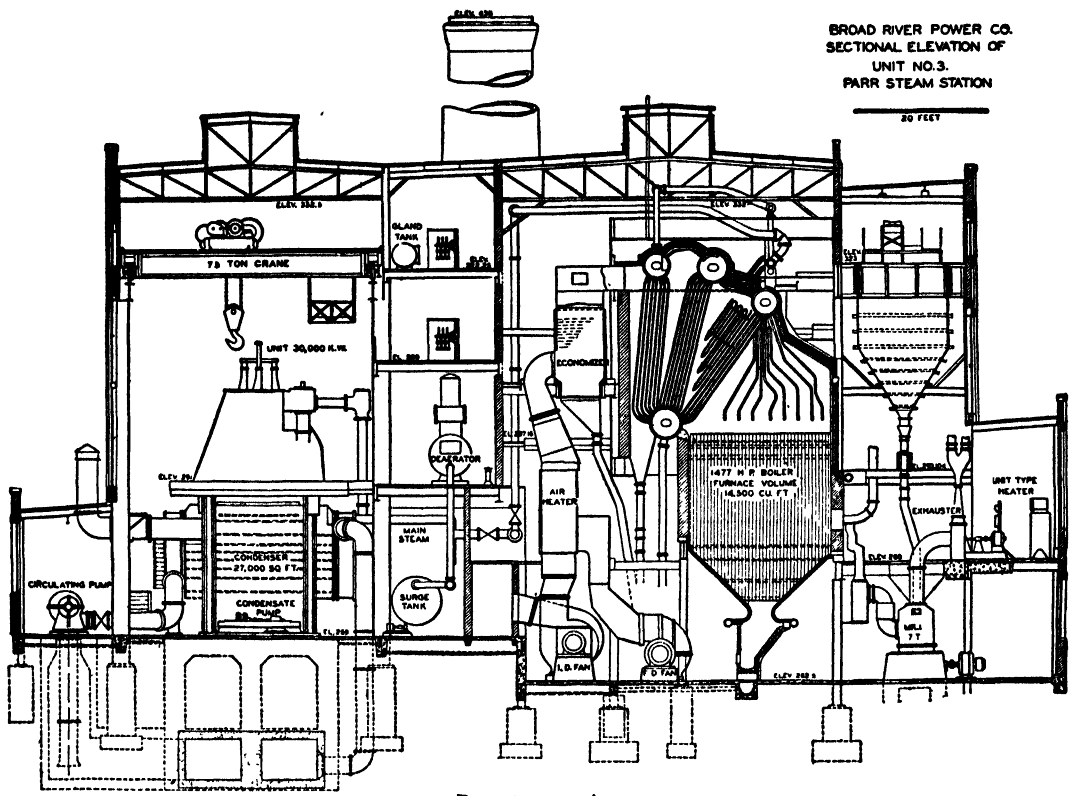
With the exception of terrestrial heat, all of the sources of energy may be traced indirectly to the sun. Evaporation of surface water to form rain clouds which continually replenish the flow of water in streams is accomplished by the heat of the sun; gravitational effects account for tides; warming and cooling of different portions of the earth's atmosphere cause winds and thereby waves; and solar rays, nourishing tropical vegetation through the prehistoric ages, may be held responsible for the deposits of coal, oil, and gas which were formed from that vegetation.

In a few instances the direct rays of the sun have been used to generate energy. The obvious fault of this source is that it is effective during the daylight hours only, and, for continuous service, some reservoir of energy such as a storage battery or a heat-accumulator tank is necessary to carry through the night operation. Also, cloudy weather seriously handicaps the operation of such a plant. In the solar plants that have been constructed, the heat in the rays is absorbed by water in a boiler. The rays are converged upon the boiler by parabolic mirrors set to follow the sun throughout the day; or the same thing may be accomplished by direct absorption on a large flat-surface boiler.

The suggestion of tremendous unleashed power in the daily silent glide of the tides and the evidences of gigantic terrestrial reservoirs of heat to be seen in geysers and volcanoes have, for years, prompted many dreams of harnessing these sources.

Natural steam escapes from surface vents in many portions of the earth. It remained for an Italian, Prince Conti, to develop the use of natural steam. This he did in a successful way at Larderello in Tuscany, Italy, bringing the steam under control by drilling wells.

The heat power plants may be classified as internal or external combustion types. The internal combustion power plant is a self-contained unit using the products of combustion as the working medium. Since it is compact, having all parts included in one machine or engine, and, since its efficiency is, on the average, higher than that of the external combustion cycle, it has been used for automotive service, and where compactness and mobility were desired.



Parr steam station.

Types of fuels which have been required by **internal combustion engines** have been more expensive than those which may be successfully employed in the external combustion cycle, and so there is large power-generating capacity installed in external combustion power plants such as the modern steam plant. A cross-section of a typical steam plant shows the complexity of the modern high-capacity, external combustion cycle. The plant shown in the accompanying figure illustrates the point. The building housing this plant is set off roughly into four regions. Beginning at the left, there is the turbine room; next, a narrow multi-storied section containing electrical galleries and certain of the steam and water auxiliaries; next, the main boiler room with its boilers having fans and other auxiliaries; and lastly, the fuel preparation room, in which fuel is in storage, and from which the fuel is taken to be prepared for burning. (F.T.M.)

POWER PUMP. A power pump is a reciprocating, **piston and cylinder** type water **pump** not driven by steam, but by motor, line shaft, belt, or some other mechanical means. The direct-acting steam pump and the steam-driven, flywheel-type pump are thus set off from the power pump. The ordinary form of power pump is known as a triplex pump. It is three-cylindered, single-acting, having three **pistons** driven from a single **crankshaft.** The triplex feature provides fairly uniform discharge, as well as a much steadier load on the motor than would be possible from a single-cylindered pump. The triplex pump has three cylinders in line, and cranks at 120 degrees. The best crankshaft speed is much lower than the usual speeds of motors and gasoline engines, so that it is best to gear drive the pump from the source of power. The efficiency of such pumps is rather high, and there is no limit to the pressures which may be carried. (F.T.M.)

POWER SERIES. An **infinite series** of the form

$$\sum_{n=0}^{\infty} a_n x^n = a_0 + a_1 x + a_2 x^2 + \cdots + a_n x^n + \cdots,$$

where $a_0, a_1, \cdots, a_n, \cdots$ are **constants** and x is a **variable,** is called a power series.

For every power series $\Sigma a_n x^n$ there exists a constant l such that the series is **absolutely convergent** for all values of x such that $|x| < l$, and is **divergent** for all values of x such that $|x| > l$. This number l is called the limit of convergence of the power series, and the interval $(-l, l)$ is called the interval of convergence. The series may converge or diverge at the ends of this interval, for $x = l$ and $x = -l$.

If $\lim\limits_{n \to \infty} \left|\dfrac{a_n}{a_{n+1}}\right|$ exists, it is the limit of convergence.

If $\lim\limits_{n \to \infty} \sqrt[n]{|a_n|}$ exists, it is the **reciprocal** of the limit of convergence.

A power series is **uniformly convergent** within the interval $(-l', l')$, where $l' < l$ and l is the limit of convergence of the given power series.

The function defined as the sum of a power series $\Sigma a_n x^n$ is a **continuous function** of x at all points within the interval of convergence.

For the operations with power series, we have the following theorems:

Two power series may be added together for all values of x for which both series are convergent, i.e., for the smaller of the two intervals of convergence.

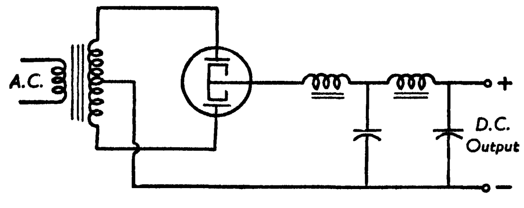
Two power series may be multiplied together for all values of x for which both series are absolutely convergent, i.e., for the smaller of the two intervals of convergence.

A power series may be **differentiated** term by term for all values of x within its interval of convergence.

A power series may be integrated term by term between any limits lying within the interval of convergence.

Power series are very useful in the analytical representation of functions by the **expansion of functions in series**, and for calculation by series. (L.L.S.)

POWER SUPPLY. This term is commonly used to denote a circuit for converting a.c. into d.c. by electronic means. The usual power supply consists of a **transformer** for changing the a-c voltage to a value which will, when rectified and filtered, give the desired value of d.c., rectifier tube or tubes, and a **filter** consisting of inductance in series and capacitance in shunt with the d-c line. A typical circuit is shown. The output of the



rectifier is pulsating d.c. and hence needs to be smoothed out by the filter before it is suitable for many applications. Power supplies of this type are almost universal components of radios, **amplifiers** and other vacuum-tube devices which operate from a-c mains. (L.R.Q.)

POWER SYSTEM. If power could be generated for the same cost at any point in the country there would be no serious questions arising from power distribution and the conditions that early prevailed would exist—each power user would operate his own plant. But, unless use may be made of the exhaust steam, the small privately owned plant is hardly able to compete with the central system on an economic basis because of the inherently higher efficiency of large generating units and the lower overhead cost of quantity production. So, while large numbers of small isolated plants are in operation at present, the major portion of installed power capacity is to be found in central stations. The bulk of this capacity is in **steam engines** and turbines, mostly **steam turbines.** Power generated by industries may or may not be converted into the electrical form before use, but that generated by central stations is invariably electrical to permit transmission to distant points. The central station is but one link of a chain joining the source of energy and its ultimate user.

The distribution system may be separated into two parts, the primary and secondary systems. The primary distribution system generally consists of a transmission line carrying three-phase current from the switchyard of the plant to a substation located near the load served. The purpose of the substation is to transform the high voltage necessary for economical long-distance transmission to voltages suitable for lines in residential districts and for the primaries of the light pole-top transformers. The secondary distribution system extends from the substation to the customer's meter through the medium of weatherproof pole-top transformers, strategically located with respect to a small group of customers which each one supplies.

Power supply systems are owned and controlled both by municipalities and by public utility companies. Power and light plants, at one time mostly municipally owned, have come more and more into the hands of public utility companies. A utility company may own one or more generating stations and a network of transmission lines serving its territory. The company must be so organized as to weld generating, distributing, and public relations departments into a smooth-working unit. The small company operating one station and servicing one community easily accomplishes this, but the large company requires a complex organization. (F.T.M.)

POWERS AND EXPONENTS. A power a^m with a positive integral exponent m is the repeated product of m factors each equal to a:

$$a^m = a \cdot a \cdot a \cdots a \text{ (m factors).}$$

The number a is called the base, m is called the exponent, and a^m is called the power.

A power a^0 with a zero exponent is defined to be always equal to 1 (if $a \neq 0$).

A power $a^{m/n}$ with a positive fractional exponent m/n, where m and n are positive integers, is defined as the **principal n^{th} root** of the m^{th} power of a: $a^{m/n} = \sqrt[n]{a^m}$.

A power a^{-r} with a negative exponent $-r$ is defined as the reciprocal of the corresponding power with the positive exponent r: $a^{-r} = 1/a^r$.

The fundamental laws of exponents are expressed by the formulae:

$$a^m \cdot a^n = a^{m+n},$$

$$a^m \div a^n = a^{m-n},$$

$$(a^m)^n = a^{mn},$$

$$(ab)^n = a^n b^n,$$

$$\left(\frac{a}{b}\right)^n = \frac{a^n}{b^n}.$$

These laws hold for all types of exponents when $a > 0$, $b > 0$, and some of them sometimes for $a < 0$, $b < 0$. Care must be exercised in their use when $a < 0$, $b < 0$, if fractional exponents occur.

Many collections of mathematical tables contain a table of powers of numbers, usually of squares and cubes and reciprocals. (L.L.S.)

POYNTING'S THEOREM. **Electromagnetic Radiation.**

POZZUOLANE. A leucite tuff occurring near Naples and famous for its use in making **cement.** (R.M.F.)

PRAIRIE CHICKEN. Aves, Galliformes. *Tympanuchus.* A **grouse** of the prairie regions of North America. This species was once very abundant over a large area but it is now much more restricted in its range and in numbers. The destruction has been due partly to hunting, partly to the spread of agriculture, and partly to wholesale trapping for the market. In the Dakotas countless birds were taken for sale during the past century. The eastern heath hen, which has recently become extinct, was a variety of the same species, (A.W.L.)

PRAIRIE DOG. Mammalia, Rodentia. *Cynomys.* Burrowing animals of several species, found chiefly west of the Mississippi but introduced into a few eastern localities. They are small stout-bodied animals with shallow cheek pouches. All are plant feeders and in settled regions they sometimes damage crops severely. Also called the prairie marmot. (A.W.L.)

PRANDTL GROUP. **Heat Transfer.**

PRASE. **Chalcedony.**

PRASEODYMIUM. Symbol: Pr. Atomic number: 59. Atomic weight: 140.92. Density: 6.48. Melting point: 940° C. No isotope, but of single atomic form: 141. Type of compound: Pr_2O_3, greenish-yellow. Color of salts: Green. Discovered by Welsbach in 1885. A member of the **cerium** sub-group of the rare earth metals. (R.K.S.)

PRATINCOLE. Aves, Charadriiformes. *Glareola.* Birds (**Aves**) of several species found on all continents

of the Old World. Their long wings and forked tail give them the appearance of swallows when in flight, but their moderately long legs are a point of resemblance with the plovers. They live chiefly near water but are insectivorous in habits. (A.W.L.)

PRAWN. Crustacea, Decapoda. Small marine **crustaceans** closely related to the shrimps. They differ from the lobsters and crabs in the compressed body and in the use of the abdominal appendages for swimming. Prawns are edible. (A.W.L.)

PRAYING MANTIS. **Mantis.**

PREAMPLIFIER. This is a class A voltage **amplifier** which receives the signal from a **microphone, pick-up** or other low-level device and amplifies it so it can supply the control and additional amplifier circuits. Thus a preamplifier is commonly used in a radio studio to amplify the microphone output before feeding it into a mixer, line to the transmitter, or other amplifying equipment at the studio. (L.R.Q.)

PREANTENNA. A sensory organ of the pair borne by the first segment of the body in the **Onychophora.** Most arthropods have the first body segment developed in the embryo but lacking in the adult, hence their antennae are appendages of a more caudal segment. The similar organs of Onychophora are named preantennae to distinguish them from the true antennae of the other classes. (A.W.L.)

PRECESSION. An effect manifested by a rotating body when a torque is applied to it in such a way as to tend to change the direction of its axis of rotation. If the speed of rotation and the magnitude of the applied torque are constant, the axis, in general, slowly describes a cone, its motion at any instant being at right angles to the direction of the torque.

A familiar example of precession is an ordinary top. If the axis of spin is not exactly vertical, the force of gravity exerts a torque tending to overturn the top; but instead of tipping over, it "wobbles" with a precessional motion about the vertical through the pivot-point. The **gyroscope** exhibits similar behavior. A hoop or a coin can roll on edge across the floor because, whenever it tends to tip either way, precession swerves its plane and changes its path, so that it automatically steers itself as a bicycle is steered by the rider.

Precession is due to the fact that the resultant of the angular velocity of rotation and the angular velocity produced by the torque is an angular velocity about a line which makes an angle with the permanent rotation axis; and this angle lies in a plane at right angles to the plane of the couple producing the torque. The permanent axis must turn toward this line, since the body cannot continue to rotate about any line which is not a principal axis of maximum moment of inertia; that is, the permanent axis turns in a direction at right angles to that in which the torque might be expected to turn it. If the rotating body is symmetrical and its motion unconstrained, and if the torque on the spin axis is at right angles to that axis, the axis of precession will be perpendicular to both spin axis and torque axis. Under these circumstances the period of precession is given by $T_p = \frac{4\pi^2 I_s}{Q T_s}$; in which I_s is the **moment of inertia** and T_s the period of spin about the spin axis, and Q is the torque. In general the problem is more complicated.

Precession, as it is manifested in astronomy, is a slow, rotary motion of the axis of a rotating body in space. The term is, perhaps, most frequently used in connection with the earth, but all rotating bodies may exhibit the effect. The earth is an oblate **spheroid** with the minor axis the axis of rotation. Hence if we subtract from the earth a sphere with radius equal to the minor axis we shall have left a shell of continually increasing thickness as we pass from the pole to the equator. Such a rotating shell, with the greatest amount of mass in the plane perpendicular to the axis of rotation, is a characteristic **gyroscope.**

The axis of rotation of the earth is inclined at an angle of 66.5° to the plane of the ecliptic. The forces of **gravitational** attraction of the sun and the moon tend to pull the equatorial shell into the plane of the ecliptic and hence a torque is applied tending to change the direction of the axis of rotation. This causes the axis to describe a cone in space (i.e., produces precession).

As the axis of rotation describes a cone, the poles of rotation describe circles in space. The radii of these circles, expressed in angular measure on the **celestial sphere,** are 23.5°. The effect of this motion of the poles is to cause the **vernal equinox** (one point of intersection of the ecliptic with the **equator**) to move along the ecliptic. The motion is slow, about 26,000 years being required for the vernal equinox to make a complete circuit of the ecliptic. The motion is not perfectly regular because of the fact that both the sun and the moon are in different planes and are moving relative to each other, causing a variation in the torque applied to the earth. The variations in the torque produce a slight irregularity in the motion of the poles known as **nutation.**

The motion of the equator among the stars causes slow, and slightly irregular, changes in the **equatorial coordinates** of the **stars.** Since celestial **longitude** is measured from the vernal equinox, the motion of this point produces a change in this coordinate of the stars. The motion of the vernal equinox also changes its location among the **constellations** along the zodiac, the "sign of Aries" (i.e., the vernal equinox) now being located in the constellation of **Pisces** instead of in **Aries.** At present the north pole of rotation of the celestial sphere is close to the star **Polaris** (**α Ursae Minoris**), but 12,000 years hence the star **Vega** (**α Lyrae**) will be close to the pole of rotation and hence be known as the pole star.

Precession enters also in a very important way into the dynamics of **atoms** and **molecules.** (L.D.W., W.K.G.)

PRE-CHELLEAN. **Paleontology of Man.**

PRECIPITATION. This process involves the separation of a solid from **solution** (1) by evaporation and cooling of certain solutions to **crystallization,** (2) by addition of or to a reagent which forms new insoluble product or products, e.g., **sulfuric acid** to **barium** chloride solution, forming barium sulfate precipitate, (3) by addition or removal of a substance to decrease the solubility of another substance in the medium, e.g., salting out of soap by salt, or removal of **carbon dioxide** from **calcium** hydrogen carbonate solution resulting in the precipitation of calcium carbonate, (4) by heating, e.g., coagulation of certain **proteins.**

The precipitate which is formed in a given case frequently separates in a characteristic form, e.g., **barium** sulfate as fine crystals, difficultly separable from the medium; **lead** chloride as medium crystals, easily separable; **ferric** hydroxide as gelatinous mass or slime, difficultly separable; **silicic** acid as gelatinous mass or as a gel; **silver** chloride as curdy mass. The concentrations used and the temperature frequently affect the form of the precipitate. Very fine crystals are increased in size by digestion, that is, by allowing to stand for some time to take advantage of the fact that small crystals are more soluble than large ones. (See **Hydrometeors.**) (R.K.S.)

PRECIPITATION HARDENING. A very considerable number of alloys are hardenable by a heat-treating procedure based on controlled precipitation throughout the grain structure of minute particles of a metal, **solid solution,** or **intermetallic compound** different from the

base metal. It is necessary that the secondary or hardening constituent be soluble in the base metal at an elevated temperature and less soluble or even insoluble at atmospheric temperature. Thus the alloy **duralumin**, for example, is heated to 930° F., which is well under its melting temperature range, until the hardening constituents are in a state of solid solution in the aluminum matrix, whereupon it is quenched in water to prevent reprecipitation and growth of the hardening constituents as their solubility decreases at the lower temperatures. This results in a supersaturated solid solution which does not remain stable at room temperature but tends, over a period of time, to revert to its normal duplex structure. However, because of the low temperature at which the hardening constituents separate from the matrix they remain submicroscopic in size, and being present in very great numbers along the crystallographic **slip** planes of the matrix they effectively interfere with movement along these planes, thus reducing the **plasticity** and increasing the **hardness** and strength of the alloy. The heating and quenching operations are known as the "solution heat treatment," while the spontaneous hardening at room temperature is called age-hardening or precipitation hardening. The latter term is reserved by some for similar treatments carried out on other alloys at slightly elevated temperatures.

In addition to the important aluminum alloys, many magnesium-, copper-, and nickel-base alloys are hardenable by the solution and precipitation heat treatments. Certain copper-bearing steels are also hardenable by this method. (R.H.H.)

PRECISION GAUGE BLOCK. **Measurement.**

PREFORM. **Plastic Molding.**

PREGNANCY. (Cyesis, gestation.) The condition of being with child. The duration of pregnancy in humans is usually about 280 days, 9 calendar or 10 lunar months, dating from the time of the last menstrual period. Presumptive signs of pregnancy are absence of the menstrual periods, nausea or vomiting in the morning (**morning sickness**), enlargement of the breasts with pigmentation of the nipples, and enlargement of the abdomen during the last half of pregnancy. Absolute signs of pregnancy are palpitation of the fetal body, movement of the child, and sound of the fetal heart. As early as the 8th day of pregnancy the **Aschheim-Zondek** test is positive.

An extra-uterine or ectopic pregnancy is one in which the fertilized ovum lodges and develops outside the uterine cavity. This usually takes place somewhere along the **fallopian tubes** and, more rarely, free in the abdominal cavity. Such ectopic gestations almost always terminate spontaneously early in the course of the pregnancy, and produce the clinical picture of ruptured ectopic pregnancy. Abdominal pain and shock due to massive hemorrhage into the abdominal cavity make this condition a serious emergency which demands immediate surgical treatment.

A phantom pregnancy, or pseudocyesis, is an hysterical manifestation in which the abdomen enlarges and resembles the enlargement associated with a true pregnancy. It is treated by treating the underlying **psychoneurosis** with psychotherapy. (R.S.M., D.M.H.)

PREHENSION. The flexion of an appendage to grasp an object by folding around it. There are two types of grasping organs among animals: forcipate and prehensile. The human hand illustrates both. Objects may be taken between the thumb and fingers as between the jaws of a forceps, or they may be grasped between the fingers and the palm by the prehensile folding of the digits. Less versatile organs are capable of one or the other type of action, as in the case of the forcipate chela of the lobster and the prehensile tails of some monkeys. (A.W.L.)

PREHISTORIC ART. **Paleontology of Man.**

PREHNITE. The mineral prehnite is an acid **orthosilicate of calcium** and **aluminum**, $H_2Ca_2Al_2(SiO_4)_3$. It crystallizes in the **orthorhombic** system, usually in masses. It has an uneven fracture; is brittle; hardness, 6–6.5; specific gravity, 2.80–2.90; luster, vitreous to pearly; color, various shades of light green to gray or white; translucent. Though not a **zeolite** it is found associated with them and with **datolite, calcite, etc.,** in veins and cavities of basic rocks, sometimes in **granites, syenites,** or **gnisses.** It is found in Austria, Italy, the Harz Mountains, France, Scotland, and South Africa, where it was originally discovered. In the United States well-known localities are Somerville, Massachusetts; Farmington, Connecticut; Paterson, New Jersey; and Keweenaw County, Michigan. Named for Colonel Prehn, its discoverer, who was an early Dutch Governor of the Cape of Good Hope colony in South Africa. (E.S.C.S.)

PREISCHIOPODITE. A segment of the **biramous appendage** of **crustaceans.** In some species the outer segment (basipodite) of the two that make up the base of the appendage is divided into two parts. The proximal part is then called the probasipodite and the distal is the metabasipodite or preischiopodite. (A.W.L.)

PRELIMINARY SURVEY. **Surveying.**

PRELOADING. **Bearings.**

PREMAXILLARY. A small bone lying in front of the **maxillary** bone of the upper jaw in the skull of **vertebrates.** The two form the median portion of the jaw and bear the incisor teeth, if present. Also called intermaxillary. (A.W.L.)

PREMENTUM. The palpiger of the insect **labium.** (A.W.L.)

PREMOLAR. A tooth lying between the canines and molars of mammals. Premolars are broader teeth than the incisors and canines but are usually less broad than the molars. Among the grazing animals, however, a number of forms have the premolars formed like the molars. The human premolars are also called bicuspids. (A.W.L.)

PRENATAL INFLUENCE. **Telegony.**

PREPUCE. **Foreskin.**

PRESENTATION. That portion of the fetal body which appears or presents at the cervical opening of the **uterus** during labor. The most c mmon presenting part is the head, usually the occipital portion. This is the normal presentation and is best for an easy delivery. Various other portions of the head may also present, face, brow, etc.

Breech presentation is presentation of fetal buttocks, making labor more difficult. (R.S.M., D.M.H.)

PRESS WORKING. Cold-working metal processes may be divided into four general groups: cutting, bending, drawing, and squeezing. Cutting processes as applied to sheet metal are further subdivided into shearing and blanking processes; the term shearing as used here implies straight cuts on plates and sheets; blanking is the process of cutting parts of almost any shape from sheet metal with a punch and die in a power-actuated press.

Blanking dies are analogous to the punches and dies used for rivet holes and may be made to cut out parts

of almost any shape. They may be made either singly or in multiple so that one, two, three, or more parts may be blanked or cut at one stroke of the press. Piercing dies are small blanking dies that are usually employed for punching circular holes in sheet metal or in previously blanked parts. Progressive dies are those placed in sequence so that successive operations may be performed; combination dies often incorporate blanking and piercing, or blanking and drawing operations in a single die.

To insure accurate work and to eliminate the possibility of chipping the edges of the punches and dies, the two members must be very carefully aligned when they are placed in position on the press ram and bolster. This operation must be performed every time a different die is used, and requires the services of an expert die-setter. To eliminate the care that is necessary in die setting and the undesirable effects of too much freedom in the ram slide, many punches and dies are mounted in a sub-press or die set.

Bending dies are used for bending or folding sheet metal or wire parts into irregular shapes, and function by pressing the stock into cavities in the die by means of a punch of corresponding shape, or by the use of auxiliary attachments such as slides or levers. Drawing dies differ in their action from bending dies in that the deformation produced in the work is usually three-dimensional; a bending die, for example, might be used for one or more parallel folds in a sheet, whereas a drawing die might be used to produce a cup-shaped article from a flat sheet. Either bending or drawing dies may be combined with blanking dies, to serve as combination blanking and bending, or combination blanking and drawing dies. Redrawing dies are second or third operation drawing dies, used where the depth of "draw" is so great that fracture of the material may occur if the shape change is attempted in one operation. In drawing open-end cups from flat circular blanks, for example, one or more redrawing dies are used whenever the depth of draw exceeds one-half the diameter of the cup.

Reducing dies are used for necking the open ends of drawn cups in such applications as cartridge case manufacture. Curling dies, are used for curling or rolling a flange or bead around the open edge of a cup. The cup should be slightly flanged in its final draw to permit the curling punch to start easily. Wiring dies are used for curling and simultaneously enclosing a wire ring inside the flange. The wire is carried by a spring plate on the die which recedes to permit the metal to be rolled entirely around the wire. Bulging dies are special drawing dies that use either a soft rubber pad or a fluid such as oil. They are used for articles that are not straight-sided or tapered inwards. In the hydraulic die, the oil within the blank is compressed by a ram so that it forces the blank to conform to the interior of the die. The die is made in two parts, a stationary half and a movable half, so that it may be opened to permit the finished part to be removed.

Metal spinning is a specialized drawing operation employed for articles which have surfaces of revolution. Metal spinning is usually employed for small-quantity production where the number of parts required does not warrant the use of a drawing die; the process is also used for shapes which are difficult or impossible to produce in dies. Metal spinning lathes are similar to engine lathes. The spinning tool may be either manually or mechanically guided. A wooden (or metal) form is fastened to the faceplate of the spinning lathe, and the sheet disk is placed against it and held in position by a rotating tail center. The material is shaped by forcing the spinning tool against the work as it rotates. The shank of the tool pivots about a stop in the tool rest.

Squeezing operations are the most severe of all cold press processes. Since more or less metal flow in a cold state is involved, squeezing operations are generally performed on hydraulic presses, or on some of the slower motion mechanical presses such as the knuckle-joint press. Sizing is a squeezing operation that is used for flattening or for surfacing parts where a very small amount of metal flow is required. Very close tolerances can be maintained by the sizing process, together with a rate of production much greater than that obtained by milling or grinding. The process is restricted, however, to relatively ductile materials and cannot be used for cast iron and hardened steels. Coining is a squeezing process employed for cold-pressing coins, metals, and emblems and is a restricted-flow process, in contrast to sizing in which the metal can flow in a direction perpendicular to the pressure application. Very high pressures are used in coining, and great care is exercised in the design and operation of the dies since it is probably the most severe of all the squeezing processes. Extrusion press operations are analogous to coining operations in that considerable flow takes place, but a major portion of the die is generally designed so that the flow is unrestricted in a direction perpendicular to the pressure application.

Multiple-slide and multi-slide strip machines are used for complex bending and forming operations on wire and narrow strip stock, for a wide variety of parts such as rings, links, hooks, clips, etc. These machines are allied to the press-working group, and usually consist of four or more cam-actuated slides to which special forming and bending dies may be attached. These machines are also used for combination manufacturing and assembling purposes; a hinge machine, for example, blanks the hinges from strip stock, punches the screw holes, slits and forms the pin bearings, and inserts the hinge pin, producing a completed hinge automatically. (H.C.H.)

PRESSURE. A type of stress, characterized by its uniformity in all directions (as distinguished from compressive stress in one direction). Its measure, as with all other stresses, is the force exerted per unit area; for example, the normal **atmospheric pressure** is about 14.7 lbs. per sq. in. Pressure is usually associated with a decrease in volume; though the opposite stress, accompanying an increase in volume, is sometimes referred to as "negative pressure." This latter must be distinguished from the same term as sometimes used to denote pressures below atmospheric, the pressure of the atmosphere being in such cases taken as an arbitrary zero. It is likewise important, especially in pneumatics, to indicate whether pressure is reckoned from vacuum or from atmospheric pressure as zero. Thus when a tire is inflated to "thirty-five pounds," the actual pressure in the tire is about 50 lbs. per sq. in.

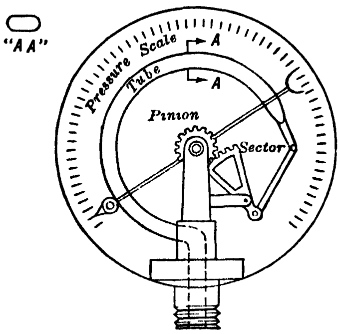
Many different units are used in expressing pressure. The absolute c.g.s. unit is the **barye** or **bar** (1 dyne per sq. cm.). The usual engineering unit is the pound per square inch. Very commonly, pressures are expressed in millimeters or inches of mercury or other liquid, meaning the hydrostatic pressure at the corresponding depth in that liquid. Another common unit in physics is the "atmosphere," standardized as 760 mm. of mercury at 0° C. and equal to about 1,013,246 bars. (See **Pressure Gauges.**) (L.D.W.)

PRESSURE ANGLE. Spur Gearing.

PRESSURE COEFFICIENT, AIRFOIL. This is a parameter often used to describe the variation of pressure over an airfoil or other aerodynamic object immersed in a fluid stream with relative velocity V. Let the free-stream static pressure be designated by p_0, the local airfoil surface pressure by p, and the dynamic pressure corresponding to V by q, then the pressure coefficient is $(p_0 - p)/q$.

Some airfoil pressure coefficients are shown in connection with **compressibility.** The area between the curves of upper and lower surface pressure coefficients when multiplied by q and chord length is the lift per ft. of span. (F.T.M.)

PRESSURE GAUGES. Pressure enters as a variable factor in a vast number of physical phenomena, and there is frequent need for its measurement over a very wide range. For ordinary pressures there are two chief types of gauge: viz., the familiar liquid manometer, of which the mercury barometer is an example, and those instruments dependent upon the deformation of a closed, thin-walled cell of elastic metal, such as the ordinary (Bourdon) steam gauge and the aneroid barometer. Such gauges are secondary instruments in that they must be calibrated in comparison with a primary gauge, such as a manometer. While the mechanical element of a gauge may be a Bourdon tube, a diaphragm, or a bellows, space permits description only of the simple widely used Bourdon type of gauge. As shown in the figure, an oval tube is bent in the form of a portion of a circle



Pressure Gauge (Bourdon Tube).

and sealed at one end. The other end is connected to a region whose pressure is to be measured. If that pressure is above atmospheric, the tube tends to change from oval to circular cross-section, accompanied by an uncurling action. This tendency is resisted by the elastic properties of the metal of the tube, but the tip executes a movement which is proportional to the change of internal pressure. If the internal pressure were below atmospheric, the effect would be reversed and the tube would tend to curve in, moving the sealed tip inward. The extent of this motion is quite small, and it must be amplified by suitable mechanism, so that the limited movement of the tip of the tube may be converted into a full swing of the indicating needle. Modification of the material of the tube, as well as the proportions and wall thickness, will adapt this instrument to a wide range of pressures.

Physical and industrial research often involves very low gas pressures. Gauges for measuring low pressures may be classified under five principal heads: 1. Pressure multipliers, represented by the well-known McLeod gauge. A measured volume of gas at the unknown low pressure is compressed isothermally into a known volume many times less, thus raising the pressure to within the range of an ordinary mercury manometer, the determination is then completed by applying **Boyle's law** or van der Waals' law. 2. Viscosity or "molecular" gauges, dependent upon the fact that the viscosity of a highly rarefied gas is a function of the pressure. In the Langmuir and Dushman design, a horizontal circular disk is rotated rapidly under and near a similar disk suspended in the gas by a quartz fiber; the molecular drag between the disks exerts a measurable torque upon the suspension, which torque is a function of the pressure. 3. Radiometric gauges, like the **Crookes radiometer,** in which the force acting on its vanes depends upon the number of gas molecules present, and hence on the pressure. Knudsen has developed gauges of this class. 4. The hot-wire type, illustrated by the Pirani gauge. A hot filament is cooled by convection, i.e., by the gas molecules coming into contact with it and carrying off its thermal energy, the rate depending, of course, upon the number of molecules present. The cooling effect is determined by observing the resistance of the filament. 5. Ionization gauges, in which the rarefied gas is subjected to ionization by thermionic emission from a heated filament, and a third electrode, of lower potential than the filament, carries off the positive ions formed. The tube can be so designed that the ionization current is proportional to the gas pressure. Such a gauge was first designed by Buckley, and the Bell Laboratories have perfected a design said to be capable of measuring one-trillionth of an atmosphere.

The highest pressures measurable with the mercury manometer are not over a few hundred kilograms per sq. cm. For very high pressures—thousands of kilograms per sq. cm.—some form of "free piston" gauge is used; that is, one in which the unknown pressure is applied to a small piston, the force exerted on which can be counterbalanced with weights or otherwise. Amagat used a double piston, the larger end balanced against the pressure of a mercury manometer; a sort of inverted hydraulic press. (L.D.W., F.T.M.)

PRESSURE HEAD. Head, as used in the science of **hydraulics,** is the height, actual or imaginary, of a column of fluid which creates a pressure at its base. Viewed in this way, head is a measurement of pressure. It is convertible to the pressure (force per unit area) by multiplying by the density of the fluid. Not only is the static pressure designated in terms of head measured as a linear dimension, but velocity as well, this being distinguished from static head by being called velocity head. This pressure, measured as a head necessary to give a fluid, originally at rest, a velocity V, is $\frac{V^2}{2g}$, wherein g is the **acceleration** of gravity. (See **Fluid Flow.**) (F.T.M.)

PRESSURE SHIFT AND PRESSURE BROADENING. **Spectrum** lines are subject to various physical influences brought to bear upon the substance emitting the radiation, and among these is pressure. When the pressure and density of a gas are greatly increased, the lines of its spectrum become less sharp, or broader (without change of total intensity). This broadening is not symmetrical but is greater in the direction of longer wavelength, so that the peak or maximum is shifted toward the red. Thus, when the pressure of mercury vapor is increased from 10 to 50 atmospheres, the 2536-angstrom line has its half-width increased from 0.2 angstrom to 0.8 angstrom, while its peak is shifted about 0.3 angstrom toward the red. These effects are attributed to the influence of atomic **collisions,** which are of course more frequent at high pressure. (L.D.W.)

PRESSURE TENDENCY. **Isallobars.**

PRESSURE VESSELS. Containers for fluids subjected to pressure may be classified as boilers and fired vessels, or unfired pressure vessels. Vessels, such as stills, autoclaves, and the like, may be fabricated in one piece or made of separate plates formed to shape and riveted or welded at the seams. Pressure vessels of spherical form permit the greatest volume for a given enveloping surface and are uniformly stressed in all directions, thereby affording the most economical utilization of material. Although they may be employed as containers for gases and volatile liquids, they are not in general use. Vessels of cylindrical form, with spherical, semi-spherical, or flat heads at each end, are preferred for liquids and gases because the plates may be more easily preformed, and because such vessels are easier to support than spherical vessels.

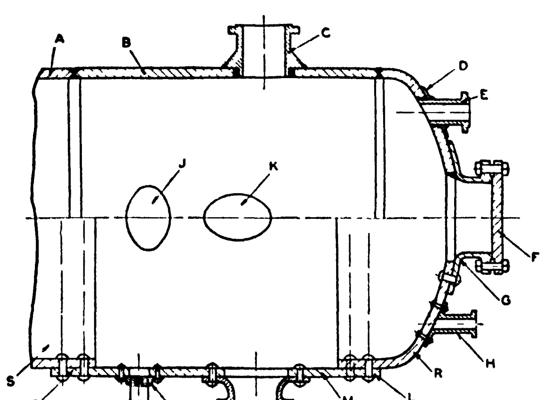
Unfired pressure vessels are designed and constructed in accordance with the provisions of the A.S.M.E. Code for Unfired Pressure Vessels; vessels made of carbon

steel, used for the storage of petroleum products only, are usually constructed in accordance with a joint code sponsored by the American Petroleum Institute and the A.S.M.E. Boilers are designed in accordance with the A.S.M.E. Power Boiler Code. (See **Boilers.**)

The A.S.M.E. Unfired Pressure Vessel Code recognizes three classifications of vessels, U-68, U-69, and U-70, so denoted from the numbers of the sections in the Code that cover the design and construction. Class U-68 vessels may be used for any purpose, temperature, or pressure; Class U-69 vessels are limited to non-lethal gases and liquids, and have pressure limitations of 400 lbs. per sq. in. and temperature limitations of 700° F.; Class U-70 vessels are limited to pressures of 200 lbs. per sq. in. and operating temperatures of 250° F. In general, class U-68 vessels are more expensive to construct, and require at least one manway to permit access to the interior for fabricating purposes. Class U-70 construction is usually the least expensive, and may be constructed so as to require no manway or access opening.

Unfired pressure vessels may be constructed either with riveted or welded joints; the latter are replacing the former to a considerable extent, since a properly fabricated welded joint requires no calking or pressure sealing. For longitudinal joints, the double-welded vee butt joint is mandatory for most classes of vessels, and is fabricated by welding the seam from both sides. Single-welded vee butt joints and single and double lap joints are used for circumferential and head seams.

The figure shows a cylindrical vessel with various fittings and a dished head; the details above the horizontal



axis are representative of welded joint practice, those below of riveted joint practice. *A* and *B* are successive courses, with the head *R* attached to *B* by a double-welded butt joint. *Q* and *S* are successive riveted courses, with double-riveted chain lap joints at the girth joint, or juncture of *Q* and *R*. *J* and *K* represent elliptical manway openings; the regular-type *J* has the minor diameter of the ellipse in alignment with the vessel axis and is referred to as "long way on sweep"; the irregular-type *K* is referred to as "short way on sweep."

Pressure vessels may be fitted with dished heads, elliptical heads, or flat heads. Dished heads have a shape correponding to a segment of a sphere, as shown in the figure; the inner radius of the dished portion of the head is termed the crown radius; the radius joining the crown radius to the cylindrical or flanged portion of the head is termed the knuckle radius. Dished heads may be employed as shown, and are then said to be "concave" to the internal pressure; heads placed in the reverse position are said to be "convex" to pressure. The latter type is considered to be only 60% as strong as the former, but will usually permit riveting or welding from the exterior of the vessel. Ellipsoidal heads are actually half oblate ellipsoids, and are somewhat stronger than dished heads. Flat heads may be flanged, with a knuckle radius joining the cylindrical flange and the head proper, or cut from flat plate, inserted in the vessel and welded around the periphery. Flat heads must usually be considerably heavier than either dished or ellipsoidal heads, for the same internal pressure.

The figure also shows various types of nozzles for attaching pipe and fittings. *C* is a welding-type nozzle, for attachment to a flanged pipe fitting. Welding-type nozzles are available in a range of sizes, and with pressure capacities from 150 to 1500 lbs. per sq. in. The fitting at *E* is a forged steel welding neck, provided with a reinforcing plate *D*, to compensate and provide replacement metal for the opening cut in the head. Straight-neck nozzles, shown at *G* and *H*, are adapted either for riveting or welding, and are obtainable with spherical seats for attachment to the head, or with offset seats as shown at *H*. The nozzle at *G* is used as a manway, with a blind flange *F* serving as a manway cover.

Flared or sweep-type nozzles, shown at *N*, are available in riveting or welding types. These can be used to advantage on all pressure vessels where a smooth orifice is required, since the design minimizes flow turbulence, erosion, and corrosion that may result from sharp-cornered outlet construction.

Forged boiler flanges *P*, are available with plain holes or standard taper pipe threads in three pressure capacities —standard, extra-heavy, and heavy marine types—corresponding to Schedule 40, 80, and 160 pipe. These flanges are usually riveted in place, and can be curved to suit offset or dished head application.

Tanks made of wood are frequently used for water storage and a wide variety of chemical solution and reaction purposes. They usually cost only about one half as much as steel tanks, particularly in the smaller sizes, and can be constructed easily in out-of-the-way places when other material is not available. They are more readily protected from freezing, and do not deteriorate as rapidly, if neglected, as do steel tanks. The life of a wooden tank, if periodically inspected and repaired, is usually fifteen years; cypress tanks often have a useful life of from 20 to 25 years. Cylindrical wooden tanks should have staves dressed on all four sides to a thickness of not less than 2¼" for tanks up to 16' in diameter and depth, or not less than 2¾" for greater diameters and depths Hoops for cylindrical tanks should be of circular section, bent to fit the outer radius of the tank, connected by malleable iron lugs. The hoops should be located on the tank that the lugs are arranged in a uniform helical line Wooden cylindrical tanks are usually built with flat bottoms, supported on a wooden or steel grill.

Cylindrical tanks with a conical bottom are frequently specified for applications where suspended solids are present and where rapid drainage may be required. A steel shell for supporting the bottom is necessary, into which the tank is grouted with acid-resisting cement. The steel shell is usually provided with brackets or legs to support the vessel. Dished bottom tanks of similar construction are also available, although dished bottom tanks less than 18" in diameter are usually supplied with steel supporting shells Support for these sizes usually consists of a wooden false-work supplied by the user.

Plastic molded tanks for internal pressure or vacuum service are available in a range of sizes from 18" to 5' inner diameter and in maximum lengths up to 14'. Vacuum tanks are provided with internal integrally molded stiffening ribs spaced about 1' apart. Drainage slots are provided at the bottom to permit complete removal of the contents of the vessel.

Rectangular plastic molded tanks in a range of sizes varying from 6" to 6' deep, and in lengths up to 15', may be obtained commercially. Such vessels are widely used in the chemical industry as storage and reaction tanks, filters, and for pickling, cleaning, and electroplating applications.

Almost any type of outlet or other fitting can be

molded into tank bottoms or sides. The design and construction of removable heads or covers is essentially similar to that employed for metallic construction. Through bolts are, however, used in preference to cap screws or tap bolts, unless the molded plastic is furnished with molded metal inserts into which the screws may be threaded. (H.C.H.)

PRESSURE-ALTITUDE RELATIONS. **Atmospheric Structure.**

PREVAILING WESTERLIES. **Atmospheric Circulation.**

PRIAPULIDA. **Gephyrea.**

PRIMARY. **Transformer.**

PRIMARY COLORS. Three colors which, when suitably mixed, will produce all the other colors, including white and black. The colors generally used are an orange-red, green and blue-violet. These colors are sometimes called the additive primaries to distinguish them from the three subtractive or minus-colors, cyan, magenta, and yellow. (H.C.C.)

PRIMARY EMBRYO. An individual formed in the brood pouch or ovicell of some of the **bryozoans**. It is nourished by the parent through a connection with the wall of the ovicell and produces other individuals by budding. The small masses of cells which arise by this process are called secondary **embryos**. Each develops into an adult. (A.W.L.)

PRIMARY STRESS. **Stress.**

PRIMATES. Man, the **apes** and **monkeys**, the **marmosets, lemurs**, and related forms, constituting an order of the class **Mammalia**.

Most primates are arboreal animals and all species either grasp by opposing the thumb to the fingers or show similarity to grasping appendages of this type in the anatomy of the hand. With the exception of the marmosets, all primaries have nails on at least part of the digits. The lemurs retain a claw on the second toe and the marmosets have a nail only on the great toe. The brain is more highly developed in the primates than in any other animals. (A.W.L.)

PRIMING. **Feedwater Treatment, Pumps.**

PRIMIPARA. A woman who is giving birth to or has borne but one child. Compare with **Multipara.** (K.S.M.)

PRINCIPAL AXES. **Dynamics of Rotation; Moment of Inertia.**

PRINCIPAL PLANE OF BENDING. A plane which coincides with a principal axis (see **Principal Axes**) of the cross-section of a flexual member (see **Flexure**) is a principal plane. There are two such planes. The flexure formula is applicable only when the plane of the **loads** coincides with one of these principal planes. (C.W.C.)

PRINCIPAL PLANES. **Principal Stress.**

PRINCIPAL ROOT OF A NUMBER. **Roots of Numbers.**

PRINCIPAL STRAINS. **Elasticity.**

PRINCIPAL STRESS. A principal **stress** is a **normal stress** acting on a plane on which the **shearing stress** is zero. At any point in a stressed body there are three mutually perpendicular planes where the shearing stress is zero. Therefore there are three principal stresses. The magnitude and kind of stress (**tension** or **compression**) depend upon the type of applied **load.** The largest of the three, numerically, without regard to the kind of stress, is called the maximum principal stress. The smallest, with due regard to the kind of stress, is called the minimum principal stress. For example, if the three principal stresses have the following values in lbs. per sq. in.: 1000 (tension), 0 and 900 (compression), the maximum is 1000 and the minimum 900, not 0.

Maximum shearing stresses of equal **intensity** occur on two mutually perpendicular planes which make an angle of 45° with the planes of the maximum and minimum principal stresses.

Principal stresses and maximum shearing stresses at any point in a body are the result of **axial, bending** or **torsional loads** or a combination of these loads.

The planes on which the principal stresses act are called principal planes. (See **Elasticity, Flexure, Stress.**) (C.W.C.)

PRINCIPLE OF LEAST SQUARES. In determining the constants in a function $x_1' = f(x_2, x_3, \cdots x_n)$ the principle of least squares states that the sum of the squared **residuals** $\Sigma(x_1 - x_1')^2$ must be a minimum. By use of calculus and algebra we ordinarily find the constants quite readily. For a polynomial relationship involving only two **variables** x_1 and x_2

$$x_1' = a_0 + a_1x_2 + a_2x_2^2 + a_3x_2^3 + \cdots + a_nx_2^n,$$

we solve the $n + 1$ equations by **Doolittle's method**

$$\begin{aligned}
\Sigma x_1 &= Na_0 + a_1\Sigma x_2 + a_2\Sigma x_2^2 + \cdots + a_n\Sigma x_2^n \\
\Sigma x_1x_2 &= a_0\Sigma x_2 + a_1\Sigma x_2^2 + a_2\Sigma x_2^3 + \cdots + a_n\Sigma x_2^{n+1} \\
&\cdots\cdots\cdots\cdots \\
\Sigma x_1x_2^n &= a_0\Sigma x_2^n + a_1\Sigma x_2^{n+1} + a_2\Sigma x_2^{n+2} + \cdots + a_n\Sigma x_2^{2n+1},
\end{aligned}$$

remembering that there are N-paired values of (x_1, x_2). (See **Empirical Equations.**) (L.A.A.)

PRINTING PROCESSES. **Photographic Printing Processes.**

PRINTING-OUT PROCESSES. Photographic printing processes which produce a visible image upon exposure to light are termed printing-out processes. Most printing processes except the familiar silver chloride, bromide or chlorobromide developing-out papers fall into this class.

Of the three silver halides employed in photography, silver chloride, silver bromide and silver iodide, only the first-mentioned produces a strong print-out image. Silver processes designed for printing-out differ from those intended for development in containing free silver. In a printing-out process free silver results in greater sensitiveness to light; its presence in a developing-out material leads to general fog.

All silver printing-out processes are now obsolete, having been superseded by developing papers. The oldest, albumen paper, was supplanted first by collodio-chloride paper and this in turn by gelatinochloride paper. Both of these were similar except in the colloid employed and in both cases the image was toned with gold or platinum, to obtain an image with a more pleasing color, before being fixed in hypo.

The processes employing light-sensitive iron compounds either alone or in combination with silver, platinum or palladium, namely, ferro-prussiate (blue print), cyanotype (positive blue print), Vandyke, kallitype, palladiotype and platinotype (see **Photographic Printing Processes**) are all printing-out processes although the image is faint before processing.

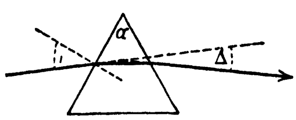
The pigment processes (carbon, gum-bichromate, etc.) are not strictly printing-out processes as the image is not visible after exposure until the water-soluble gelatin is washed away. They are usually considered in this category, however, as the image formed does not require chemical development.

Printing-out processes do not have sufficient sensitivity to adapt them to projection printing which tends to limit their usefulness today. (C.B.N.)

PRIONODESMACEA. An order of bivalve mollusks (Lamellibranchiata) in one of the classifications now in use. (A.W.L.)

PRISM. Glass and other transparent materials are cut into many different forms of prism for various optical purposes. Incident light may pass directly through a prism, or may emerge after one or more internal reflections; in some cases it is **polarized.**

The common triangular prism, familiar in older forms of **spectroscope,** receives light upon one face and passes



Ray of light passing through triangular prism.

it through another after two refractions, resulting in a total deviation Δ dependent upon the angle of the prism and its **refractive index** for the light used. If the light is incident at angle i on the first prism face, and if the prism angle is α and the refractive index is n, the total deviation after passage through the prism in a plane at right angles to the prism edge is given by

$$\Delta = i - \alpha + \arcsin\left[n \sin\left(\alpha - \arcsin\frac{\sin i}{n}\right)\right].$$

A little experimenting shows that this deviation has a minimum value when the light traverses the prism symmetrically, entering and emerging at the same angle with the corresponding faces. This angle of minimum deviation is easily shown to be

$$\Delta_{\min} = 2 \arcsin (n \sin \tfrac{1}{2}\alpha) - \alpha,$$

from which the refractive index may be obtained, by experiment, as

$$n = \frac{\sin \frac{1}{2}(\Delta_{\min} + \alpha)}{\sin \frac{1}{2}\alpha}.$$

The effect of a prism on heterogeneous light may be deduced from the formulae for refractive **dispersion.** (See **Amici Prism, Nicol Prism, Binocular, Monochromatic Illuminator, Total Reflection.**) (L.D.W.)

PRISMOIDAL FORMULA. Earthwork.

PRIVATE EXCHANGE. PAX and **PBX.**

PROBABILITY. The probability that, among several equally likely events, a given event will happen is the ratio of the number of favorable cases to the total number of cases; the probability that this event will fail is the ratio of the number of unfavorable cases to the total number of cases.

It is important to emphasize the assumption in this definition that the events are equally likely.

If the number of favorable cases is a and the number of unfavorable cases is b, the probability that the event will happen is $p = \frac{a}{a+b}$, and the probability of failure is $\frac{b}{a+b}$.

The probability of certainty is 1 and the probability of impossibility is 0.

In many important cases it is not possible to determine the exact probability of the happening of an event by enumerating all the possible equally likely ways in which an event can happen or fail. This is the case, for instance, in the probabilities involved in life insurance and fire insurance. But it is often possible to make a practical determination of the probability by statistical data based on experience and observation over a large number of cases. If it is found by observation that an event has happened m times out of a total of n cases, we may take m/n as an approximation to the probability of the event, if n is large.

The events of a set are said to be mutually independent or dependent according as the occurrence of one of them does not or does affect the probability of occurrence of others of the set.

The probability that two independent events will both happen is equal to the product of their separate probabilities: $p = p_1 \cdot p_2$. This also holds for three or more independent events.

For dependent events, if the probability of a first event is p_1, and if, after this has happened, the probability of a second event is p_2, then the probability that both events will happen in the order stated is: $p = p_1 \cdot p_2$.

Two events are said to be mutually exclusive if the happening of one excludes the happening of the other.

The probability that one or other of a set of mutually exclusive events will happen is the sum of the probabilities of happening for the separate events: $p = p_1 + p_2 + \cdots$.

The probabilities of happening of the separate events of a set of mutually exclusive events are called the partial probabilities, and the probability that one or other of the events will occur is called the total probability. The total probability is therefore the sum of the partial probabilities.

If p is the probability that an event will happen in any single trial, and $q = 1 - p$ is the probability that the event will fail in any single trial, then the probability that this event will happen exactly r times in n trials is ${}_nC_r p^r q^{n-r}$; and the probability that it will happen at least r times in n trials is

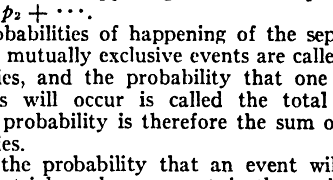
$$p^n + {}_nC_1 p^{n-1} q + {}_nC_2 p^{n-2} q^2 + \cdots + {}_nC_r p^r q^{n-r}.$$

(L.L.S)

PROBABILITY CURVE. In the mathematical theory of **probability,** it is shown that the probability of committing an error of magnitude x is given by the ordinate of the curve whose equation is

$$y = \frac{h}{\sqrt{\pi}} e^{-h^2 x^2},$$

where h measures the accuracy of the observer. This curve is called the probability curve and is shown in the accompanying figure. (L.L.S)



Probability curve.

PROBABLE ERROR. Least Squares.

PROBABILITY FUNCTION. A probability function is always positive or zero. In the case of a **discrete variable** the probability function directly gives the probability that x will occur. An example is the **Bernoulli probability function,** $P_x = {}_sC_x p^x p^{s-x}$. For a **continuous variable** probability is given by an element

of area $P_x dx$, and this is generally called the probability function. The ordinates of the probability function are given by P_x. An example is the **normal probability function**

$$P_x dx = \frac{1}{\sigma_x\sqrt{2\pi}} e^{-\frac{(x-m)^2}{2\sigma_x^2}} dx$$

whose ordinates are given by

$$P_x = \frac{1}{\sigma_x\sqrt{2\pi}} e^{-\frac{(x-m)^2}{2\sigma_x^2}}.$$

(L.A.A.)

PROBASIPODITE. A segment of the **biramous appendage** of **crustaceans.** It is the proximal part of the basipodite where this segment is subdivided. In such appendages it usually bears the exopodite. (A.W.L.)

PROBOSCIDEA. The **elephants.** An order of **mammals** including only two species now living. (A.W.L.)

PROBOSCIS. A protruding or protrusible organ associated with the mouth and therefore at the front of the head in most animals. It is used in feeding and in some cases for other purposes.

Among the more primitive animals, such as the flatworms (**Platyhelminthes**) and **annelids,** a portion of the alimentary tract can be everted through the mouth, and is called a proboscis. It may ingest food merely by muscular action but in the annelids it may also be armed with sharp teeth for grasping prey. The proboscis of the flatworm appears near the middle of the lower surface of the body. The **nemertine** worms also have a proboscis but in the phylum it arises independently, although it is associated with the mouth in the adult. Many **arthropods** have an elongate structure which may be termed a proboscis, although there is little uniformity in the different groups. A familiar example is the long sucking tube of the butterflies and moths, formed of the maxillae.

In the **vertebrates** the proboscis consists of the elongated nose and upper lip, and is developed only in the elephants to a conspicuous degree. It serves the animal in respiration, since it is traversed by the nasal passages, and is a delicate and powerful grasping structure. It grasps larger objects by **prehension** and smaller ones by means of small lobes at the tip. (A.W.L.)

PROBOSCIS MONKEY. Mammalia, Primates. A moderately large **monkey** of Borneo, *Nasalis larvatus,* characterized by the long, fleshy, and somewhat drooping nose. This part is largest in adult males and is relatively small and upturned in the young. The nostrils open near each other on the lower surface. The species is closely related to the **langurs.** (A.W.L.)

PROCELLARIIFORMES. The **albatrosses** and **petrels.** An order of marine birds known for their powerful flight. The feet are webbed and the horny sheath of the beak is composed of several parts. (A.W.L.)

PROCESS METALLURGY. Metals and Alloys.

PROCTITIS. Infection of the rectum which may be caused by a variety of bacteria. The most frequent organisms causing infection are the various kinds of **Streptococci, Staphylococci, Gonococci,** etc. Proctitis is characterized by pain and spasm of the rectum. Constitutional symptoms are not usually marked. (R.S.M.)

PROCTODAEUM. A hollow structure formed by the invagination of the outer layer of the body (ectoderm). It associates with the gut of the **embryo** to form the caudal end of the alimentary tract. In the **insects** the proctodaeum is relatively long, forming the entire hind intestine, which consists of the small and large intestines and the rectum. The proctodaeum of **vertebrates** is less extensive, forming only the **anus.** (A.W.L.)

PROCTOLOGY. That division of surgery which deals with the diagnosis and treatment of diseases of the rectum. (R.S.M.)

PROCYON. Procyon (**α Canis Minoris**) is a brilliant star which receives its name from the fact that it precedes the star **Sirius** in its nightly journey across the sky. These two "dog stars" are referred to in the most ancient literatures and were objects of veneration and worship both by the Babylonians and the Egyptians. Astrologically, the star portended wealth, fame, and good fortune.

Procyon, like the other "dog star" Sirius, has a faint companion which is suspected to be a **white dwarf.** (W.K.G.)

PRODUCER'S RISK. The producer's risk is the **probability** that a lot manufactured by the producer should be rejected by a consumer on the basis of sampling when in reality the lot should be accepted by the consumer. (L.A.A.)

PRODUCT FORMULAE. Multiplication.

PROEPIPODITE. A process of the **biramous appendage** of **crustaceans** borne by the pleuropodite. An epipodite. (A.W.L.)

PROFILE. Differential.

PROFILE LEVELING. Differential.

PROFILER. Milling.

PROGESTERONE. Sex Hormones.

PROGLOTTID. A reproductive segment of a tapeworm (**Cestoda**). These segments are budded from the head or **scolex** in a long series which makes up the ribbonlike body of the worm. Each proglottid contains reproductive organs of both sexes and is traversed by the longitudinal nerve cords and the excretory canals. As they mature, the proglottids break away from the caudal end of the worm and pass out of the body of the host with the feces. (A.W.L.)

PROGNATHISM. Protrusion of the lower jaw. Some animals are normally prognathous but the term is usually applied only to abnormal prominence of the jaw in man. Some breeds of bulldogs are conspicuously prognathous; here the term undershot is used with the same meaning. (A.W.L.)

PROGRESSIONS. This term covers the topics of **arithmetic progression, geometric progression,** and **harmonic progression.** (L.L.S.)

PROJECTED AREA. In a bearing or a rivet, the projected area is equal to the product of the diameter of the element and the length along which it is in contact with some other element. (H.C.H.)

PROJECTION, OPTICAL. By far the most common form of projecting apparatus is the stereopticon or magic lantern. This instrument consists essentially of a concentrated source of light L, as an arc, divergent rays from which are caught by a condensing-lens system C (see figure) and made to illuminate the transparent slide S, which thus becomes a secondary source, like the slit of a spectroscope. The objective O, a system of achromatic lenses, forms an enlarged, inverted image of S on a distant white wall at W. For the image to ap-

pear right side up, the slide itself must, of course, be inverted. The ratio of enlargement, or magnifying power, M, depends in a simple manner upon the dis-

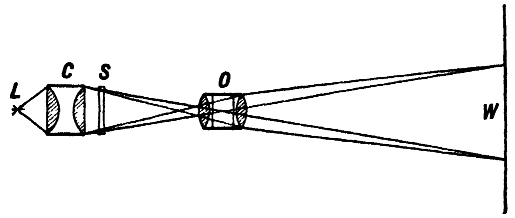


Diagram of stereopticon lens system.

tance D from the slide to the screen and the focal length f of the objective: $M = (D - f)/f$.

In order to exhibit an opaque object, like a postal card or the page of a book, it must be placed at S and illuminated by very strong light focused upon it obliquely from one side by means of lenses or mirrors. Any such picture will appear reversed, right to left, on the screen unless a more complicated optical system is used.

A motion-picture projector differs in no essential way from the stereopticon. The "slides" are, of course, films, and much smaller than standard slides; and the machine is provided with a mechanism for abruptly shifting from one picture to the next on the film while the shutter is closed, and for holding the film stationary while it is open. (L.D.W.)

PROJECTION PRINTING. Projection printing is normally employed to make photographic prints (1) larger than the negative, (2) smaller than the negative, or (3) for correcting the distortion in negatives.

In projection printing, the exposing light passes through the negative and lens and is brought to a focus on a sheet of photographic projection paper placed on the easel. The size of the image formed depends on the focal length of the lens and the relation between the distances from negative to lens and lens to paper. If the latter is greater than the former, the projected image will be larger than that of the negative and the print is an enlargement. If the reverse is true, the projected image is smaller and the print is a reduction.

The projection printer, or enlarger, consists of a light source mounted in a light tight housing, a reflector, set of condensing lenses or diffusion plate, negative carrier, bellows or sliding tube, projection lens, diaphragm, focusing control, support, easel for holding paper, and a light switch.

The illumination may be of various types: tungsten lamp, opal glass enlarger lamp, photoflood lamp, fluorescent tube, or an electric arc. The latter is used in enlargers for large-scale projection, as photomurals or template processes.

Lenses used for projection should be corrected for spherical and chromatic aberration and have an anastigmatic field. All corrections should be made for a plane close to the lens. The better types of enlargers are equipped with projection anastigmats specially designed for projection printing. Some of these are coated to prevent internal reflection. The focal length of the lens is usually equal to, or greater than, the diagonal of the largest negative that the enlarger will accommodate.

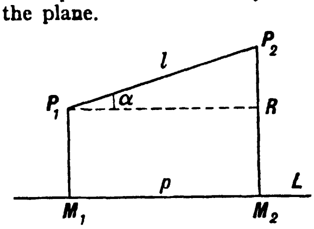
Focusing is accomplished either manually—with a screw, which is often equipped with a coarse and fine adjustment, or automatically by means of a system of levers, or rollers, that move along a guide as the projector is raised or lowered.

Projection printing has become very popular, due to the ease with which print sizes can be changed, negatives can be "blown up" so uninteresting areas of negative can be eliminated from print, and because of the greater convenience for printing-in or shading during exposure. (S.M.T.)

PROJECTIONS. If M_1 is the foot of the perpendicular from P_1 to a line L, then M_1 is called the projection of P_1 on L.

If M_1 and M_2 are the projections of two points P_1 and P_2 on a line L respectively, then the line-segment M_1M_2 is called the projection of the line-segment P_1P_2 on L.

Similarly, the projections of a point and of a line segment upon a plane are defined by drawing perpendiculars to the plane.



The length of the projection of a line-segment l upon a line L is equal to the length l of the given segment multiplied by the cosine of the angle between the lines: $p = l \cos \alpha$.

The projection of any area upon a plane is equal to the original area multiplied by the cosine of the angle between the given area and the plane.

A fundamental projection theorem is: the projection of a broken line is equal to the sum of the projections of the parts. (L.L.S.)

PROJECTIVE GEOMETRY. Projective geometry may be described as dealing primarily with the properties of figures which are unaltered by central projection. By central projection we mean that, from a fixed point or center of projection, straight lines are drawn through the various points of a given figure, and then a section is taken of these projecting rays by a fixed line or plane, giving a new figure. (L.L.S.)

PROJECTORS, MOTION PICTURE. The projector is similar to the motion picture camera except that it is provided with a light source and condensing lenses for illuminating the film, the illuminated picture being formed on a screen by a projection lens. The intermittent film movement may be obtained either by a pull-down claw of the type used on the camera or the so-called Maltese-cross movement. This is shown in Fig 1. The cross, which is shown shaded, is attached directly to the sprocket which engages the perforations

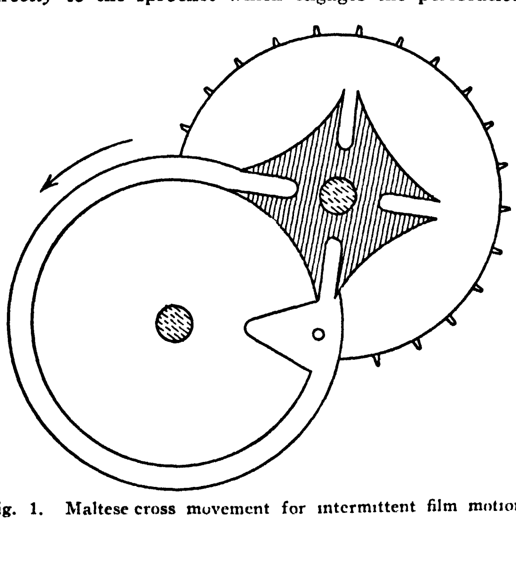


Fig. 1. Maltese cross movement for intermittent film motion

along the edges of the film and serves to move the film downwards. The disk with the pin shown entering the cross moves continuously. The pin entering one of the four slots in the cross moves the cross through a 90°-angle before leaving it. The pin does not enter the cross again until it has made a complete revolution. Thus the continuous movement of the disk is converted into intermittent movement of the sprocket and the film is pulled down one picture at a time just as is the case with the claw pull-down used on the camera. (See also **Camera, Motion Picture.**) (C.B.N.)

PROLAMINES. **Aminoacids, Polypeptides, and Proteins.**

PROLAPSE. The falling or protrusion of an organ or structure due to lack of support, usually secondary to weakness of the ligaments or surrounding muscles. Prolapse of the rectum is a protrusion of a part of the rectal wall externally. Prolapse of the **uterus** is a protrusion of the uterus through the **vagina,** and inverting the vagina so that in an extreme case the uterus hangs between the legs. (R.S.M.)

PROLEG. A fleshy appendage developed in the larvae of certain insects to support the hinder part of the wormlike body. The prolegs bear numerous small hooklets called crochets which grip the supporting surface. Whether these appendages are derived from jointed appendages of the abdomen or not is uncertain; there are evidences to show that such is the case.

The larvae of many sawflies (Hymenoptera) have 6–8 pairs of prolegs and those of most butterflies and moths have five pairs. (A.W.L.)

PROLINE. **Aminoacids, Polypeptides, and Proteins.**

PROMINENCES. Prominences are regions of the solar **chromosphere** which, for some unexplained reason, extend out to a considerable height from the normal upper surface of this region of the solar atmosphere. In common with the chromosphere the prominences usually appear with a brilliant scarlet color. Up to the middle of the 19th century prominences could be observed only during a total **eclipse** of the sun. In 1868 Lockyer and Janssen discovered a method for observing these interesting phenomena at any time. A high dispersion **spectroscope** will spread out, and hence greatly dilute, the continuous **spectrum** of the sun. The prominences, however, shine by means of hot hydrogen and calcium, elements which have strong isolated bright lines which will appear strongly against the dispersed sunlight. By setting the view telescope of the spectroscope to observe any of these strong lines, usually the red line of hydrogen, the slit of the instrument may be set tangent to the limb of the sun and widened until the entire prominence may be observed.

Prominences are of two general types. The quiescent prominences bear considerable resemblance to clouds in our own atmosphere but are very large and extend out frequently as much as 50,000 miles from the sun. Eruptive prominences are smaller than the quiescent ones, but extend out from the sun to much greater distances, frequently more than 500,000 miles, and are found to have high velocity, as great as 200 miles per sec., out from the sun. Both the quiescent and eruptive prominences contain hydrogen, calcium, and helium, but the eruptive prominences are also found to contain iron, magnesium, and other elements apparently carried up from the lower atmosphere of the sun.

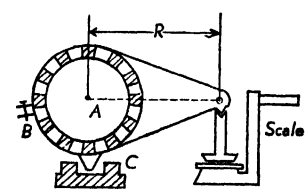
There is no adequate explanation for the enormous force necessary to project matter out from the sun with such high velocity against the strong surface gravity. The number of prominences is directly correlated with the number of **sun spots.** The quiescent prominences may appear at any portion of the sun's disk, but the eruptive type are limited to the latitude zones in which the sun spots are found, and frequently rise from the vicinity of active spots. (W.K.G.)

PROMOTER. **Catalysis.**

PRONG-HORN ANTELOPE. Mammalia, Artiodactyla. *Antilocapra.* A plains animal of the western half of North America. It is distinguished by the erect horns, hooked at the tip, and bearing a short branch in front. The prong-horn differs from all true **antelopes** in the branching of the horn sheaths and in the periodical shedding and renewal of these sheaths. It is, however, much like the antelopes in appearance. Also called the prongbuck. (A.W.L.)

PRONUBA MOTH, AND YUCCA. **Pollination.**

PRONY BRAKE. Mechanical horsepower is often conveniently determined by measuring the reaction on a **brake** which bears against a **pulley** or brake drum in such a way as to create a **friction** drag which converts the mechanical **energy** of the rotating shaft into **heat.** Engines and motors are often tested with the use of the Prony brake. The brake which is shown diagrammatically in the figure consists of the brake drum or wheel mounted on the shaft and surrounded by a band of



Prony brake.

steel, belting, or some other flexible material, to which are fastened, internally, blocks of wood. A band-tightening mechanism allows the operator to adjust the pressure between the brake blocks and the drum. In this way the frictional drag and the load upon the engine can be varied. To the brake band is rigidly attached an arm having a radius R by means of which the band is kept from rotating. The torque effect of the friction drag is found by measuring the force necessary to keep the brake arm from moving. This scale reading in pounds, multiplied by R, is equal to the pound-feet of **torque** set up as a frictional drag at the surface of the drum. The torque, when multiplied by the angular speed, radians per minute, is the power delivered in foot-pounds per minute. The brake horsepower, then, equals

$$\frac{2\pi RWN}{33{,}000}.$$

N is the rotative speed of the drum, revolutions per minute, W is the net weight on the scales, net weight meaning the gross recorded weight less the weight necessary to support the dead weight of the unbalanced brake arm. This deduction is known as the tare. The tare could be found by balancing the brake on a knife edge to locate its center of gravity, and then applying the principle of **moments** to determine the reaction at the end of the brake arm. If it is possible to rotate the brake drum slowly backwards, the brake band should be loosened, and the drum rotated slowly forward, then backward. If during this time the weight on the scales is w_1 for forward rotation, and w_2 for backward rotation, the tare is $\frac{1}{2}(w_1 + w_2)$.

The mechanical energy must be absorbed by the brake itself, as this is an absorption type **dynamometer.** For every horsepower 42.4 B.T.U. are generated by friction each minute. The large flywheels of engines have so

much windage or fan action that this heat can usually be dissipated to the atmosphere. Small brake drums suitable for motors must be water-cooled to prevent their overheating. To accomplish cooling of this nature, the drum should be provided with internal flanges, and a layer of water will be held against it by centrifugal force. Water can be admitted from a stationary supply tube and removed by a scoop which clears the circumference of the rim. (F.T.M.)

PROOF STRESS. **Tension Test.**

PROPAGATION; VEGETATIVE REPRODUCTION. It is often very convenient and even essential that plants be propagated by other means than by seeds. One of the principal reasons for this is to perpetuate desirable individual plants, another to increase the stock rapidly. One way of accomplishing this is by **grafting.** Another is by vegetative propagation, by means of cuttings or slips. Various parts of the plant may be used, advantage being taken of the ability of the part used to form **adventitious roots or buds.** Individuals capable of propagation in this manner are patentable in the United States.

A few plants can be propagated by root cuttings. These sections or pieces of the root form buds and also put out roots. The sweet potato is mainly propagated by this method. Roses are also sometimes increased by root cuttings. In many plants the formation of adventitious buds on the roots is advanced by exposure to light. If the roots of a poplar tree are exposed, in a short time adventitious buds grow and form erect stems. Cutting the root which connects this plant with the parent causes the latter to become independent. Such adventitious buds are freely formed on the roots of many thistles. Since the latter become troublesome weeds the habit is one of annoyance, but not of importance to man in this case.

Vegetative propagation is also obtained by means of stem cuttings, often called slips. The stem of the plant to be propagated is cut into sections, each section having several nodes. Usually all or many of the leaves are removed or clipped to reduce transpiration. The cuttings are then placed erect and half buried in moist sand. Pretreatment with **auxin** insures root production in difficult species. In a short time the **parenchyma** cells just back of the cut surface begin to divide rapidly, forming a loose spongy mass of cells, called a callus, which completely covers the wounded end. From this callus tissue, adventitious roots are formed and in some cases adventitious buds also. Not every plant can be rooted with equal facility by this means. Some, like the common *Pelargonium*, usually called geranium, and *Coleus*, root very quickly and easily. The cuttings may be rooted as easily by sticking in water as by burying in sand. Others can be propagated by stem cuttings only when the proper condition obtains. In some plants only young actively growing stems can be used; in others mature hardened wood is necessary. Often such cuttings remain for months before any roots are formed. It has been said that if proper conditions are obtained any plant may be increased by stem cuttings.

Modified stems, such as **rhizomes** and tubers, usually propagate much more readily. The white potato is propagated by cuttings of the ripened tubers, or potatoes. **Bananas** are increased by planting sections of the rhizome. The ubiquitous pest, witch grass, *Agropyron repens,* propagates itself readily by this method. Cultivation by hoe or cultivator breaks the creeping rhizome into sections, each of which becomes a new plant, which seems to grow with increased vigor.

Some plants are propagated by their leaves. Many species of *Sedum,* common rock garden plants, may be thus propagated, the fleshy leaves being removed from the plant and pushed part way down into moist soil. Adventitious roots and an adventitious bud form from the base of the leaf. Some begonias may be readily reproduced by their leaves. The latter are placed flat on the surface of moist sand, partially covered with sand

Adventitious roots. 1, growing from node of Wandering Jew; 2, growing from cut end of geranium; 3, growing from lenticels of willow; 4, growing from internode of *Coleus.*

and left undisturbed. Tiny plants soon form on the upper surface of the leaf, along the veins. Cutting across the main veins often helps to cause formation of new plants. *Sanseveria zeylanica,* the common bow-string hemp plant, can be readily propagated by leaf cuttings. The long linear tough leaves are cut into 3- or 4-in. sections and treated like stem cuttings. Species of *Bryophyllum* and the related *Kalanchoë* naturally reproduce by means of their leaves, tiny plants forming in great abundance in the notches or at the apex of the leaves. (R.M.W., B.S.M.)

PROPAGATION CONSTANT. This is a transmission characteristic of a line and indicates the effect of the line on the wave being transmitted along the line. It is a complex quantity having a real term, the attenuation constant, and an imaginary term, the wavelength or phase constant. (See **Vector** and associated topics.) The attenuation constant is a measure of the loss in signal strength as the wave travels along a matched line while the wavelength constant is a measure of the phase shift which it undergoes. These relations may be expressed by the following equations:

$$r = a + jB \quad E_r = E_s\epsilon^{-(a+jB)}$$

$$|E_r| = |E_s|e^{-al}$$

$$|I_r| = |I_s|e^{-al}$$

$$\text{Phase displacement} = Bl$$

where r is the propagation constant, a the attenuation constant, B the wavelength constant, l the line length, E_r the received voltage, E_s the sending end voltage and I the corresponding currents. Because of the attenuation on lines used for communication purposes it is necessary

to insert **amplifiers** or repeaters at intervals to build the signal back to suitable levels. For sound work the phase shift is usually not important but for **television** and picture transmission it is extremely important and necessitates correcting circuits. (L.R.Q.)

PROPANE. Hydrocarbons.

PROPELLER, AIR. As a propeller is any device for propelling a craft through a fluid, an air propeller is a device for the propulsion of aircraft, especially one having blades which produce a thrust when mounted upon a power-driven rotating shaft.

An air propeller consists of a hub and one or more blades. The hub is constructed to be mounted on and rotated by an engine shaft. The blades are affixed securely to it at one end (root). The blades are usually 2, 3, or 4 in number. Propellers with more than 2 blades are used only if the power to be absorbed is so large that the diameter of a 2-bladed propeller would exceed the space conveniently available for it on the airplane. Large diameter propellers revolving at 1800–2500 rpm are preferable to those of smaller diameters at higher speeds, but cannot always be accommodated.

The blades of a propeller are **airfoils** of high **aspect ratio.** Thickness and blade angle decrease from root to tip. The relative wind increases in magnitude from

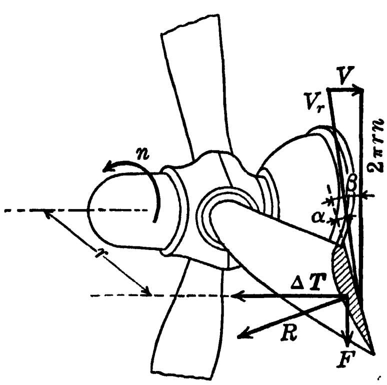


Fig. 1. Aerodynamic action on an element of a propeller blade at radius *R*.

root to tip because of the increase of tangential component. The twist built into the blade is designed to keep the **angle of attack** at or near the optimum (maximum efficiency) value over the whole blade. The chord of the airfoil usually decreases toward the tip from the mid-blade station. The necessary transition to a thick structural section at the root modifies the inner third of the propeller blade away from an effective airfoil shape.

Propellers may be classified as: 1. Fixed-pitch. 2. Adjustable-pitch. 3. Controllable-pitch. 4. Automatic-pitch. The latter two are described elsewhere. The 2-bladed fixed-pitch propeller has blades and central *boss* in one piece which is bolted between the flanges of a simple steel hub. Since no adjustment of blade angle is possible, this type of propeller must be correctly selected for the average flight condition to be experienced and its performance will be inferior under all other conditions. An adjustable-pitch propeller has separate blades and can therefore be adjusted to new average conditions, but as it is adjustable only at rest, its advantages over the fixed-pitch propeller are limited. It could be adjusted to low pitch to accelerate the take-off, or to high pitch to limit engine speed, but not for both on the same flight. For this feature the more complicated controllable or automatic-speed propellers are necessary.

The action by which thrust and engine counter-torque are produced stems from the aerodynamic pressures on the blades. The resultant of these is resolvable into thrust and torque components. The velocities involved on a small element of the blade at radius

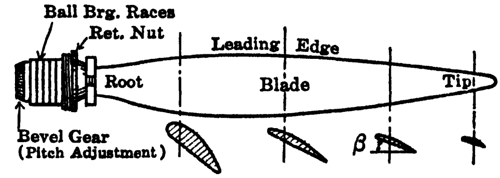

Fig. 2. Typical aluminum alloy propeller blade (with adjustable pitch shank).

r from the center are (1) tangential component $2\pi rn$, (2) airplane forward speed (including any inflow) *V*. These create a relative wind V_r at α angle of attack. The **propeller blade angle** β will be chosen to make efficiency maximum, so it is near the point for maximum $\frac{\text{Lift}}{\text{Drag}}$ of the profile, and much smaller than the angle for maximum lift.

The resultant, *R*, of the aerodynamic force on the blade element has a thrust component ΔT and a torque component *F*. The thrust, *T*, of the whole propeller is the summation of ΔT for all blade elements of which the engine counter torque, *Q*, is ΣFr. Necessary engine power $= 2\pi nQ$ and thrust power $= VT$. Propeller efficiency is the ratio of thrust power to engine power. Notice that during the first part of a take-off run where *V* is very small compared to $2\pi rn$, α virtually equals β. Since β at ¾ radius is usually above the stalling angle of attack of a conventional airfoil profile, the thrust is weak until *V* has increased sufficiently to incline V_r to an α of maximum lift. Then the thrust increases rapidly and a noticeable improvement in take-off acceleration is had. This suggests one of the advantages of being able to control the angle β while propeller is in motion.

A fixed-pitch propeller will be subject to variation of efficiency with air speed. Also, propellers of a geometrically similar family, which would absorb the same engine power at rated rpm, will have different efficiencies, depending on the blade angle. The **propeller coefficient,** known as the speed-power coefficient, is a convenient variable against which to plot efficiency of geometrically similar propellers. The characteristic plot of a group of 3 propellers is shown in Fig. 3 to illustrate why a fixed-pitch propeller of maximum efficiency

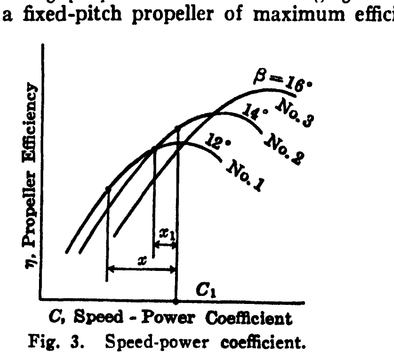

Fig. 3. Speed-power coefficient.

is not the best one (except possibly for a racer). Assume that rated air speed, power, and rpm correspond to a coefficient of *C*, and that *x* is the expected operating range of the engine. Propeller No. 2 has the highest efficiency at *C*, but excels No. 1 only over the partial range x_1. Propeller No. 1 of smaller blade angle is superior in performance over most of the operating range. This aspect of propeller efficiency is confined to the fixed-pitch field as there is no comparable situation if the propeller has controllable or automatic blade angle adjustment.

The efficiency of a propeller at the same *effective pitch* (i.e., V/nd, d being the diameter) is unaffected by changes in altitude since the ratio of $\frac{\text{Thrust power}}{\text{Counter-torque power}}$ involves air density in both numerator and denominator. An unsupercharged engine with fixed pitch propeller will not operate at constant V/nd when altitude varies. Lesser air reactions at higher altitudes have a tendency to let n increase, but losses of volumetric efficiency of the engine more than overcome this tendency and the net result is a decrease

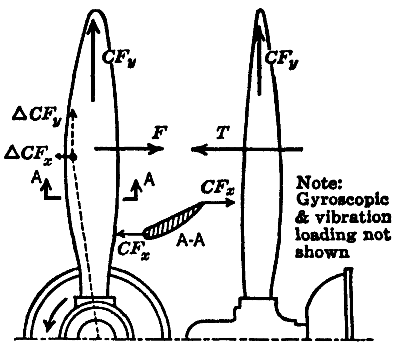

Fig. 4. Structure loads: T, thrust; F, torque force; CF, centrifugal force.

of n. Supercharged engines with manual or automatic adjustment of blade angle can be operated at rated speed at any altitude and do not lose power until the critical altitude (rated manifold pressure with open throttle) is reached.

Propeller blades are made of laminated wood, aluminum alloy, and steel. The fixed-pitch wooden propeller used to propel almost all light airplanes, as well as many of heavier category, is usually of one-piece construction, being carved from a glued, laminated blank of birch and/or walnut. Except for a regrettable tendency to unbalanced warping, from long exposure to excessive moisture, this material is excellent for low-power propellers. The propellers are inexpensive, and not subject to failure from fatigue cracks. They have a small moment of angular inertia, hence the engine can be "revved" rapidly in emergencies such as an over-shoot of the landing area. The blades are reasonably thin, giving good efficiency, but this virtue diminishes rapidly as horsepower and blade diameter increase.

Aluminum alloy propellers are machined from forgings, then heat treated. Only the blades are of this material, the hubs being steel. The blades are shaped with cylindrical flanged shanks that are clamped into the hub on adjustable propellers and held by ball-bearing races on controllable and automatic types.

Steel propeller blades have been made both solid and hollow. The hollow types must be used for stiffness of the thick section they permit if the propeller is a large one.

Loading forces cause tension, cantilever bending, and torsion. These come from transverse air reaction and radial centrifugal force. As the mass of the blade is not concentrated on the blade center line (although the center of gravity usually is), centrifugal action on the leading and trailing edge mass has transverse components creating torsion. Although not large, these forces, together with aerodynamic moments, if any, need counterbalancing in variable blade angle propellers, otherwise they might impress a continuous load on the blade-setting mechanism. Centrifugal force tends to relieve bending stress on the forward side of the blade and increase it on the rear side (face). A slight rake or tilt (½°) forward of the blade center line causes centrifugal force to produce a moment which alleviates somewhat the transverse air reaction moment. This effect is amplified by the forward deflection of the blade under the transverse bending moment of the air reaction (thrust).

Summarizing desirable propeller attributes, some of which are conflicting in nature, they are:

1. High aerodynamic efficiency, resulting in converting the maximum practical amount of engine output into propulsive energy.
2. Uniformly high performance over the operating speed range.
3. Small diameter for ground clearance.
4. Low tip speeds for quietness of operation.
5. Propeller weight and angular moment of inertia as low as possible.
6. Resistance to sudden failure, like extended fatigue cracks.
7. Resistance to abrasion.
8. Resistance to moisture absorption and resultant change of shape.
9. Low cost, consistent with reliability. (F.T.M.)

PROPELLER, AIR, CHARACTERISTICS. Except in the field of propeller design, it is not expedient to derive air propeller operating characteristics from basic aerodynamics. A number of special characteristics, whose nature is that of coefficients or parameters, have been found to be of use in judging the over-all performance of propellers. Frequently, propeller data appear to have a random character until plotted against one of these coefficients, whereupon it assumes an orderly character, displayable as a family of curves. Commonly used characteristics include:

Effective pitch ratio, V/nd.
Power coefficient, $P/\rho n^3 d^5$.
Thrust coefficient, $T/\rho n^2 d^4$.
Speed-power coefficient, $V\left(\frac{\rho}{Pn^2}\right)^{1/5}$.
V = Air speed.
n = Revolutions per sec.
d = Propeller diameter.
P = Engine brake horsepower.
ρ = Mass density of air.
T = Propeller thrust. (F.T.M.)

PROPELLER, AIR, PITCH OF. *Effective Pitch.* The distance an aircraft advances along its flight path for one revolution of the propeller.

Geometrical Pitch. The distance an element of a propeller would advance in one revolution if it were moving along a helix having an angle equal to its blade angle.

Pitch Ratio. The ratio of geometrical pitch to diameter.

Effective Pitch Ratio. The ratio of effective pitch to diameter, i.e., V/nd. (F.T.M.)

PROPELLER, AUTOMATIC. Some of the characteristics of an air propeller may be controlled under variable operating conditions by a suitable adjustment of the blade pitch. If manually accomplished by remote control, the propeller is said to be of "controllable pitch." If the control originates in an automatic governor, the propeller is an "automatic propeller."

Generally the characteristic to be controlled is the rotative speed—the "rpm." Engine speed should be held constant at rated rpm for maximum power delivery; also, there are other advantages of automatic control for constant speed. The automatic propeller is built as a *constant-speed propeller* with a centrifugal governor for automatically maintaining constant engine speed through appropriate changes in blade angle. The automatic propeller is therefore a *controllable-pitch propeller* with a speed-responsive governor. Various constant speeds in the range from maximum take-off rpm to minimum cruising rpm may be impressed on the governor by a governor spring-loading control, available to the pilot

Various electrical, hydraulic, and mechanical operating mechanisms have been devised to fit compactly into the hub of the propeller, but all employ the centrifugal governor for primary control. Fig. 1 shows a diagram of the mechanism of an hydraulically operated blade

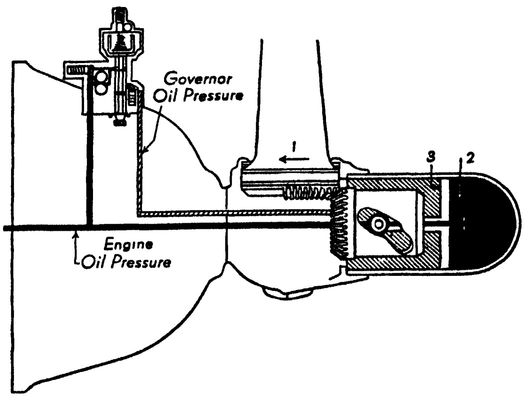

Fig. 1. Diagram of the "Hydromatic" constant speed propeller. When speed decreases the governor acts to drain the cylinder inboard, causing piston (3) to move rearward under engine oil pressure (2), thus causing the cam mechanism to rotate the blade in the direction (1) for pitch decrease. (*Hamilton Standard Propellers.*)

adjustment. The governor, driven by the engine, boosts engine oil pressure and automatically meters oil to and from the propeller to maintain the proper blade angle. The forward section of the propeller hub is an hydraulic cylinder. The straight-line motion of the piston in this cylinder is, by means of a plate-and-roller cam, converted to rotation of a ring gear. This gear's motion will rotate all blades in their sockets, thus effecting a pitch change. For on-speed operation of the propeller the air forces twisting the blade and the net oil pressure acting on the piston leave the mechanism in equilibrium.

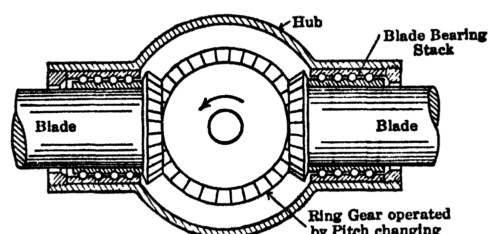
When the engine speed falls below the selected rpm, spring force overcomes centrifugal force of the governor weights. The new equilibrium position forces the oil relay valve to open the rear side of the piston to drain, causing a rearward movement of the piston and a decrease in blade pitch. Following this change, an easing of propeller torque allows the engine to pick up speed until desired speed is reached. In case of engine overspeed the flyweight centrifugal force exceeds spring force, with the result that the oil relay moves to admit boosted oil pressure to the rear side of the piston, moving it forward. (F.T.M.)

PROPELLER BLADE ANGLE. The acute angle between the chord of a section of a propeller and a plane perpendicular to the axis of rotation. As the blade angle of an air propeller varies from maximum at hub to minimum at tip it is necessary to localize a section in order to validate a numerical reference to this angle. In the United States, by custom the blade angle of a propeller is the angle at 75% of the radius to the blade tip. (F.T.M.)

PROPELLER, CLUB. A propeller (usually 4-bladed) so called from its short, inefficient, club-like blades. Also it is sometimes called a "test club" or a "test propeller." This is a non-flight propeller of purposely inefficient design. When mounted in place of the normal propeller, the test club provides sufficient torque load to enable power testing of aeronautical engines on fixed test stands. The abnormally small thrust created is of no consequence, but the club must throw enough air back over the engine to accomplish the cooling satisfactorily. (F.T.M.)

PROPELLER COEFFICIENTS. **Propeller; Air.**

PROPELLER, CONTROLLABLE-PITCH. This is an air propeller constructed to allow adjustment, by the pilot, of the blade angle during flight. This action is called changing the *pitch.* No matter what the airplane speed may be, there will always be a blade angle which will allow rated speed to be attained by the engine. Thus pitch changing allows maximum use of engine power, regardless of airplane speed. In this, it resembles the change speed transmission of an automobile. Usually propeller pitch is continuously variable between extreme positions, whereas automotive transmissions include only three or four forward gear ratios.



Schematic diagram of controllable pitch hub.

Controllable-pitch propellers have been constructed to operate on hydraulic, electric, and purely mechanical principles. A steel hub is fitted to the engine shaft, this hub having sockets machined to receive the ball- or roller-bearing races which support the shanks of the blades, holding them in proper position but leaving them free to rotate about the blade center line. A gear, fastened to each blade shank, is meshed with another operated by the change pitch mechanism. In an hydraulic mechanism, engine oil pressure is admitted to or released from an operating cylinder which is part of the propeller hub. Motion of the piston is used to effect the change of pitch. The electric propeller has a small reversible electric motor to accomplish the same object. Electric energy is taken from the aircraft electric system, and, after passing through control equipment, enters the hub through insulated slip rings.

Since the controllable propeller is operated mainly with the thought of maintaining some standard engine speed, the automatic propeller, which is a controllable propeller with speed-responsive governor instead of human control, is rapidly replacing it. The blades and the hub mechanism of **automatic propellers** differ but little from the controllable propellers. (F.T.M.)

PROPELLER, COUNTER-ROTATING. An aviation development of considerable interest to the high-power field is the counter-rotating propeller. This is a propulsive arrangement of two propellers for one engine, the two having concentric centers of rotation but being revolved in opposite directions. The planes of rotation are parallel and quite close together, there being about 15″ clear space between the blades of the two propellers. The rear propeller has a bearing on the hub of the other and is driven at the same speed, but oppositely in direction, by gearing in a nose section of the engine crankcase. The hubs are of the automatic-pitch type, the pitch being changed simultaneously and equally on the two propellers.

Counter-rotating propellers were created in response to the increasing power capacity of aviation engines. As these capacities grew first 3-, then 4-bladed propellers were introduced. After the multi-bladed propeller had been developed to the maximum practical diameter the counter-rotating propeller followed. In addition to being capable of absorbing the power of the largest engines developed, the counter-rotating principle possesses some definite aerodynamic advantages. The torque

reaction is neutralized. There is no swing to be combatted at take-off. Air flow is smoother over the control surfaces, and lifting surfaces may develop their normal lift, even in the slip-stream of the propeller. (F.T.M.)

PROPELLER THRUST. The thrust of a propeller is the component of fluid reaction on a propeller which is parallel to the direction of advance. The following discussion will relate to the *air propeller*.

The thrust of an air propeller is the result of aerodynamic lift and drag forces on the airfoil-shaped propeller blades, the resultant of which is a thrust normal to the plane of rotation and a *couple* acting counter to the direction of rotation in the same plane.

The magnitude of thrust is related to engine power by "propeller efficiency," η, since

$$\text{Thrust} = \frac{\text{Engine Horsepower} \times 550 \times \eta}{\text{Air Speed, ft. per sec.}}.$$

During flight of an airplane the thrust can be exactly parallel to the relative wind at one air speed only. Since the variation from parallelism over the usual range of flight speed is only about 7–10°, the propeller reactions are generally analyzed as if the plane of rotation were always normal to the relative wind.

Thrust is normally positive, i.e., forwardly directed, but some recent propeller designs have incorporated blade adjustments permitting setting to negative angles of attack. The thrust would then become negative. Uses claimed for negative thrust are (1) to reduce the diving speed of dive bombers, (2) to permit more maneuverability of large flying boats when taxiing, (3) to reduce the length of landing run by decelerating more rapidly than brakes allow, or when wheel friction is abnormally small (icy runways). (F.T.M.)

PROPER ENERGY. Energy.

PROPER MOTION. The individual motion of a star relative to the other stars is known as the proper motion of the star. Up to the early part of the 18th century the belief was current that the stars were all fixed on a sphere commonly known as the **celestial sphere.** Since this sphere was apparently rotating about the earth and possessed other motions such as **precession** and **nutation,** all of the stars had certain motions in common. In 1718, Edmund Halley, while reducing his observations of the positions of the stars, noted that the positions which he obtained for **Sirius** and **Arcturus** differed in position relative to the other stars from the positions given by Ptolemy. Since the differences were greater than could be ascribed to errors in observation, Halley concluded that these two stars were actually not fixed on the celestial sphere but were in motion.

Since Halley's time, many stars have been observed to have proper motion and many long programs are at present under way to study these motions. The standard method of procedure is to compare positions of the stars at two epochs as widely separated as possible. Visual observations made with extreme precision with a **meridian circle** may be used for this purpose, but the photographic methods are far more fruitful since a large number of star positions may be obtained on a single plate. The longer the interval of time between the observations, the more accurate is the determination of the proper motion, and also the smaller the proper motion which can be detected.

Proper motion can only be determined in angular units, and the results are usually expressed in terms of seconds of arc per year. In case the **stellar parallax** of the star is known the velocity in linear units may be computed in accordance with methods discussed under **space velocity** of a star. The largest known proper motion is 10″.25 per year and was found by Barnard for a tenth **magnitude** star. Such a star would require about 200 years to change its position by an amount equal to the apparent diameter of the moon. There are only about 50 stars known to have proper motions greater than 2″ per year and not more than 1000 with values greater than ½″ per year. Hence, we should not expect the **constellation** figures to have altered appreciably in the 5000 years since they were first described. (W.K.G.)

PROPLIOPITHECUS. Paleontology of Man.

PROPODITE. A segment of the **biramous appendage.** (A.W.L.)

PROPOLIS. A material gathered by **honey-bees** and used for closing crevices in the hive and for filling in sharp angles and attaching loose parts. It is also applied as a varnish to the combs and to the smooth surfaces in the hive. The substance is composed chiefly of resins gathered from plants and has an aromatic fragrance much like that of the leaf buds which furnish some of these resins. (A.W.L.)

PROPORTION. A proportion is a statement of equality between two **ratios.** It may be written in the form $a{:}b = c{:}d$ (formerly $a{:}b{::}c{:}d$), or perhaps better $a/b = c/d$.

In a proportion $a{:}b = c{:}d$, we call the first and fourth numbers a and d the extremes, and the second and third numbers b and c the means of the proportion.

Properties of a proportion, as $a{:}b = c{:}d$, are expressed by the following:

1. In any proportion, the product of the means is equal to the product of the extremes: $ad = bc$.
2. In any proportion, the terms are in proportion by inversion, that is, $b{:}a = d{:}c$.
3. In any proportion, the terms are in proportion by alternation, that is, $a{:}c = b{:}d$.
4. In any proportion, the terms are in proportion by composition, that is, $a + b{:}b = c + d{:}d$.
5. In any proportion, the terms are in proportion by division, that is, $a - b{:}b = c - d{:}d$.
6. In any proportion, the terms are in proportion by composition and division, that is, $a + b{:}a - b = c + d{:}c - d$.

If $a{:}b = c{:}x$, then x is called a fourth proportional to a, b, and c.

If $a{:}b = b{:}x$, then x is called a third proportional to a and b.

If $a{:}x = x{:}b$, then x is called a mean proportional between a and b; this is the same as the **geometric mean** of a and b. (L.L.S.)

PROPORTIONAL LIMIT. The maximum unit **stress** which can be obtained in a structural material without causing a change in the ratio of the unit stress to the unit **deformation** is called the proportional limit. (See **Ultimate Strength, Modulus of Elasticity, Tension Test.**) (C.W.C.)

PROPORTIONAL REDUCERS. The principal value of proportional reducers is in the reduction of overdeveloped negatives.

Proportional reduction can be obtained with acid solutions of ferric ammonium sulfate (Krauss) and with a mixture of potassium permanganate and ammonium persulfate (Deck). (See also **Photographic Reduction.**) (C.B.N.)

PROPYLITIZATION. Processes, both magmatic and post-magmatic, by which **andesitic** rocks are altered through the action of water, **carbon dioxide,** and **sulfur.** (R.M.F.)

PROSAURIA. Reptilia.

PROSOBRANCHIATA. **Synonym of Streptoneura. Gasteropoda.** (A.W.L.)

PROSOMA. **Cephalothorax.**

PROSOPYLE. A minute pore connecting the inhalant and radial canals of sponges. **Porifera.** (A.W.L.)

PROSOSTOMATA. **Trematoda.**

PROSTATE GLAND. A gland associated with the ducts of the male reproductive system. Its secretion forms part of the seminal fluid.

The name is applied to a gland of some flatworms. The spermiducal glands of earthworms are also called the prostates, although they do not open into the sperm ducts. Some of the **cephalopod** mollusks also have a prostate associated with the sperm duct. In the mammals the gland is well developed, lying at the junction of the urinary bladder and the urethra.

In man, this gland is chestnut-shaped and measures 1¼ by 1½". It is composed of glandular and fibrous tissue. The openings of the glandular ducts empty into the urethra. It is not known whether there is any **hormone** secretion by this gland. The function of the prostate is to secrete a fluid which forms a part of the seminal fluid. This gland is subject to infection (prostatitis), **hypertrophy,** and **cancer.**

Prostatitis may occur in an acute or chronic form. It is an exceedingly common disease which affects the adult male. It is usually seen as a complication of **gonorrhea,** but may at times be caused by other organisms such as the *Streptococcus, Staphylococcus,* and *tubercle bacillus.* In an acute infection, an **abscess** may develop. This requires surgical drainage.

The symptoms of prostatitis are many and may be divided into three groups. 1. Sexual. 2. Urinary irritation and obstruction of urinary flow. 3. Referred symptoms. These referred symptoms are usually those of pain, which is often severe, involving the hips, buttocks, legs, thighs, back, or groin. Acute gonorrheal **arthritis** may stem from a focus of infection in this gland.

Hypertrophy (enlargement) of the prostate is exceedingly common in men over 50 years of age. More than 20% of the men past middle life are said to suffer from some degree of prostatic enlargement. The chief symptoms resulting from hypertrophy are due to the obstruction to the outflow of urine. The usual chain of events is as follows: first there is frequency of urination during the night and in the daytime, progressive difficulty in urination, partial retention of urine, and when obstruction is complete, complete retention occurs. Pain referred to the urethra during urination is present in from 75–80% of cases. The most frequent complication of prostatic obstruction is infection which may be limited to the bladder, or may involve the kidneys and ureters as well.

At the present time, excellent results are obtained with surgery of the prostate gland in the treatment of benign hypertrophy, with an exceedingly low mortality. This is remarkable, considering the fact that many of these patients are aged, arteriosclerotic men, who would ordinarily be poor operative risks. The excellent results are due more to the advances made in pre-operative treatment than to the refinements of operative technique. Before a patient is ready for surgery, an attempt is made to relieve the obstruction, and to clear the urinary tract of infection with local installations or with sulfonamides orally. Attention to fluid balance and a good nutritional state are important.

There are two surgical approaches used for removal of the prostate. Before either of them is carried out, the urinary obstruction must be gradually relieved. This is accomplished by one of two methods, depending on the individual case. One method is to drain the bladder through a lower abdominal incision, so that the urine can be removed by suction for a period of time before doing the second stage operation. The other method relieves the obstruction by means of the indwelling catheter. Operation for the removal of the prostate is done at a later date, either (1) through the inside of the bladder by an abdominal incision, or (2) through the perineal route. Both methods give excellent results.

The prostate gland is a common site for the development of cancer. There may be no symptoms from the primary tumor, or the symptoms may be similar to those of benign hypertrophy. If diagnosed sufficiently early, radical surgical removal and the use of radium give the best results. Inoperable cases can only be treated by palliative measures.

In recent years, female **sex hormones** have been used in the treatment of both benign prostatic hypertrophy and cancer of the prostate. The results with benign hypertrophy have not been striking, but in cancer which is inoperable because it has progressed beyond the stage of a solitary tumor mass, diethyl stilbesterol (or similar compounds) causes marked improvement and prolongs useful life in many patients. The use of ovarian hormones is based on the knowledge that the male sex hormone exerts a stimulating effect on the growth of prostatic cancer. By inactivating this hormone with an **estrogen,** the growth of the **tumor** is slowed down, and the tendency to spread or metastasize is diminished. At the same time the patient improves in that his pain disappears and his appetite and weight increase. (A.W.L., R.S.M., D.M.H.)

PROSTATITIS. **Prostate Gland.**

PROSTOMIUM. A protuberance of the first segment of **annelid** worms, lying in front of the mouth. In the earthworms it is a simple rounded structure. In the **leeches** it enters into the formation of the anterior sucker. Its most remarkable form is the long proboscis, forked at the tip, which appears in the annelids of the genus *Bonellia* (Gephyrea). (A.W.L.)

PROTACTINIUM. Symbol: Pa. Atomic number: 91. Atomic weight: 231. Recognized by the International Committee on Atomic Weights in 1937. A radioactive element of the actinium series. (See **Radioactive Changes.**) (R.K.S.)

PROTAMINES. **Aminoacids, Polypeptides, and Proteins.**

PROTECTIVE COATINGS. Materials which are usually given protective coatings fall into three general classifications, wood, concrete and metal.

Wood may disintegrate from two causes, weathering and rotting. When unpainted or untreated wood is subjected to the weather it will eventually split and crack due to alternate swelling and shrinking occurring during periods of wet and dry weather. Rotting is caused by living organisms of which there are many types, molds, fungi, bacteria and such parasites as termites. Protection from weathering can usually be obtained by giving the wood a protective coating of paint. This also suffices to keep the wood from rotting, except when in contact with soil. Wood thus employed is usually impregnated with creosote, zinc chloride, or mercuric chloride to prevent rotting.

Most important of the artificial coatings is paint. (See **Pigments, Paints, Varnishes.**)

Although concrete is usually considered quite stable to weathering it will gradually disintegrate, therefore a protective coating can be used to advantage. Alternate wet and dry periods gradually swell concrete to the point where it may crack, and the formation of ice in the surface of concrete chips out pieces of it. One of the best ways to protect concrete against serious disintegra-

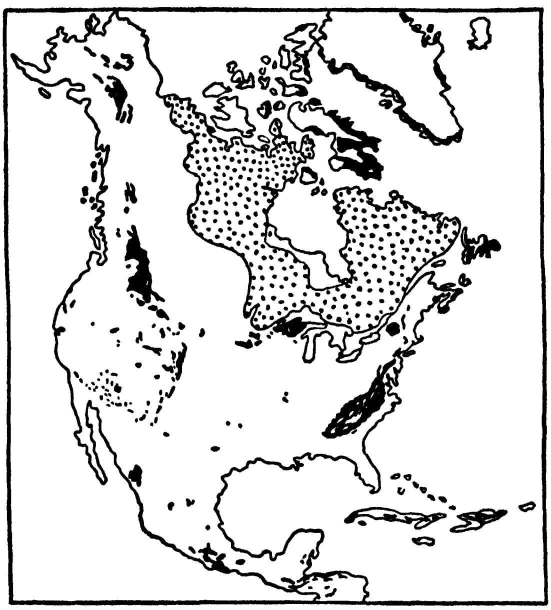
tion is to give it a coating of tar or asphalt. Concrete roofs, for example, are usually given several coatings of tar and asphalt impregnated felt to make them waterproof. Concrete walls can be made water-repellent by incorporating soap into the concrete mixture during pouring. The soap makes the concrete have a somewhat greasy surface. The greasiness keeps the water from penetrating into the pores of the concrete, thereby keeping the inside of the concrete dry even during a rain. Sodium silicate is also used for the same purpose.

Metals which cannot be given a natural protective oxide coating (see **Corrosion**) must be covered by an artificial coating. (See **Pipe Coatings.**) (D.E.M.)

PROTEINS. **Aminoacids, Polypeptides, and Proteins.**

PROTEOMYXA. **Sarcodina.**

PROTEROZOIC (Algonkian). Next to the oldest of the five **eras** of the earth's history. Separated from the **Archeozoic** (the oldest Era) by a profound **unconformity.** The formations of the Proterozoic contain a preponderance of red sandstones and shales suggesting



Map showing the surface of pre-Cambrian (Archeozoic and Proterozoic) rocks in North America. Largest area shown by dotted pattern; smaller areas by solid black. (*Modified after Willis, U. S. Geological Survey.*)

increasing aridity. **Tillites** also prove that continental glaciers existed in Eastern Canada, Australia, Tasmania, Norway, South Africa and India. The only undoubted forms of life appear to have been low forms of marine plants called calcareous algae. The sedimentary formations of the Proterozoic, especially in North America, contain important ores of **iron** and **copper.** Length of time since the beginning of the Proterozoic, 1000 million years. (R.M.F.)

PROTHALLIUM. **Ferns.**

PROTOBRANCHIATA. **Lamellibranchiata.**

PROTOCEREBRUM. The first of the three principal parts of the **arthropod** brain. It is derived from the pair of ganglia in the first segment of the head and innervates the eyes, both simple and compound. In some **arthropods** a median archicerebrum lies in front of this pair of ganglia and the two components together make up a procerebrum. The remaining two regions of the **brain** are the **deutocerebrum** and the **tritocerebrum.** (A.W.L.)

PROTOCILIATA. **Ciliophora.**

PROTOCLASTIC STRUCTURE. The type of structure which results from differential flow during fractional and granular differentiation of the crystals from the partly congealed **magma.** (R.M.F.)

PROTOGINE. An old and obsolete term proposed by Turine in 1806 for the central crystalline core of the Alps. Of historic significance because intimately connected with the origin of **granites, gneisses** and mountain building. (R.M.F.)

PROTOHIPPUS. **Fossil Mammals.**

PROTOMONADIDA. **Mastigophora.**

PROTON. The proton is most familiar as the nucleus of the **atom** of ordinary **hydrogen** (H^1); that is, as the ionized hydrogen atom. But there is ample evidence that protons exist also in the nuclei of other atoms. Until recently it was supposed that all atomic nuclei are built up of protons and **electrons;** now it appears that there may be other constituents (see **Neutron** and **Positron**), and the existence of electrons as such in the nucleus is in doubt. The mass of the proton is equal to the mass of the hydrogen atom minus the mass of the electron, that is, to about 1.672×10^{-24} gram. (See **Nuclear Particles.**) (L.D.W.)

PROTONEMA. **Bryophytes.**

PROTOPLASM. The material of which all living things are formed, usually a jelly-like or fluid substance of grayish translucent appearance.

Protoplasm is a complex mixture in which the elements, **carbon, oxygen, hydrogen** and **nitrogen** are always present. **Sulfur** is another constituent of most protoplasm and many other elements, such as **iron, phosphorus, calcium** and **iodine** frequently occur in it. These elements appear in three complex types of chemical compounds and in many others which are intermediate or waste products in the chemical processes of the living body. The three are proteins (see **Aminoacids**), **carbohydrates** and fats (see **Esters**). Proteins are made up of carbon, hydrogen, oxygen and nitrogen and usually sulfur. Nucleo-proteins contain the additional element phosphorus. Both carbohydrates and fats contain carbon, hydrogen and oxygen but in carbohydrates the hydrogen and oxygen are in the same proportions as in water while in fats there is relatively much less oxygen. The proteins are chiefly materials of construction and the carbohydrates and fats are sources of energy.

These materials are associated in a finely divided state known as a **colloid,** in which the extensive surface contacts of particle with particle or with surrounding fluids facilitate all chemical interactions of which they are capable.

Living matter displays several physiological properties which are of paramount importance. First among them is **metabolism,** the power of chemical interchange with the environment by which the organism secures materials and energy. As a result of metabolism **growth** by intussusception is accomplished and the animal adjusts itself to its surroundings by the property of **adaptability,** carried on through the four subordinate properties, **irritability, conductivity, contractility,** and **secretion.** The substance is capable of **reproduction.** By this process any unit characteristic of the **organization** of a given kind of protoplasm is repeatedly produced. These units are not simpler than a single cell; any sim-

pler structure is an end product of the cell and is not capable of complete exercise of these vital properties. (A.W.L.)

PROTOPLAST. The living unit of **protoplasm** contained within the wall of a cell forms the protoplast of the cell. This protoplast is an organized unit of protoplasm. (R.M.W.)

PROTOPODITE. A segment of the **biramous appendage.** (A.W.L.)

PROTORE. **Enrichment.**

PROTOTHERIA. **Mammalia.**

PROTOZOA. The 1-celled animals, constituting a major division (**Phylum**) of the animal kingdom. They occur in soil or water and many species live as parasites or symbionts in the bodies of other animals. Some protozoans are colonial and in some colonies a division of labor occurs, accompanied by structural specialization of the individuals. Some species are very widely distributed.

Since the body of a protozoan is a single cell it has the subordinate structures of the cell in addition to other specialized parts. It contains one or more nuclei surrounded by cytoplasm. The body may be naked and without permanent form or held in a definite shape by a delicate surface membrane called a pellicle. Some species secrete a shell or test and some form internal hard parts.

The structures which perform special functions are called organelles, since they resemble the multicellular organs of other animals in function but are simpler than the cell itself in structure. Among the more evident and important are the external organelles for locomotion and for securing food. In the various forms of protozoans these are **pseudopodia, cilia, flagella, cirri, membranelles, undulating membranes,** or **tentacles.** Some are associated with a depression in the surface of the body called the cytosome through which food is ingested. Within the body the cytoplasm is differentiated into a clear layer of ectoplasm at the surface and an inner granular endoplasm containing the nucleus. Here also masses of food with a little water from the food vacuoles in which digestion takes place. One or more pulsating or contractile vacuoles are interpreted as excretory organelles. They fill periodically with clear liquid and then discharge. Slender rod-like defensive structures, the trichocysts, lie in the ectoplasm of some species and are discharged when the animal is irritated.

In the bodies of the species which carry on a type of nutrition like that of green plants colored bodies (chromatophores) containing chlorophyll are found in the cytoplasm. These organisms have been interpreted both as plants and as animals, and have in reality some properties of each kingdom. They and some of the parasitic species absorb dissolved foods and do not ingest solids.

The protozoans reproduce commonly by the asexual process known as **fission** although sexual reproduction also takes place at intervals through the process of **conjugation.**

Protozoans are economically important chiefly as the causes of several serious diseases, among them amoebic dysentery, African sleeping sickness, and malaria.

The phylum is divided into two subphyla and five classes as follows:

Subphylum **Plasmodroma.** **Cilia** never present.
- Class **Mastigophora.** Animals with **flagella.**
- Class **Sarcodina.** Animals which form pseudopodia.
- Class **Sporozoa.** Usually incapable of locomotion as adults but sometimes able to form pseudopodia in immature stages.

Subphylum **Ciliophora.** Ciliated either throughout life or when young.
- Class **Ciliata.** Always ciliated or with related organelles such as membranelles and cirri.
- Class **Suctoria.** Cilia present only in immature individuals. Adults with tentacles. (A.W.L.)

PROTRACTOR. A muscle that draws some part of the body forward. (A.W.L.)

PROTURA. Minute insects of very primitive form. The body is elongate. Neither antennae nor eyes are present. The mouth is formed for sucking. There are three pairs of thoracic legs as in the insects, and a few rudimentary abdominal appendages. Also named Myrientomata and variously considered as a class of **arthropods** and an order of the class **Insecta.** (A.W.L.)

PROUSTITE. A silver-bearing **arsenical** mineral corresponding to the formula Ag_3AsS_3 sometimes with a little **antimony.** It rarely is found in **hexagonal** crystals, being usually in compact or disseminated masses or crusts. It is a brittle mineral; hardness, 2–2.5; specific gravity, 5.57–5.64; color, scarlet, vermilion; luster, adamantine, sometimes very brilliant; streak, same as color; transparent to translucent. It is found associated with **pyrargyrite.** Well-known deposits occur in the Harz Mts., Bohemia, Chile and Mexico. In the United States proustite has been found in Colorado, Idaho and Nevada. It was named for the famous French chemist, Louis Joseph Proust. (E.S.C.S.)

PROXIMATE ANALYSIS. The proximate analysis of coal is the determination of moisture, volatile material, fixed carbon, and ash. Much information regarding the firing characteristics and fuel value of coal will be conveyed by the proximate analysis. The test for proximate analysis may be obtained with a small amount of laboratory equipment. For that reason it is useful for checking, from time to time, the quality of coal bought. The proximate analysis is of little use in combustion calculations which are essentially chemical equations. The chemical, or **ultimate, analysis** is required for that work. (F.T.M.)

PRUNE. **Rose Family.**

PRUNING. The removal of parts of a plant for the purpose of improving it in some desired way is called pruning. Pruning may have as its aim the formation of a plant of more desirable shape. It may be done to reduce the transpiring surface of the plant and so aid it in its struggle to survive when the available water supply is inadequate, a practice of particular value when plants are transplanted and much of the root system is destroyed. Pruning may be done to improve the product of the plant, whether flower or fruit, by throwing greater amounts of food into fewer flower clusters. Finally diseased or damaged portions may be removed to prevent spread of disease and further damage to the plant.

Plants growing in competition for light prune each other. In a dense stand of pines, or other trees, increasing size decreases light penetration to the lower branches. Gradually the latter cease to grow, die, and finally fall off, leaving the trunk straight and unbranched.

Artificial pruning may be done at any time, but is usually best done during the winter or early spring before growth starts. The wound made heals over by means of **callus** tissue which results from increased activity of the **cambium** cells. When a large branch is removed, some time, often years, may be required before the wound is covered. To prevent entrance of disease- and decay-producing organisms, the wound is generally covered with some antiseptic substance, such as white lead paint. When branches are to be pruned, the cut should be made as close as possible to the main trunk

and parallel to the surface of the latter, so that the cut surface may be covered as soon as possible by the callus tissue which forms around its edges. Long stubs are rarely covered and provide paths for the entry of fungi which destroy the central portion of the tree trunk. (R.M.W., B.S.M.)

PRURITUS. Intense itching, a symptom of many skin and some constitutional diseases. Pruritus is found at times in the aged due to the degeneration of the skin. It is also present in **jaundice.**

Pruritus of the anus is very common. In children, the common cause is pinworms; in adults, it is **hemorrhoids.** Infection and pruritus of the **vulva** and anus occur in **diabetes.** (R.S.M., D.M.H.)

PRUSSIAN BLUE. **Ferrocyanic Acid and Ferrocyanides.**

PSAMMITIC. **Arenaceous.**

PSEUDOACONITINE. **Alkaloids.**

PSEUDO-ADIABATIC. **Adiabatic Changes in the Atmosphere.**

PSEUDOBRANCHIA. A small respiratory structure on the inner surface of the **operculum** in certain fishes. The Pseudobranchiae serve as supplementary **gills.** (A.W.L.)

PSEUDOCRYSTALLINE. **Crystallography.**

PSEUDOEPHEDRINE. **Alkaloids.**

PSEUDOMORPHINE. **Alkaloids.**

PSEUDOMORPHS. In mineralogy, defined as minerals having the crystal form of one species and the chemical composition of another. Typical pseudomorphs are **malachite** in the form of **cuprite, barite** in the form of **quartz, limonite** in the form of **pyrite.** In such cases as these the evidence seems to be that there has been a complete chemical and molecular change but without any change of the original outward form. (R.M.F.)

PSEUDOPHYLLIDEA. **Cestoda.**

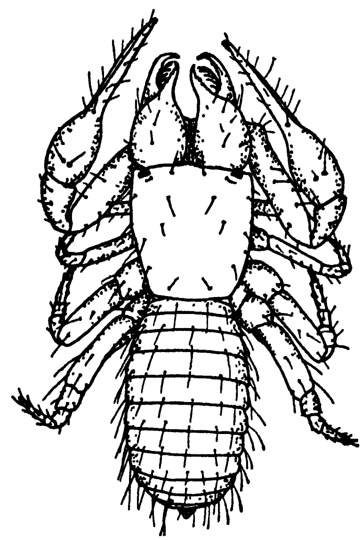
PSEUDOPODIOSPORE. A form of reproductive body or spore produced by some of the 1-celled animals. It is a naked cell like *Amoeba* and is able to form **pseudopodia.** Also called an amoebula. (A.W.L.)

PSEUDOPODIUM. A cytoplasmic protuberance formed at the surface of the body of 1-celled animals, especially those of the class Sarcodina. Pseudopodia are temporary or semi-permanent structures whose formation and retraction can be observed in many species during brief observation. They serve for securing food and as organs of locomotion.

Four types of pseudopodia are recognized. Lobopodia are temporary and relatively thick structures containing both ectoplasm and endoplasm. The common species of **Amoeba** form them. Filopodia are also temporary. They are more slender and usually contain only ectoplasm. Rhizopodia are temporary projections which branch and anastomose. Axopodia are very slender and usually straight radiating pseudopodia. They are semi-permanent. This form is characteristic of the **heliozoans** and **radiolarians.** (A.W.L.)

PSEUDOSCOLEX. The anterior end of a tapeworm (**Cestoda**) which lacks a true **scolex.** The true scolex is provided with one or more suckers or a group of hooks for attachment to the intestine of the host. The pseudoscolex has neither. (A.W.L.)

PSEUDOSCORPION. A small animal resembling the **scorpions** slightly in appearance. The abdomen is rounded and has no slender posterior part and no sting,



Pseudoscorpion.

but the pair of chelate pinchers at the anterior end of the body resemble those of the scorpions. Pseudoscorpions are commonly found in leaves at the surface of the ground and under the bark of decaying logs. They are only a few millimeters long. The relatively few species make up the order Chelonethida of the class **Arachnida.** (A.W.L.)

PSEUDOSCORPIONES. Synonym of Chelonethida. **ARACHNIDA.** (A.W.L.)

PSEUDOSTIGMATIC ORGAN. A bristle, often clubbed at the tip and conspicuously large, which occurs in some of the **mites.** A pair of these structures arise from pits near the anterior end of the body. (A.W.L.)

PSEUDOTROPINE. **Alkaloids.**

PSEUDOVELUM. A narrow rim of tissue near the margin of the body of **jellyfishes.** These animals lack the true **velum** as found in hydrozoan medusae; the pseudovelum differs in its lack of muscle fibers and a nerve ring. (A.W.L.)

PSILOMELANE. Psilomelane is a massive black mineral of indefinite composition, being chiefly **manganese** oxide with various amounts of **barium, potassium** and **sodium** with water.. It may be considered as **colloidal** manganese dioxide plus impurities. It is commonly associated with **pyrolusite** and is of secondary origin. Psilomelane is found in Saxony; France; Cornwall, England; India; Brazil and in the United States in Michigan. It is an ore of manganese. The word psilomelane is derived from the Greek words meaning smooth, and black, in reference to the smooth black surfaces so often exhibited. (E.S.C.S.)

PSITTACIFORMES. The **parrots** and related species, including **cockatoos,** macaws, **paraquets,** etc. The strong hooked beak, adapted for opening nuts and seeds, is the most conspicuous character of the group. Two toes are directed forward and two back. An order of the class **Aves.** (A.W.L.)

PSITTACOSIS (Parrot fever). A very contagious epidemic disease occurring chiefly in parrots but easily transmissible to human beings who handle infected birds. Epidemics of this disease have been reported in Europe, South and Central America. Recently there have been outbreaks in various North American cities. In 1929 during one of the epidemics in the United States a filtrable **virus** was isolated from patients and parrots who had contracted this disease. The disease was successfully transmitted to laboratory animals.

The onset of psittacosis is sudden, with malaise, chills, headache, and backache. At the height of the disease, high fever, restlessness, and delirum may be present. The primary **pathology** is a **pneumonia**; x-ray of the chest reveals involvement of the lungs although the physical signs may not appear until quite late. There is no specific curative treatment and convalescence is slow. The mortality rate in epidemics has been as high as 30–40%. (R.S.M., D.M.H.)

PSOCID. Corrodentia.

PSORIASIS. A chronic inflammatory skin disease of unknown origin, characterized by a recurrent scaling eruption. The **lesions** are reddish, round or oval plaques, usually dry, and covered with silvery scales. They tend to be symmetrically distributed over the limbs, particularly over the knees and elbows. The scalp is often involved. The disease appears in adults and tends to recur throughout life. Treatment of an attack of psoriasis is usually successful, particularly if begun early, but recurrences cannot be prevented. One of the most effective drugs is chrysarobin, obtained from deposits in the wood of a tree indigenous to India and Brazil. Ammoniated **mercury, salicylic acid** and betanaphthol, applied directly to the lesions are also used. If the disease has been present for several months or longer, it is more resistant to treatment. (D.M.H.)

PSYCHOANALYSIS. A method of eliciting from patients their past emotional experiences, dreams, and subconscious feelings to interpret and explain their present mental state or actions and use them for psychotherapeutic procedures. This form of treatment should only be used by an expert **psychiatrist.** (R.S.M.)

PSYCHONEUROSIS. A disturbance of the emotional life which is based on some conflict between the desires of an individual and what that individual believes is "right," or what society considers to be acceptable behavior. Most psychoneuroses are not associated with abnormal outward behavior, but the inner battle is manifested by a variety of distressing emotional reactions which are expressed in the form of symptoms of physical disease. Quite unconsciously, psychoneurotic patients develop symptoms of "nervous indigestion," "nervous heart," "nervous headache," which they use to protect themselves from conflicts and difficulties which make life too much to bear without some support. Physical disease is an excellent protection because in our society a sick man is the object of sympathy, care, and consideration. And the psychoneurotic is sick; his stomach pain hurts him just as much as such pain arising from an organic disorder.

Some degree of psychoneurosis is an extremely common thing; many individuals who are respected, useful members of society are psychoneurotics. There are no organic causes for the condition, no change in brain structure, or chemical or physical function to account for it. Certain types of personality, however, seem more susceptible. The one who is sensitive, "high-strung," and of asthenic body build, is probably more often affected. These traits are apt to be hereditary, but are influenced greatly by the home environment, particularly in childhood. That environment plays an enormous role is well illustrated by the fact that in wartime, the incidence of psychoneuroses increases tremendously. As many as 60% of medical discharges from the United States Army are on the basis of this type of disease, precipitated by the abnormal stresses and strains which army life imposes on men who, under normal conditions, would have only mild psychoneurotic trends, or none at all.

For convenience, the psychoneuroses are classified as (1) neurasthenia, (2) anxiety states, (3) hysteria, and (4) obsessive-compulsive states.

1. Neurasthenia. In this type of psychoneurosis, the patient complains of mental and physical weakness, irritability, inability to concentrate, insomnia, loss of appetite, and various bodily aches and pains. These symptoms may appear as the cumulative result of early years of maladjustment in an unfortunate home situation, or they may be precipitated by a situation of recent development. Thus the discovery that he dislikes his wife, or his business partner with whom he is forced to work closely, may cause the onset of neurasthenia in a man who has previously been well. Psychotherapy is directed toward uncovering the emotional conflict, explaining its nature to the patient, helping him to adjust his attitude toward the situation, and helping him to face the problem directly rather than take cover behind physical symptoms. In an intelligent, cooperative patient, the prognosis is excellent.

2. Anxiety states. These are the commonest of the psychoneuroses, and the most responsive to treatment. They are manifested by such symptoms as palpitation, breathlessness, lack of appetite, a sensation of fullness in the abdomen, frequency of urination, diarrhea or constipation, tremors, pains, blurring of vision, ringing in the ears, and easy fatigability. Mental symptoms are irritability, depression and fears of all kinds—fears of mental or physical ill-health, fears of heart disease, venereal disease, or any other. Psychiatrists call this abnormal fear of disease with subsequent development of symptoms referable to many diseases, **hypochondriasis.**

The anxiety states are most apt to develop in emotionally unstable individuals who are, or have been, exposed to adverse environment in the home. The influence of a dominant, overanxious parent is a common starting point for an anxiety state. The immediate precipitating factors may be dissatisfaction or disappointment and fears about sexual, financial, domestic or any other matters. The actual form that the symptoms take depends on the cause of the anxiety and the general type of personality, environment, education, etc., that the patient possesses.

Treatment with psychotherapy, as in the neurasthenic, discovers the cause of the anxiety and helps the patient to overcome his fears and make a normal adjustment.

3. Hysteria. An hysterical manifestation, as it is popularly understood, can be part of neurasthenia or an anxiety state. "Crying spells" are hysterical attacks. In medicine, the term usually refers to psychoneurotic symptoms which develop an anatomical expression. Thus fear of developing certain diseases may cause hysterical blindness or hysterical paralyses of limbs in the presence of normal eyes and normal muscles. The patient is unaware of the connection between his fear and the hysterical manifestation. If a visceral organ is involved, hysterical vomiting, retention of urine, or dysmenorrhea may occur. All of these signs are apt to have symbolic significance. For instance, hysterical blindness may be closely related to some distressing visual experience.

In general, hysteria is more apt to occur in young women of unstable emotional makeup. Emotional immaturity, moodiness, self-consciousness, vanity, egocentricity, oversensitiveness, etc., are common personality traits in these individuals.

The treatment of hysteria is psychotherapy. **Hypnosis** and suggestion are often employed successfully.

4. Obsessive-compulsive states. In this form of pychoneurosis, the individual is repeatedly forced against his will, and with no apparent reason or purpose, to think certain thoughts, perform certain acts, or utter certain words. The thoughts may be of a speculative or questioning nature on philosophical subjects, or they may be such an absurd preoccupation as wondering why a chair has four legs instead of one. The action may be a socially prohibitive one, and the words are sometimes obscene. The patient may be tortured by his constantly recurring compulsion, but he is helpless against the insistence of the process.

Compulsion neuroses occur in individuals who are shy, oversensitive, precise, meticulous, and are full of phobias, doubts, fears, and indecisions. Fears of dirt, of bacteria, of insanity, and of cancer are common in them. They translate their own inner conflicts and anxieties into fears of these objects or diseases without being aware of the connection between the two. The compulsive thought or act thus becomes an unconscious symbol, perhaps of some painful experience which has elicited remorse, conflict and repression.

The treatment of the compulsive-obsessive neuroses, as with the other psychoneuroses, is psychotherapy aimed at clarifying the cause of the abnormal behavior and adjusting the patient's attitudes and reactions to avoid recurrence. (D.M.H.)

PSYCHONEUROTIC. **Psychoneurosis.**

PSYCHOSIS. A mental illness characterized by profound changes in the personality, abnormal behavior and, in certain types, mental deterioration. There are many types of psychoses. The chief ones are (1) the major psychoses, **Schizophrenia,** Manic-depressive psychoses, and involutional **melancholia.** These are functional; they are not associated with any demonstrable structural or chemical change in the brain. (2) Those associated with organic disease of the central nervous system such as **syphilis, encephalitis,** brain **tumor, arteriosclerosis, endocrine** disease, **pellagra,** etc. The commonest example of this group is the senile psychosis associated with cerebral arteriosclerosis. (3) Those due to drug intoxication, the alcoholic psychoses, **lead, mercury,** and **carbon monoxide poisoning.** (D.M.H.)

PSYCHOSOMATIC MEDICINE. An aspect of medical science which stresses the psychobiological unity of the human being. The close interaction of mind and body in health and disease, and the role that the mind plays in the genesis of organic disease, form the basis of psychosomatic medicine. The common diseases in which psychic as well as organic causes seem to operate are **asthma, hypertension, ulcerative colitis,** and peptic **ulcer.** (D.M.H.)

PSYCHROMETER. **Hygrometers.**

PSYLLIUM SEED. **Plantains.**

PTARMIGAN. Aves, Galliformes. *Lagopus.* Birds (**Aves**) related to the true grouse but with the feet and legs fully clothed with feathers. They are found in the far northern parts of Europe, Asia and North America and at high altitudes, above timber line, as far south as Colorado. They are largely mottled gray and brown in the summer but assume white plumage in winter. The change is not, however, always complete but is somewhat conditioned by the climate. The red grouse and the willow grouse or ripa of northern Europe are closely related to the ptarmigans. (A.W.L.)

PTERANODON. **Cretaceous.**

PTERASPIS. **Fossil Fishes.**

PTERICHTHYS. **Fossil Fishes.**

PTERIDOPHYTES. **Ferns; Paleobotany.**

PTERIDOSPERMS. **Paleobotany.**

PTEROBRANCHIA. **Hemichordata.**

PTEROPOD. A marine mollusk whose foot is formed as winglike processes used in swimming. These **mollusks** belong to the class **Gasteropoda.** (A.W.L.)

PTEROPOD OOZE. **Oceanic Deposits.**

PTEROPSIDA. Members of the Pteropsida have large leaves, and definite gaps in the **vascular** cylinder, where a vascular strand, or leaf trace, passes from the **stele** to the leaf. It is also characteristic of the Pteropsida that the **sporangia** are located on the lower surface of the leaf. Most of the vascular plants of today, including all **ferns, gymnosperms** and **angiosperms,** belong to this group. (R.M.W.)

PTEROSAUR. **Fossil Reptiles.**

PTERYGOTA. One of two subclasses into which the class **Insecta** is divided. The members of this subclass are either winged or closely related to winged forms. Some show evidence of derivation from groups which are typically winged. The great majority of insect orders belong here, only three falling into the suborder **Apterygota.** (A.W.L.)

PTOMAINE. A class of **amines** formed by the action of **bacteria** on proteins or by the **metabolism** of **amino-acids** which are broken down into toxic products. (R.S.M.)

PTOMAINE POISONING. A misnomer generally used in describing gastric and intestinal disorders which are usually caused by food poisoning due to the ingestion of food contaminated by bacteria. (R.S M.)

PTOSIS. 1. A weakness of the muscles of the eyelid causing it to droop over the eye. 2. Falling of any organ or part due to weakness of its supporting tissues—muscle, fat, or ligaments. (D.M.H.)

PTYGMATIC. A term proposed in 1907 by the Swedish geologist, Sederholm, for the primary folding in **migmatities.** (R.M.F.)

PUBERTY. The period of life when the human reproductive organs begin to function. This usually occurs between the 12th and 17th years, being somewhat later in the male than in the female. Puberty is marked by the development of secondary sexual characteristics, by the appearance of hair in the pubic and **axillary** regions, enlargement of the breasts and menstruation in the female. The male develops facial and increased body hair, deepened voice, and seminal discharges. In addition to the physical changes, profound psychological alterations and adjustments occur in both sexes. (D.M.H.)

PUBIS. The anterior ventral bone in each half of the pelvic girdle of the vertebrates. **Skeletal System.** (A.W.L.)

PUBLIC ADDRESS. This is a sound-amplifying system used in connection with large gatherings or where it is desired to cover a large area with sound. The system contains the **microphone** or phonograph (frequently both), a multistage **amplifier** to build up the power to a suitable level and finally a loud-speaker or **speakers.** These systems have come into wide use in recent years as the vacuum tube amplifier has been developed and

are now standard equipment in all large auditoriums, stadia, and other places where it is necessary to reach a great number of people with sound announcements or entertainment. (L.R.Q.)

PUDDING WIFE. Pisces, Teleostei. A marine fish (**Pisces**), *Iridio radiatus*, of the wrasse family (Labridae), found in warmer seas. Also called the pudding fish and blue-fish. (A.W.L.)

PUDDINGSTONE. Conglomerate.

PUERPERAL SEPSIS (Child-bed fever). An acute infection of the genital tract which follows childbirth. Long **labor** and manipulations predispose to infection. Its infectious nature was first realized in the middle of the 19th century by the Viennese physician, Semmelweiss, and by Oliver Wendell Holmes, both of whom crusaded for sterile technique in handling obstetrical patients. The etiologic agent is often the hemolytic **streptococcus**, and blood stream invasion (**septicemia**) is common. Treatment is with **sulfonamides** or **penicillin**; the prognosis, with adequate treatment, is good. Before the use of these chemotherapeutic agents, the mortality in severe infections was very high, the disease constituting the major cause of maternal deaths. (D.M.H.)

PUFF-BALLS. Basidiomycetes.

PUFFIN. Aves, Charadriiformes. Marine birds (**Aves**) of several species whose thick compressed beaks are almost as large as the head. They are found on both sides of the Atlantic, nesting in northern latitudes and wintering south to New York and the Mediterranean. Related species of the Pacific are commonly called shearwaters. All belong to the genus *Puffinus*. (A.W.L.)

PUKU. Mammalia, Artiodactyla. A moderately large African **antelope** with fairly long horns which curve forward and are ringed throughout their length. (A.W.L.)

PULASKITE. A variety of **alkali-syenite** containing soda-rich **orthoclase**, usually with **aegirite-augite** and **biotite**. The type locality is Pulaski County, Arkansas, whence the name. (E.S.C.S.)

PULLEY. Belting; Machines.

PULMONATA. Gasteropoda.

PULSE. The pulse is the expansion and elongation of the arterial walls, produced passively by changes in intra-arterial pressure during contraction (**systole**) and relaxation (**diastole**) of the heart. The pulse is usually felt in the radial artery at the wrist, but it may be felt in any artery which lies near the surface. The heart, with systole, forces blood into the arterial circulation. This blood is accommodated partly by moving the entire arterial column on at greater velocity, and partly by distending the arterial walls. The increase in pressure and distention of the vessel walls is transmitted from one segment of the artery to the next as the pulse wave. The ability of the vessel wall to distend is dependent upon its elasticity. In old age, when the vessel becomes sclerotic and inelastic, it offers increased resistance and this results in elevation of the **blood pressure**.

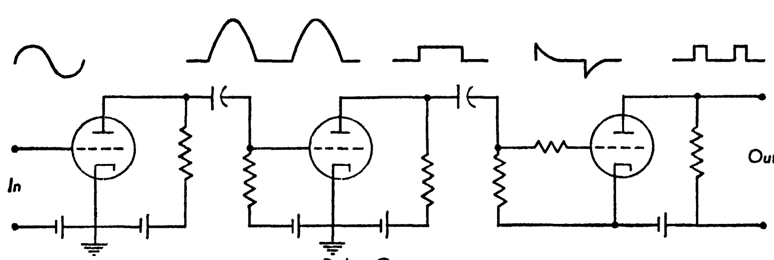
The examination of the pulse in disease is one of the oldest customs in medicine. Variations in the rate, rhythm and force are significant, particularly in heart disease. The normal rate is 60–80 in adults, and 80–140 in children. With fever the rate increases as a general rule. A disproportionately slow pulse with a high fever is of diagnostic significance in certain infections, notably **typhoid**, **typhus** and so-called virus **pneumonia**. An increase in the pulse rate is a normal reaction to emotional stimuli, being dependent in this case upon a release of epinephrine (**adrenalin**) by the adrenal glands.

Abnormalities in rhythm may occur as a toxic reaction to **digitalis** or other drugs, or as a result of organic heart disease (**arteriosclerosis, rheumatic fever, diphtheria**) which interferes with the conduction of impulses setting off the contraction of the heart muscle.

Abnormalities in the force of the pulse occur in certain types of heart disease and in severe illness. In shock, the pulse is characteristically weak and thready, in addition to being rapid.

The term pulse is also used in physics. (See **Vibrations and Waves.**) (D.M.H.)

PULSE GENERATOR. Many electronic devices or circuits utilize sharp pulses of current or voltage as a basic part of their operation. Such pulses must frequently be of very short time duration (microseconds) and accurately spaced in time. Others need not be repeated at regular time intervals but are initiated by some signal and are single narrow pulses each time a signal is received. The various types of circuits for generating these are termed pulse generators. As a simple illustration we might examine a basic pulse generating circuit as shown in the figure. The wave patterns above the circuit diagram represent the wave form at the respective points in the circuit. A sine wave is applied to the **grid** of the first **tube**, which is biased so it clips the wave to the form shown applied to the second tube. This in turn clips the rounded top and gives the square wave shown at its output circuit. By passing this through a condenser-resistor circuit a series of triangular pulses is obtained. These pulses are applied through a grid resistor to the grid of a tube as shown. This tube levels them to produce a series of very narrow pulses spaced at the same intervals as the cycles of the original sine wave. The particular shapes shown in the diagrams are obtained by the proper choice of grid bias and condenser-resistor values in the coupling circuits. When the condenser has a low reactance compared to the resistance in series, the wave is passed without appreciable change of shape but, when the relative values are reversed, the wave form is materially changed as shown in the grid circuit of the final tube. While the circuit shown is relatively simple, it does illustrate some of the possibilities of shaping circuits. (L.R.Q.)



Pulse Generator

PULVERIZED COAL. The burning of fuel in pulverized form has both advantages and disadvantages, but present trends indicate a continually increasing use of pulverized coal as fuel costs rise, as supplies of the better grades of coal are exhausted, and as pulverizing practice becomes widespread. The capacity for heat liberation in a pulverized coal furnace is not limited by the capacity of the burners, but by the inability of the furnace walls to resist the effects of high temperature, and by the limitations inherent in the physical characteristics of the ash. Pulverized coal therefore can be selected for high-capacity firing. The combustion of pulverized coal is readily adaptable to automatic control, responding rapidly to control manipulation. There is but little loss analogous to the banking loss of stoker fires. High-capacity boilers with their high exit-gas temperatures require some heat-saver such as the air preheater if they are to operate efficiently. Pulverized coal firing utilizes preheated air to good advantage and without limitation of the preheated air temperature. Boiler room cleanliness is another asset of the pulverized coal installation.

These advantages are not secured without some undesirable features. Pulverized coal brings with it additional costs and complications of equipment. Forty per cent of the finely divided flocculent ash would pass up the stack and spread itself upon the surroundings were not strenuous efforts made to precipitate most of it. More power is required than for stokers. Low excess air and high capacity raise the temperature of the furnace to where it must be water-cooled to avoid excessive refractory maintenance. Low fusion point ash in particular must be carefully handled or else the boiler will be out of service for slag removal most of the time.

The extremely small size of the pulverized coal particles must be realized. A typical sample will have better than 99% through a 40-mesh screen, 90% through 100-mesh, and 65% through 200-mesh. Thus, it can be seen that the particles are extremely small, and an enormously larger combustion surface is presented than with lump coal. Hence, combustion occurs rapidly—from ¼ to 4 seconds is required with different fuels and burners.

There are two pulverized coal systems. They are called the central system (bin system) and the unit system. A central pulverizing system employs a limited number of larger capacity pulverizers at a central preparation point to prepare coal for all the burners. The driers as well are conveniently installed at this preparation point. From the pulverizers the coal is transported to a central storage bin where it is deposited and its transporting air vented through a "cyclone." The central bin will contain from 12 to 24 hours' supply. The coal is then transported from the central bin to secondary bins, each supplying a burner or group of burners through the medium of "feeders" of varied design. Primary air is added at the feeders.

The unit system is so called from the fact that each burner, or burner group, and pulverizer constitute a unit. Crushed, and sometimes dried, coal is fed to the pulverizing mill at a variable rate governed by the combustion requirements of the boiler and furnace. Preheated primary air is admitted to the mill and is the transport air which carries the coal through the short delivery pipe to the burner.

The pulverizing mills of present design may be classified as (1) impact mills in which a series of swinging hammers or falling balls pulverize the coal, (2) roller mills in which grinding is done by crushing between rollers or balls and a race, (3) chopping or attrition mills.

Pulverized coal can be transported mechanically or pneumatically. Screw conveyors are generally short, straight, and horizontal. The pneumatic system offers more flexibility. The air pressure system is one of intermittent delivery, suitable for transporting from bin to bin. In the air mixture system primary air, representing a weight several times that of the coal, is mixed with the coal and carries the coal along in suspension. The air pumping system uses much less air, only enough to render the coal sufficiently fluid to be pumped by pumps.

Type of burners depends on fineness of coal, moisture and volatile content, method of mixing air and fuel, percent total air as primary, and characteristics of the furnace. There are two general types of burners, the long and the short flame. The long flame is produced by moderate-tip velocities coupled with an admission of secondary air through openings in the setting located along the traverse of the flame. These long-flame burners are generally in multiple, directed vertically downwards into the furnace. Short-flame burners are ordinarily set in horizontal position. A short-flame burner produces complete mixture just beyond the burner tip by violently whipping the secondary air through the primary air and fuel. (F.T.M.)

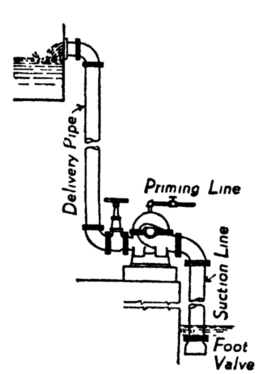
PULVERIZED COAL COMBUSTION. Burner.

PULVINUS. Movement in Plants.

PUMA. Mammalia, Carnivora. A large North American cat of uniform tawny to brownish color. The puma proper, *Felis concolor,* is—or was—a species of the eastern half of the continent, ranging from Virginia into Canada. It is now extinct in the settled parts of the country but may still exist in wilder areas. A darker species, *F. coryi,* is found in Florida, a third species, *F. arundivaga,* in Louisiana, and a fourth variable species called the western puma or mountain lion, *F. oregonensis,* ranges from Mexico into Canada. The eastern species has been variously called the cougar, mountain lion, panther, catamount, and painter. It is a menace to stock and sheep but is cowardly in its relations with man. (A.W.L.)

PUMICE. Rhyolitic lavas with a high gas content, when suddenly discharged by volcanic action, congeal in the form of highly vesicular natural glass called pumice. When ground, mixed with an appropriate binder and pressed into cakes it is the "pumice stone" of commerce which is used as a light abrasive. (E.S.C.S., R.M.F.)

PUMP EFFICIENCY. The static head is the height (usually in ft.) of the surface of the water above the gauge point. The pressure head is the static head plus gauge pressure on the water surface plus friction head, all being reduced to the same unit of pressure. Velocity head is the head required to produce a flow of water. The dynamic head is the pressure head plus the velocity head. Except for water velocities considerably above average, or for large volumes handled at low heads, the velocity head can be neglected. For water at atmospheric temperature, 8.33 lbs. = 1 U. S. gal. = 231 cu. in.; also 2.31 ft. head of water = 1 lb. per sq. in. pressure. Hot water weighs less. If the suction head is less than atmospheric, it is given a minus sign. When the suction arrangement is as shown in the accompanying figure, the suction head = −(static head + velocity head + suction pipe and fittings friction loss + loss at entry to suction pipe (which is usually taken at $\frac{1}{2}V^2/2g$)).



Pump with vacuum suction.

Hydraulic efficiency

$$= E_h = \frac{\text{operating head}}{\text{operating head} + \text{pump head losses}},$$

$$\text{Over-all pump efficiency} = E_p = \frac{\text{water hp.}}{\text{drive hp.}},$$

Mechanical efficiency

$$= E_m = \frac{\text{theoretical pump head} \times \text{capacity}}{\text{drive hp.}},$$

$$E_p = E_h \times E_m.$$

(F.T.M.)

PUMPKIN. *Cucurbita Pepo.* **Gourd Family.**

PUMPKIN-SEED. Pisces, Teleostei. The common **sunfish,** *Eupomotis gibbosus.* A pond fish of the eastern and north central states, found also to a limited extent in streams. A good pan fish. (A.W.L.)

PUMPS, WATER. The function of a pump is to add to the pressure existing in a liquid an increment sufficient for the required service. This service may be the production of a velocity, or the overcoming of friction or external pressure. One of the earliest types of pump to be used was the suction or lift pump (Fig. 1). The

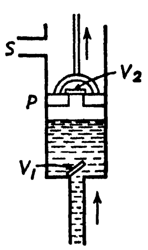


Fig. 1.
Suction or lift pump.

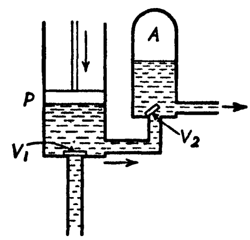

Fig. 2.
Cylinder force pump.

upward movement of the piston P lowers the pressure in the cylinder and pipe below it, and the liquid is forced up into this space by the atmospheric pressure. On the down-stroke, the valve V_1 closes, imprisoning the liquid in the cylinder; while the piston valve V_2 opens, allowing the piston to plunge into the liquid and draw it up on the subsequent up-stroke, so that it can escape through the spout S. An ordinary cistern pump is of this type.

Another elementary type of pump is the cylinder force pump (Fig. 2). In this the first operation is the same as in the lift pump. There is, however, no valve in the piston, but instead one in the outlet at the side of the cylinder, opening outward, so that the down-stroke forces the liquid out against a pressure limited only by the force available to operate the piston. Such pumps usually have an air-chamber A to equalize the outflow of liquid.

Pumps are generally classed as follows:

1. Reciprocating pumps.
   a. Direct-acting steam; simplex and duplex.
   b. Power; single-acting simplex and triplex.
2. Centrifugal pumps.
   a. Single and multi-stage.
   b. Volute and turbine types.
3. **Rotary pumps.**
   a. Gear and screw pumps (mostly used for pumping oil).
   b. Propeller pumps.
   c. Lobe pumps.
4. Jet pumps.
   a. Steam jet injectors and ejectors.
   b. Water jet ejectors.

Essential data relating to any pump include the head in feet, capacity in gallons per minute, and properties of the liquid such as viscosity, temperature, corrosiveness, grittiness. Secondary data concerning the pump equipment are speed of rotation, power required, and first cost.

The **direct-acting** steam pump is a simple, inexpensive, and reliable piece of equipment—but inefficient as a pumping unit. Its principal use is as a steam boiler auxiliary and as the heat of the exhaust steam can often be recovered in the boiler feed water the low thermal efficiency is not of much importance.

Pumps driven by electric motors, or by steam used expansively, are called **power pumps.** Their over-all efficiencies are high because of the efficient drives.

The triplex pump is often used when the conditions indicate the reciprocating pump in preference to the

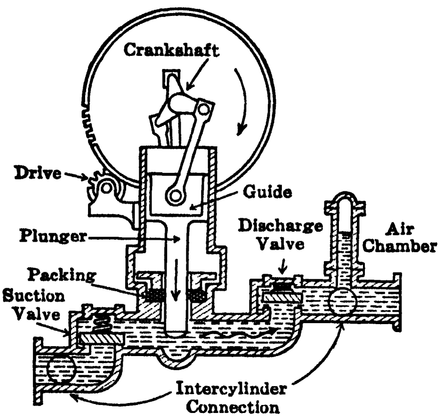

Fig. 3. Diagram of three-cylinder single-acting displacement pump.

centrifugal, and where an efficient pumping unit is required. Calling n the number of pumping strokes per minute, $D \times S$ the diameter $\times$ stroke, and E the volumetric efficiency of the pump (about 90% for pumps in good order) the

$$\text{Capacity} = \frac{ESnD^2\pi}{4 \times 231} \text{ gallons per minute.}$$

The **centrifugal pump** is a velocity machine, that is, its pumping action requires first, the production of a water velocity; second, the conversion of velocity **head** to pressure head. The velocity is given by the rotating impeller, the conversion accomplished by diffusing guide vanes in the turbine type, and in a volute casing surrounding the impeller in the volute type. With few exceptions, all single-stage pumps are of the volute type.

The **specific speed** of a centrifugal pump is $\frac{N\sqrt{Q}}{H^{3/4}}$. Ordinarily N is expressed in rpm, Q in gal. per min., and head H in feet. The specific speed of an impeller is an index to its type. Impellers for high heads usually have low specific speeds, while those for low heads have high specific speeds. The specific speed is a valuable index in determining the maximum suction head that may be employed without danger of cavitation or vibration, both of which adversely affect capacity and efficiency.

Allied to the centrifugal pump in several ways are the axial-flow pumps. An **axial-flow** pump, sometimes called a propeller pump, develops most of its head by the propelling action of the vanes in the liquid. It has a single-inlet impeller with the flow entering axially into a guide case. Where the head is developed partly by centrifugal action and partly by vane propulsion, the pump is called a **mixed flow** pump.

The injector is a jet-type feed pump, limited to regular service on small boilers and stand-by service on small and medium-sized boilers. Like the centrifugal pump, the

injector operates on the principle of a velocity-pressure conversion but differs from the centrifugal in the manner of creating the velocity. The water acquires its velocity by impact with high-velocity steam leaving an expanding nozzle. The injector will produce a pressure about 50 lbs. per sq. in. higher than the steam pressure used, but the water temperature should not exceed 150° F. The injector is simple, compact, inexpensive, and with no moving parts to wear or require adjustment. As a combined feedwater heater and pump its efficiency is high, but, as a pump alone, very low (less than 5%). Its characteristics recommend it to locomotive service but not to regular service in an efficient stationary plant where feed water is heated by other than live steam.

The selection of any pump is to be made with due regard to the drive. Reciprocating pumps are slow-speed machines, centrifugal pumps high-speed. Power pumps and centrifugal pumps require a driving motor, engine, or turbine. Variable capacity is obtained by throttling the discharge or changing the driver speed.

Mistakes are likely to be made in pump installation by overestimating the possible suction lift. For instance, suppose water is at 140° F. Water will begin to produce steam at this temperature as soon as the pressure is reduced to 2.887 lbs. per sq. in. Hence, the theoretical maximum static head is 2.31 (14.7–2.887), or 27 ft. But, under dynamic operating conditions, steam would be formed at this lift. To be safe against steam binding and separation of the water column, the maximum suction head should be limited. Hot water above 160° F. should be supplied under a positive head—at 200° F. there should be from 5 to 10 ft. head on the pump. Pumps, especially centrifugal, must be filled with water when starting under considerable suction head. A foot valve on the suction intake, if tight, will retain water in the pump, but the foot valves frequently leak slowly if the water contains grit or debris. To prime the pump a check valve by-pass line is satisfactory if there will always be water against the check valve; otherwise an independent fill line can be run to the pump. Steam jet ejectors and other vacuum equipment are often used to prime large pumps. (See **Ram, Hydraulic.**) (F.T.M.)

PUNCHING. Forging.

PUNKIE. Insecta, Diptera. Small biting **midges,** also called sandflies. They are found in abundance at certain times along streams in the eastern mountains, and at some parts of the seashore. (A.W.L.)

PUPA. The third stage of **insects** with complete **metamorphosis.** The pupa is a more or less inert stage but in some insects it retains the power of locomotion to a high degree. The pupae of mosquitoes are an example; they swim as freely as the larvae when disturbed. In contrast the pupae of butterflies and moths can merely move the abdominal segments and those of many flies are quite rigid. Among these inactive pupae some, like those of the **beetles** and **wasps,** have the legs and wings free and are called exarate. Others have the appendages closely attached to the body and are said to be obtected. Those of **Diptera** in some cases are enclosed in a hardened larval skin, the puparium, and are called coarctate pupae. The pupae of butterflies, often brightly colored and strangely shaped, are called chrysalids (singular, chrysalis or chrysalid). (A.W.L.)

PUPIL. The opening in the center of the iris of the eye for the transmission of light. The normal pupil is circular and regular in outline and is larger in the young than in adults. Both pupils should be of the same size. The iris acts as a shutter so that the pupil becomes smaller in bright light and when looking at nearby objects, and larger in darkness and upon looking at distant objects. The characteristics of the pupils, their size and speed of reaction, are of considerable value in the diagnosis of various diseases of the nervous system. In certain forms of late syphilis such as locomotor **ataxia** and **paresis,** the pupils do not dilate or contract in response to light and may be irregular and unequal in size. When morphine is given the pupils contract, and with large doses they become pin-point in size. **Belladonna,** or **atropine,** and **cocaine** dilate the pupil. (D.M.H.)

PURE BENDING. Bending Moment.

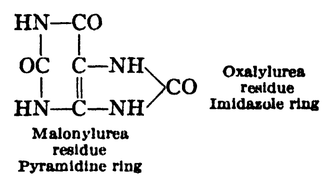
PURE CHEMISTRY. Chemistry.

PURE LINE. The descendants of a single self-fertilized individual. The term was established by the botanist, Johanssen, in his work with beans. He found that rigid selection according to size resulted in the establishment of strains in which the seeds varied constantly between certain limits, regardless of further selection. This constancy was most readily obtained by self-fertilization of the plants.

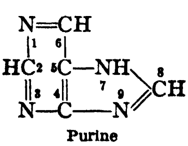
Since this discovery it has been recognized that **clones** and the descendants of genetically identical parents are equally uniform in heritage. These discoveries have an important bearing on **selection** as a factor in organic **evolution.** (A.W.L.)

PURE SHEAR. Shear.

PURINE AND URIC ACID COMPOUNDS. Purine compounds are derivatives of the dicyclodiureide of **malonic** and **oxalic acids.** The dicyclodiureide compound is uric acid



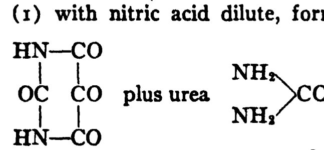
and purine, the parent compound, is



Purine

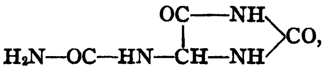
so that uric acid is 2,6,8-trioxypurine or the keto form of 2,6,8, trihydroxypurine. Caffeine, theobromine, and theophylline are other important purine compounds.

Uric acid ($C_5H_4O_3N_4$—formula above) is a white solid, insoluble in cold water, alcohol or ether, sparingly soluble in hot water. Uric acid is a weak dibasic acid thus forming two series of salts, most of which are very slightly soluble in water (**lithium** urate soluble). Uric acid reacts (1) with nitric acid dilute, forming alloxan

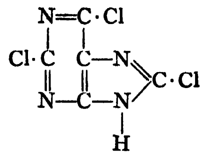


more vigorous treatment yielding oxalylurea 
plus **ammonia** plus **carbon dioxide.** The murexide test for uric acid is related to this reaction: Uric acid plus **nitric acid** dilute is evaporated to dryness, yielding red residue, which with **ammonium** hydroxide turns purple

or with **sodium** hydroxide blue, (2) with **potassium** permanganate in sodium hydroxide solution, forming allantoin



(3) with **phosphorus** oxychloride, forming 2,6,8-trichloropurine



and 2,6-trichloro-8-hydroxypurine. In these compounds chlorine may be replaced by such groups as methoxy (CH_3O—), ethoxy (C_2H_5O—), hydroxyl (HO—), hydrosulfide (HS—), iodide (I—), hydrogen (H—), and thus many derivatives are obtainable.

Uric acid is found in the urine, blood, and muscle juices of carnivorous animals (herbivorous animals secrete hippuric acid), in the excrement of birds, serpents and insects, and is an oxidation product of the complex nitrogenous compounds of the animal organism.

The following are other important purine compounds, which are also **alkaloids**:

1. Caffeine (theine)	1,3,7-trimethyl-2,6-dihydroxypurine
2. Theobromine	3,7-dimethyl-2,6-dihydroxypurine
3. Theophylline	1,3-dimethyl-2,6-dihydroxypurine
4. Xanthine	2,6-dihydroxypurine
5. Hypoxanthine	6-hydroxypurine
6. Guanine	2-amino-6-hydroxypurine
7. Adenine	6-aminopurine

Caffeine is present in tea leaves (2–5%), in coffee beans (0.75–1.75%), in cola beans (Soudan coffee), (1–2.5%), in cocoa beans (0.1–0.8%); theobromine in cocoa and cola beans, in small amount in tea leaves, and absent from coffee beans; xanthine in beet root juice, in tea leaves, and in sprouting seeds; hypoxanthine and guanine in beet root juice and in tea leaves. (R.K.S.)

PURKINJE EFFECT. This effect, discovered by Abney and studied in some detail by Precht (1899), is perhaps better known as the gamma-wavelength effect. It refers to the variation in **gamma** with the wavelength region used in exposing a photographic material. The variation of gamma with the wavelength of the light makes it necessary to develop 3-color separation negatives for different times to secure three negatives of equal contrasts. It is a source of difficulty in the manufacture of integral tripack materials for color photography. Some present-day panchromatic emulsions show a marked decrease in contrast when exposed to red light, others an increase in contrast. There is as yet no satisfactory explanation of this effect. (C.B.N.)

PURLIN. Bent.

PURPURA. Bleeding into the skin or mucous membranes, producing areas of discoloration which vary in size from pin-point (petechiae) to several inches or more (ecchymoses). Purpura occurs as a symptom of many diseases and its mode of production varies. It is a characteristic feature in the disease **purpura hemorrhagica.** Symptomatic purpura occurs in **scurvy,** as a result of lack of **vitamin** C; in liver disease and disease of the biliary tract due to interference with the production of **vitamin** K; in some acute infections, particularly meningococcus **meningitis,** due to a toxic factor which increases capillary permeability; in **leukemia** and allied disorders, in toxic reactions to drugs (arsenicals, gold salts, phenobarbital), and acute or chronic **purpura hemorrhagica,** in all of which diminished blood platelets are responsible for failure of blood coagulation and abnormal bleeding. Purpura also occurs in various obscure blood diseases of unknown origin. (D.M.H.)

PURPURA HEMORRHAGICA (Thrombocytopenic Purpura). A disease of unknown etiology, characterized by diminution of the blood platelets (see **blood**) and spontaneous hemorrhages into the skin and **mucous membranes.** Females are affected more often than males, and the disease is commonest in children. Acute and chronic forms occur. Treatment of the acute case consists of repeated blood **transfusions.** Remissions and not infrequently permanent recovery occur with this form of purpura. Surgical removal of the spleen is effective in the control of chronic cases, although the mechanism by which such cure is achieved is not understood. (D.M.H.)

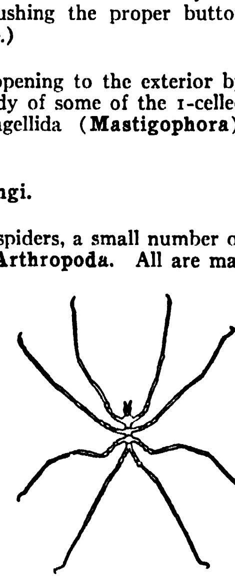
PUS. The liquid product of infection in the body. It is made up of cellular debris, micro-organisms, and white **blood** cells (leukocytes). Pus varies greatly in color, consistency and odor. When pus is present as a localized collection in tissue, an abscess is said to be present. Treatment is incision and drainage of the abscess. (R.S.M.)

PUSHBUTTON TUNING. Pushbutton tuning is a semi-automatic method of tuning a radio **receiver** to any one of several preselected stations. The usual types may be divided into two classes, mechanical and electrical. The first is simply a mechanical linkage between the pushbutton on the panel and the tuning condenser or coil in the set. To set this type the linkage is adjusted to vary the tuning just the right amount to set the receiver to the desired station. In the more refined electrical system each button switches in a fixed tuning unit which has been pre-set to the desired frequency. Since these frequencies can be very accurately set and require no mechanical linkages, the results are more satisfactory than the mechanical type. In either type, however, the various buttons and associated circuits or mechanisms are pre-adjusted for various commonly desired stations and then by pushing the proper button the station is tuned in. (L.R.Q.)

PUSULE. A large vacuole opening to the exterior by a canal. It is found in the body of some of the 1-celled animals of the order Dinoflagellida (**Mastigophora**). (A.W.L.)

PYCNIOSPORE. Rust Fungi.

PYCNOGONIDA. The sea spiders, a small number of species constituting a class of **Arthropoda.** All are marine, crawling about on plants and sessile animals. The body is very small and the legs very long, hence the animals seem like clusters of legs attached to each other. They have a sucking mouth. (A.W.L.)



Sea spider.

PYCNOMETER. A device for measuring densities of liquids. It is a container, usually in the form of a bottle or a pipette-like tube, the capacity of which is accurately known and which may be completely filled with the liquid. The difference in weight when filled and when empty, together with the known volume of the liquid, gives the density. The pipette form has a mark to show how far to fill it, and is bent into a V-shape to facilitate immersion in a temperature bath. A familiar

design is the "specific gravity bottle," a small flask with a ground and perforated stopper, and sometimes provided with a thermometer. In one of the most precise forms the stopper has a conical top with the capillary leading to the apex, and both neck and stopper are covered by a tight-fitting ground-glass cap to prevent evaporation.

A preliminary step necessary to precise work with the pycnometer is the determination of its two volume constants; that is, the constants of the linear equation expressing the capacity as a function of the temperature. This is done by filling with distilled water and weighing accurately several times at each of two temperatures near the ends of the range for which the pycnometer is to be used. The bottle form is also adapted to the precise measurement of densities of solids. (See **Density and Specific Gravity.**) (L.D.W.)

PYELITIS, PYELONEPHRITIS. Pyelitis is an infection of the pelvis of one or both **kidneys.** *B. coli* is the commonest causative bacterium, although **streptococci** and **staphylococci** may cause the disease. Infection may occur from the blood stream, or by way of retrograde extension from infection in the **bladder** and **ureters.** Local conditions in the pelvis of the kidney such as congenital anomalies of structure, stones, or stasis due to obstruction to the flow of urine at any point in the urinary tract, predispose to pyelitis. Dilatation of the ureter and kidney pelvis are not uncommonly associated with pyelitis in **pregnancy.**

The symptoms of acute pyelitis are usually sudden in onset; chills, high fever, pain in the flanks and back, and sometimes nausea and vomiting occur. Frequent, painful urination is common. The urine is cloudy, and loaded with **bacteria** and pus cells (white **blood** cells). The symptoms subside rapidly with early treatment with **sulfonamides** in the majority of cases.

Pyelonephritis is an almost invariable complication of pyelitis. It is a more serious disease because the infection spreads to invade the functional part of the kidney, the parenchyma of the organ. The symptoms and signs are similar to those of pyelitis, but more severe Treatment, as with pyelitis, is with sulfonamides and large amounts of fluid. If pyelonephritis becomes chronic, late cardio-vascular complications with **hypertension** and kidney failure may occur.

Pyelonephrosis, or dilatation of the pelvis of the kidney with pus, occurs as the end-picture of severe pyelonephritis. It is associated with marked destruction of kidney tissue. Surgical removal of the kidney is usually necessary. (D.M.H.)

PYELOGRAM. A diagnostic **x-ray** picture of the kidney and **ureter.** This is made by one of two methods. In one, opaque fluid is injected upward through fine catheters inserted into the ureters, after a **cystoscope** has been passed into the bladder. With the other method a radio opaque substance is injected into the blood stream. This material is excreted by the kidneys and shows up the urinary passages when the x-ray is taken. (D.M.H.)

PYGIDIUM. 1. The united caudal segments of the extinct **trilobites,** a group of **arthropods** ancestral to the insects. 2. A caudal portion of the body of some scale insects made up of four fused segments. 3. The terminal segment of the abdomen of a **beetle** when exposed beyond the elytra. (See **Invertebrate Paleontology.**) (A.W.L.)

PYLORUS. The narrow muscular passage from the stomach into the **duodenum.** The pylorus is under a complex nerve control and food can only pass from the stomach when this muscular **sphincter** relaxes. It is in the immediate vicinity of the pylorus that **ulcers** most frequently occur. **Peptic ulcer** or **cancer** in this location may obstruct the passage of food through the pylorus and make surgical interference imperative. Pyloric stenosis is a congenital constriction of the pylorus which results in vomiting and obstruction in early infancy. The situation is remedied surgically by cutting the constricting bands. (R.S.M., D.M.H.)

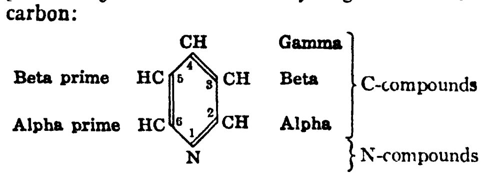
PYORRHEA. A disease of the gums and structures supporting the teeth, characterized by degeneration and infection of these tissues, resorption of the alveolar bone, and loosening of the teeth. Pyorrhea occurs commonly in old age. Although the primary cause is not known, predisposing causes are manifold. They include local irritation, trauma, malocclusion, ill-fitting fillings and crowns, poor hygiene, faulty tooth-brushing, etc. The role of nutrition and general health is not well understood. Treatment is directed toward clearing the infection and removing badly involved teeth. (D.M.H.)

PYRARGYRITE. An **antimony**-bearing **silver** mineral corresponding to the formula Ag_3SbS_3. It crystallizes in the **hexagonal** system, commonly in **rhombic** prismatic forms. It displays a rhombohedral **cleavage;** fracture, conchoidal to uneven; brittle; hardness, 2.5; specific gravity, 5.77–5.85; luster, metallic; color, grayish-black to black. In thin fragments deep red by transmitted light, otherwise practically opaque; streak, purplish red. Pyrargyrite occurs with **proustite,** other silver minerals, and **galena, sphalerite,** etc. It is found in the Harz Mountains, in Czechoslovakia, Bolivia, Chile, Mexico, and in the United States in Colorado, Idaho, and Nevada. In Canada it is found in the Cobalt region of the Province of Ontario. It derives its name from the Greek words meaning fire and silver. (E.S.C.S.)

PYRHELIOMETER. **Meteorological Instruments.**

PYRIBOLE. A convenient term for the **hornblende** and **pyroxene** groups of dark minerals which are easily distinguishable with the naked eye from the black **mica, biotite,** but not from each other, when they occur in a fine-grained rock. (R.M.F.)

PYRIDINE AND RELATED COMPOUNDS. Pyridine, monazine (C_5H_5N), contains a ring of 1 nitrogen and 5 carbons with 1 hydrogen attached to each carbon:



Pyridine is a colorless liquid, boiling point 115° C., of unpleasant odor, miscible in all proportions with water, alcohol, or ether, forms salts with acids, the **perchlorate** and **ferrocyanide** sparingly soluble in water and used in the separation and identification of pyridine, reacts only under drastic conditions with **chlorine, bromine, sulfuric acid** (forms beta-pyridine sulfonic acid at 300° C. with concentrated sulfuric acid); non-reactive with **nitric acid, chromic acid, potassium** permanganate. Pyridine may be reduced by **sodium** and **alcohol** to piperidine (below), and by heating with **hydriodic acid** to normal-pentane. Pyridine is obtained in the destructive distillation of fat-containing bones—in Dippel's oil—and in small proportions in the similar distillation of coal, peat, carboniferous shales, wood, and in the treatment of various **alkaloids** with **alkalis,** or when they are heated alone or with zinc dust. Pyridine may be detected by the appearance of a red color on addition, to the aqueous solution, of a trace of cyanogen bromide and a few drops of aniline. Pyridine is used

as a solvent, especially in the purification of **anthracene,** and as a denaturant of **ethyl alcohol.**

Picolines and Pyridine Carboxylic Acids. Alpha-picoline, alpha-methylpyridine, 2-methylpyridine  colorless liquid, boiling point 128° C., on oxidation yields picolinic acid, pyridine-alpha-carboxylic acid, sublimes 135° C.

Beta-picoline, beta-methylpyridine, 3-methylpyridine  colorless liquid, boiling point 144° C., on oxidation yields nicotinic acid, pyridine-beta-carboxylic acid, sublimes 228° C.

Gamma-picoline, gamma-methylpyridine  colorless liquid, boiling point 143° C., on oxidation yields isonicotinic acid, white solid, melting point 309° C.

Lutidines. Six dimethylpyridines and three ethylpyridines are known.

Collidines. Collidine, symmetrical-trimethylpyridine (2,4,6), is  colorless liquid, boiling point 172° C. Other isomerides numbering 21 are theoretically possible.

Hexahydropyridine, piperidine  colorless liquid, boiling point 106° C., miscible in all proportions with water, alcohol, ether, or benzene, is formed by the action of sodium and alcohol on pyridine. Piperidine may be obtained by treatment of the **alkaloid** piperine of the pepper plant, by heating with **alkali.**

Azines. When **carbons** of pyridine (monazine) are replaced in succession by **nitrogen,** polyazines are formed, thus:

Orthodiazine (pyridazine)  colorless liquid, boiling point 205° C. (755 mm.).

Metadiazine (pyrimidine)  melting point 21° C., boiling point 124° C. This nucleus is contained in purine compounds and cyclic ureides. Derivatives of pyrimidine are of great importance in physiological processes, e.g., 5-methyl-2, 6-dihydroxypyrimidine (thymine) of the cell nucleus.

Paradiazine (pyrazine)  melting point 55° C., boiling point 115° C., of agreeable odor.

Reduction of pyrazine yields hexahydropyrazine (piperazine)  melting point 104° C., boiling point 145° C., soluble in water, and strongly basic.

Quinoline and isoquinoline are benzopyridines (C_9H_7N).

Quinoline  is a colorless liquid, boiling point 238° C., of characteristic odor, slightly soluble in water, miscible with alcohol, ether, and many organic liquids in all proportions, forms **salts** with **acids,** the dichromate sparingly soluble in water, reacts with concentrated sulfuric acid by sulfonation of the **benzene** nucleus, with nitric acid with difficulty (5-nitroquinoline and 8-nitroquinoline), with **chromic** acids in sulfuric acid not reactive, with **permanganate** forms quinolinic acid  melting point 192° C., plus oxalic acid. Quinoline may be reduced to tetrahydroquinoline  boiling point 245° C., by sodium plus alcohol, or zinc plus hydrochloric acid, and to decahydroquinoline  solid, melting point 48° C., boiling point 204° C., by **hydriodic acid** and **phosphorus** heated. Quinoline is found in bone oil and coal tar, and is produced by distillation of many **alkaloids,** e.g., cinchona alkaloids. The classical synthesis of quinoline by Skraup is the reaction of aniline  plus **glycerol** ($CH_2OH{\cdot}CHOH{\cdot}CH_2OH$), using **nitrobenzene** in **sulfuric acid** heated as oxidizing agent.

Methylquinolines are quinaldine, 2-methylquinoline  boiling point 247° C., lepidine, 4-methylquinoline  boiling point 257° C. When either of these is treated with ethyl iodide plus ethyl orthoformate in the presence of pyridine, cyanine compounds are formed. Cyanines are dyes used in color photography.

Carboxylic acids of quinoline are of two types, (1) those where the carboxyl group (—COOH) is attached to the **benzene** nucleus. These can be made by the Skraup method using the desired aminobenzoic acid, (2) those where the carboxyl group is attached to the pyridine nucleus, thus, quinoline-2-carboxylic acid, quinal-

dinic acid  melting point 156° C., quinoline-4-carboxylic acid, cinchoninic acid  melting point 254° C., 6-methoxyquinoline-4-carboxylic acid, quininic acid  melting point 280° C. (decom.).

Isoquinoline  white solid, melting point 23° C., boiling point 243° C., forms salts with acids, the sulfate sparingly soluble in water. Isoquinoline is important as a constituent of certain vegetable **alkaloids.**

Acridine is dibenzopyridine ($C_{13}H_9N$ or $C_6H_4\langle \substack{CH \\ N} \rangle C_6H_4$ or ) white solid, melting point 108° C., boiling point 346° C. Phenazine is dibenzopyrazine (dibenzoparadiazine) ($C_{12}H_8N_2$ or $C_6H_4\langle \substack{N \\ N} \rangle C_6H_4$ or ) yellow solid, melting point 171° C., from which important dyes, e.g., safranines, are derived.

Phenoxazine is  white solid, melting point 148° C.

Where **nitrogen** of pyridine is occupied by **oxygen,** pyrone is the compound, and where occupied by **sulfur,** penthiophene; similarly, where nitrogen of quinoline by oxygen chromone is the compound, and where by sulfur, thionaphthalene, and where nitrogen of acridine by oxygen, xanthene, and by sulfur, thioanthracene.

Compounds containing 1 (or more) nitrogens and 4 (or less) carbons in the ring (5-membered) are discussed under **Pyrrole and Related Compounds.** (R.K.S.)

PYRIFORM GLAND. Glands of the **spiders** which secrete silk for the formation of the disks by which threads are anchored. (A.W.L.)

PYRIFORM ORGAN. An organ of unknown function found in the Cyphonautes **larvae of bryozoans.** (A.W.L.)

PYRITE. The mineral pyrite or iron pyrites is **iron disulfide,** FeS_2, its **isometric** crystals usually appearing as cubes or **pyritohedrons.** It has a slightly conchoidal to uneven fracture; brittle; hardness, 6–6.5; specific gravity, 4.95–5.10; metallic luster; color, pale to normal brass-yellow; streak, greenish-black; opaque. **Arsenic, nickel, cobalt, copper,** and **gold** may be found in small quantities in pyrite, auriferous pyrite being sometimes a very valuable ore. Pyrite is the commonest of the sulfide minerals, and is of world-wide occurrence. It is found associated with other sulfides, or with oxides, in **quartz** veins, in **sedimentary** and **metamorphic** rocks, in coal beds, and as the replacement material in **fossils.** There are many well-known pyrite localities, among which are the Rio Tinto mines in Spain, where copper-bearing pyrite is obtained from huge deposits. In the United States pyrite is found in California, New York, and Virginia in workable deposits. Pyrite is used in the production of sulfur dioxide for the paper industry and the making of sulfuric acid. Its use seems to be on the wane because of the cheapness of Louisiana sulfur. By-product pyrite, obtained from coal, however, is a commercial source of sulfur dioxide in the Illinois region. The name pyrite is derived from the Greek word meaning fire, because of the sparks which result when pyrite is struck with steel. (E.S.C.S.)

PYROCLASTS. A general term for fragmental, volcanic ejectamenta such as **agglomerates,** ashes and **tuffs.** (R.M.F.)

PYROGENETIC MINERALS. A term for the primary **magmatic** minerals of **igneous rocks** as distinguished from those minerals which are the result of special and later processes such as come under the head of pneumatolytic, hydrothermal, etc. (R.M.F.)

PYROLUSITE. The mineral pyrolusite, **manganese** dioxide, MnO_2, appears to be **orthorhombic,** but may be only **pseudomorphous** after **manganite.** It is found massive or in indistinct crystalline aggregates, often acicular. It is soft, hardness, 2–2.5; specific gravity, 4.73–4.86; luster, metallic; color, steel gray to black; streak black; opaque. Pyrolusite is found as replacement deposits and as residual and sedimentary masses. **Psilomelane** is its usual associate. European localities for pyrolusite are in Bohemia, Saxony, the Harz Mountains, England, and elsewhere. Other deposits occur in India and Brazil. In the United States it is found in Arkansas and Michigan. It is an ore of manganese, is used as a pigment and as an oxidizing agent in glass manufacture. It is from this latter use that it derives the name pyrolusite from the Greek words meaning *fire* and *to wash.* (E.S.C.S.)

PYROMETER. By common usage, the pyrometer is the device for measuring high temperatures. Actually, there are pyrometers which are much used for measuring temperatures in the same range as thermometers, but several of the pyrometers are suitable only for high temperatures. Three types of pyrometers are described as being typical of the entire group. These are (1) the thermoelectric (see **Thermel**) pyrometer, (2) the **optical pyrometer,** (3) the **radiation pyrometer.** (A fourth type, the **resistance pyrometer,** is not commonly used for high-temperature industrial work.)

The thermocouple pyrometer is a convenient meter for measuring a number of high-range temperatures. By means of the rotary switch shown in the diagram a number of thermocouples may be connected in turn to the indicator. The thermocouple is a pair of electrical conductors of different material permanently joined at one end, the other ends being free to connect to an instrument for measuring electromotive force. The indicating instrument is essentially a potential **galvanometer** measuring e.m.f.'s of the magnitude of 50–70 millivolts. The thermocouple itself is delicate and is enclosed in a protecting tube.

An optical pyrometer, as the diagram shows, is one in which the eye compares the radiation emanating from an incandescent object whose temperature is to be measured, with that of a filament electrically heated in the tube of the pyrometer. By interposing between the eye and the hot body a red glass screen, monochromatic light is received by the eye. The current to the bulb is adjusted by rheostat until the intensity of emission

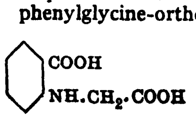
feces, (2) C-methyl indole (2)  white, odorous solid, melting point 60° C., boiling point 268° C., (3) N-methyl indole  colorless liquid, boiling point 240° C., without unpleasant odor.

Carboxylic acids of indole are (1) indole-3-acetic acid  white solid, melting point 164° C., heated above this temperature decomposes into skatole plus **carbon dioxide,** (2) indole-3-alpha-aminopropionic acid, tryptophane  melting point 289° C. (decomp.), which gives rise to the derivatives of indole formed during the putrefaction of **proteins,** and yields indole-3-ethyl alcohol, trypophol  white solid, melting point 59° C., by **fermentation** with **yeast** in the presence of sugar.

Indoxyl is 3-hydroxyindole  yellow solid, melting point 85° C., disagreeable odor, reacts also as keto-form, pseudo-indoxyl  hypothetical, on exposure to air oxidizes to indigotin.

Indoxylic acid is 3-hydroxyindole-2-carboxylic acid

 or 
white solid, melting point 178° C. (decom.), and forms an intermediate product in the technical synthesis of **indigo** from phenylglycine-ortho-carboxylic acid



Isatin  or 
red solid, melting point 199° C., sublimes, is related to indole and indigo.

Indigo blue, indigotin 
may be made synthetically by reaction of anthranilic acid (ortho-aminobenzoic acid),  and monochloroacetic acid to form phenylglycocoll ortho-carboxylic acid, which with fused sodium hydroxide yields indoxyl carboxylic acid and then indoxyl. Indoxyl, upon exposure to air, oxidizes spontaneously to indigotin. Since indigotin is insoluble and has no dyeing properties as such, it is customary in dyeing to reduce to soluble indigo white  by **calcium** hyposulfite (CaS_2O_4) in alkaline solution, to immerse the cotton fiber in the solution (vat-dyeing), and then withdraw the fiber from the bath and expose to the air, whereupon indigotin is formed in the fiber. In dyeing wool, soluble indigo disulfonic acid, "indigo-carmine," is used.

Monobromo and dibromoindigotin are valuable **dyes,** sometimes used instead of indigo.

Carbazole is dibenzopyrrole, diphenyleneimine ($C_{12}H_9N$ or $C_6H_4 \cdot NH \cdot C_6H_4$ or ) white solid, melting point 245° C., boiling point 355° C.

Indazole  and isindazole  hypothetical are benzopyrazoles, derivatives of which have been prepared.

Benziminazole is  melting point 170° C.

Where **nitrogen** (group —NH) of pyrrole is occupied by **oxygen,** furane is the compound, and where occupied by **sulfur,** thiophene; similarly, where nitrogen of indole by oxygen, coumarone is the compound, and where by sulfur, benzothiophene; and where nitrogen of carbazole by sulfur, diphenylene sulfide.

Compounds containing 1 (or 2) nitrogen and 5 (or 4) carbons in the ring (6-membered rings) are discussed under **Pyridine and Related Compounds.**

Oxygen-nitrogen ring compounds:

Oxazole  Isoxazole 
Benzoxazole

 melting point 30° C., boiling point 182° C.

The following tetrapyrrole pigments are known:

1. Chain-compounds. Bile pigments.
   - a. Bilirubin .... ($C_{33}H_{36}N_4O_6$). The orange pigment of **bile.**
   - b. Biliverdin ..... ($C_{33}H_{36}N_4O_8$). The green pigment of bile.
   - c. Mesobilirubinogen .... By reduction of bilirubin.
   - d. Mesobilirubin.. The brown pigment of **urine.**
   - e. Uteroverdin ... The green pigment of egg-shells, of the **placenta** of the dog, and of the gall-stones of the ox.
2. Ring-compounds. Porphyrins: chlorophyll and blood pigments.
   - f. Ooporphyrin... ($C_{34}H_{34}N_4O_4$). The brown pigment of egg-shells.

g. Uroporphyrin . ($C_{38}H_{38}N_4O_{16}$). Found in the blood and urine in cases of congenital porphyrinuria.

h. Haematoporphyrin . . ($C_{34}H_{38}N_4O_6$).

i. Aetioporphyrin ($C_{32}H_{38}N_4$).

3. Metallic compounds. Porphyrans.

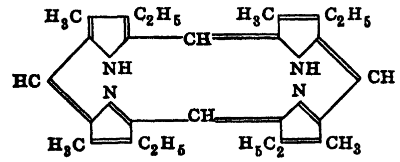
j. Aetiophyllin . . . The **magnesium** porphyran of **chlorophyll.**

k. Haematin . . . . . The iron porphyran of **haemoglobin**

l. Cytochrome . . The respiratory iron porphyran of tissues.

m. Turacin . . . . The copper porphyran of the feathers of birds.

Aetioporphyrin has been derived from natural sources, and also made synthetically. Chlorophyll, the green pigment of leaves, and haemoglobin, the red pigment of blood, are related to aetioporphyrin. The formula of aetioporphyrin is



(R.K.S.)

PYRROLIDINE. Pyrrole and Related Compounds.

PYTHON. Reptilia, Sauria. Large **snakes** related to the boas. The several species are distributed through Asia, Africa, and Australia. They are largely arboreal, living in forests, usually near the water, which they enter freely. Some of these snakes are very large, the Regal python, *Python reticulatus,* attaining a length of 30′, and one of the African species, *Python sebae,* more than 20′. They are not poisonous, but because of their size and strength they may be dangerous to man under some conditions. (A.W.L.)

Q

Q. This is the figure of merit of a coil and is the ratio of its reactance to its resistance. (L.R.Q.)

QUADRANTAL ANGLES. Angles.

QUADRANT ELECTROMETER. Electroscopes and Electrometers.

QUADRATE BONE. A small bone of roughly quadrangular shape in the **vertebrate** skull. In the **reptiles** and lower forms it is included in the articulation of the lower jaw with the skull, and a similar condition persists in the birds. In the mammal the incus or anvil, one of the three small bones of the middle **ear**, is regarded as the homologue of this bone. (A.W.L.)

QUADRATIC EQUATIONS IN ONE UNKNOWN. A quadratic equation in one unknown is an **equation** of the form

$$ax^2 + bx + c = 0 \quad (a \neq 0),$$

where a, b, c are **constants** (independent of x), and x is the unknown.

A quadratic equation may be solved (1) by **factoring,** (2) by completing the square, (3) by the quadratic formula, or (4) graphically.

If a quadratic equation can be factored by inspection into linear factors, as $a(x - \alpha)(x - \beta) = 0$, then the **roots** are α and β.

The method of completing the square consists in transposing the constant term, adding a term to both sides to make the left-hand side a perfect square of a binomial, extracting the square root of both sides and solving the resulting **linear equations.**

The roots of the quadratic equation $ax^2 + bx + c = 0$ may also be found immediately by use of the quadratic formula:

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}.$$

One graphical method for solving a quadratic equation $ax^2 + bx + c = 0$ is to plot in **rectangular coordinates** the **graph** (a **parabola**) **of the function** $y = ax^2 + bx + c$, and then find the **abscissas** of the points where this parabola cuts the X-axis. This gives only the real roots of the equation.

Another graphical method for the solution of the equation $ax^2 + bx + c = 0$ is obtained by drawing the graph in rectangular coordinates of the equation $y = x^2$ and on the same diagram the graph of the straight line $ay + bx + c = 0$, and finding the abscissas of the points of intersection of these two graphs.

The character of the roots of a quadratic equation is determined by an inspection of the discriminant of the equation, as follows:

If the coefficients a, b, c of the quadratic equation $ax^2 + bx + c = 0$ $(a \neq 0)$ are real numbers, then:

if $b^2 - 4ac > 0$, the roots are real and unequal,

if $b^2 - 4ac = 0$, the roots are real and equal,

if $b^2 - 4ac < 0$, the roots are complex numbers.

If the coefficients a, b, c are rational numbers and if $b^2 - 4ac > 0$, then:

if $b^2 - 4ac$ is a perfect square, the roots are rational,

if $b^2 - 4ac$ is not a perfect square, the roots are irrational.

For this reason, the expression $b^2 - 4ac$ is called the discriminant of the equation.

The relation between the roots x_1 and x_2 and the coefficients of the equation $ax^2 + bx + c = 0$ are given by:

the sum of the roots $x_1 + x_2 = -b/a$,

the product of the roots $x_1x_2 = c/a$.

An equation is said to be in the quadratic form if it can be transformed into a quadratic equation by means of the substitution of a new variable representing an expression involving the original unknown. Such equations can be solved by use of the methods for quadratic equations. (L.L.S.)

QUADRATIC EQUATIONS, SYSTEMS OF. The usual types of **systems of equations** involving **quadratics** are: the linear-quadratic systems, in which one equation is **linear** and one quadratic, and the quadratic-quadratic systems, in which both equations are quadratic.

Both types of systems of equations may be solved graphically, by constructing the **graphs** of the equations on the same diagram and finding their intersection points. In the case of the linear-quadratic system, the graphs will be a **straight line** and a **conic,** which will intersect in, at most, two points. For the case of the quadratic-quadratic system, the graphs will be two conics, which will intersect in, at most, four points. The **coordinates** of the intersection points in either case will give only the real solutions.

Linear-quadratic systems of equations may be solved algebraically by solving the linear equation for one unknown in terms of the other, and this result substituted in the quadratic equation gives a **quadratic equation** in one unknown.

There is no single uniform method for solving quadratic-quadratic systems, but several simple methods will handle the majority of cases.

If both equations of the system are of the form $ax^2 + by^2 = c$, they can be solved as a linear system in x^2 and y^2, and then x and y immediately found.

If both equations are of the form $ax^2 + bxy + cy^2 = d$, we may eliminate the constant terms between the two equations and obtain a single equation of the form $Ax^2 + Bxy + Cy^2 = 0$; this quadratic equation may be solved to obtain one unknown as a **linear function** of the other. Substitution of the linear expressions in one of the given equations and solving the resulting equation for the remaining unknown enables us to obtain the corresponding values of the other unknown by substitution.

Another method for this case is to substitute $y = vx$ in both equations, solve each resulting equation for x^2 and equate them, and solve the resulting equation for v, then substitute these values of v in one of the equations giving x^2, and thus find x; y can then be found from $y = vx$.

Other special devices can also be used. Systems of equations symmetrical in x and y can often be solved by special devices preserving symmetry, or often by the substitution $x = u + v$, $y = u - v$. (L.L.S.)

QUADRATIC FORM, EQUATIONS IN. Quadratic Equations.

QUADRATIC FORMULA. Quadratic Equations.

QUADRATIC FUNCTION. A quadratic function is a **polynomial function** of the second degree, and is therefore a **function** of the form $ax^2 + bx + c$, where a, b, c are **constants** and x is the **variable.**

The **graphic representation** in **rectangular coordinates** of a quadratic function $y = ax^2 + bx + c$ is a **parabola** with principal axis vertical (i.e., parallel to the Y-axis).

The value of x for which the quadratic function $ax^2 + bx + c$ takes its least value if $a > 0$, and its greatest value if $a < 0$, is $x = -b/2a$. This extreme value of the function is $\frac{4ac - b^2}{4a}$. (L.L.S.)

QUADRATURE. **Planetary Motions.**

QUADRIC SURFACES. A surface represented by an equation (in **rectangular coordinates**) of the second degree in x, y, z of the form $Ax^2 + By^2 + Cz^2 + Dyz + Ezx + Fxy + Gx + Hy + Iz + J = 0$ is called a quadric surface or a conicoid.

Every plane section of a quadric surface is a **conic section.**

By translation and rotation of axes, the general equation of the second degree in x, y, z may be reduced to one of several type forms, representing the types of surfaces: **ellipsoid** (including the **sphere**), **paraboloid, hyperboloid, cone, cylinder.**

A quadric surface which has a center of symmetry is called a central quadric. The ellipsoid and the hyperboloids are surfaces of this character. (L.L.S.)

QUADRUPLE PRODUCTS OF VECTORS. Important formulae for products of four **vectors** are:

$$(\mathbf{a} \times \mathbf{b}) \cdot (\mathbf{c} \times \mathbf{d}) = (\mathbf{a} \cdot \mathbf{c})(\mathbf{b} \cdot \mathbf{d}) - (\mathbf{a} \cdot \mathbf{d})(\mathbf{b} \cdot \mathbf{c}),$$

$$(\mathbf{a} \times \mathbf{b}) \times (\mathbf{c} \times \mathbf{d}) = [(\mathbf{c} \times \mathbf{d}) \cdot \mathbf{a}]\mathbf{b} - [(\mathbf{c} \times \mathbf{d}) \cdot \mathbf{b}]\mathbf{a}.$$

(L.L.S.)

QUAGGA. Mammalia, Perissodactyla. A South African animal, *Equus quagga,* related to the zebras and asses. It is reddish-brown above, blending to white on the legs, and is marked with dark brown stripes on the head, neck, and fore part of the body. A dark stripe also runs along the middle of the back and down the tail, but otherwise the hind quarters are unmarked. Also spelled couagga. (A.W.L.)

QUAIL. Aves, Galliformes. Small compactly built game birds (**Aves**) related to the partridges. Every continent has species of this name, but those of North and South America and those of the Old World belong

Quail (partridge, bob-white) *Colinus Virginianus.* Above, mottled, reddish brown and gray; under parts white barred with black. White spots on head in male; yellow in female.

to different divisions of the family. The widely distributed bob-white, *Colinus virginianus,* is the best known North American species. Some of the western species are known both as partridges and as quails, notably the valley quail of California, *Lophortyx californica,* and in the south the bob-white also receives the name partridge. Quails are swift-footed but their wings are short and they fly only short distances. Although their colors are mostly very quiet, they are beautiful birds. Both their appearance and their interesting habits make them desirable residents in any locality. (A.W.L.)

QUALITATIVE VARIABLE. A qualitative variable is one which is not measurable but possesses certain characteristics such as curliness of hair or type of body structure. In **industrial statistics** a product may be classified as defective or non-defective, a qualitative variable. (L.A.A.)

QUALITY. Quality is a term used in connection with **musical sounds.** It is also used technically to describe the condition of a **saturated vapor.** A vapor in a condition intermediate between liquid and a dry vapor is said to have a certain quality which may be defined as the ratio of the vaporized portion to the total weight of liquid and vapor. The vaporization of a liquid requires the expenditure upon it of the latent **heat of vaporization.** When heat to this amount is added, the liquid is converted to a dry vapor. If $x\%$ of this heat is added, only $x\%$ of the liquid is vaporized. x is the quality. (F.T.M.)

QUANTIC. A quantic is a **homogeneous algebraic function** of two or more variables, in general containing only positive integral powers of the variables, and so is usually a **polynomial** in several variables. Quantics are classified into quadratic, cubic, quartic, quintic, etc., according to degree, and into binary, ternary, quaternary, etc., according to the number of variables involved. (L.L.S.)

QUANTITATIVE VARIABLE. A quantitative variable is one which possesses measurable characteristics such as length, age, time, etc. (L.A.A.)

QUANTUM MECHANICS. A very general physical theory, or method of physical reasoning, recently recognized as necessary in dealing with entities so small that our laboratory instruments cannot furnish direct observations upon them. The underlying, revolutionary idea, developed primarily by Heisenberg, is that we are not justified in assuming any precisely foreordained and determinate position or motion for such a thing as an atom or an electron. If one throws a baseball, there are instruments which can measure its position and its velocity within limits small as compared with the size of the ball and the speed of its motion; and its subsequent behavior can be calculated with such precision as is afforded by those measurements. But with an atom or an electron, no corresponding proportionately accurate data can be obtained by any method of measurement at our command. Hence any prediction as to the particle's future performance is subject to error or ambiguity, large as compared with the quantities concerned. Instead of saying that an electron will be at such and such a place and have such and such a momentum at a given time, it is possible only to say that the position or momentum in question is more probable than any other, and to calculate how much more probable one assumed value is than another, neighboring value. Thus, the idea of a definite point occupied by an electron is replaced by a whole distribution of possible points, like the spatter of shots on a target. One curious feature, incidentally, is that the more accurately the position of one of these minute particles can be specified, the less determinate is its velocity, and vice versa. To deal with problems involving this "uncertainty principle," Heisenberg has developed a mathematical procedure involving the use of **matrices,** and this phase of the subject is known as "matrix mechanics." **Wave mechanics** is also an important feature of the more general theory. (L.D.W.)

QUANTUM NUMBERS. **Quantum Theory.**

QUANTUM THEORY. A general physical theory wherein it is recognized that in many, if not all, processes involving transfer of energy, the energy must be regarded as having an atomistic character, that is, as passing from one system to another only in discrete, finite increments or "quanta." Processes which, on the mass scale directly observable to our senses, appear to be quite continuous, may, when carried to atomic or electronic orders of magnitude, prove to be "quantized," that is, to proceed by small but finite jumps or readjustments. When water is poured from a tub, we observe no discontinuity in its flow, but when allowed to trickle from a pipette, it flows drop by drop. This is only a very crude analogy. A more valid illustration is this: if a spinning grindstone slows down, it appears to do so gradually; but there is reason to believe that when a molecule loses angular speed of rotation, it passes abruptly from one speed to another that is sometimes a little and sometimes much slower, and that the lost energy is emitted as a small or a large quantum of radiation (see **Molecular Spectra**).

The quantum theory had its inception when, in 1900, Max Planck first recognized, in the **spectral energy distribution of thermal radiation**, a statistical distribution of individual entities. This may be illustrated by supposing a whole season's crop of apples graded as to size, and the number of bushels of each size tabulated in order. Likewise the radiation output of a hot body can be graded into different-sized quanta (corresponding to wavelength), and the total amount of energy made up of each tabulated as the spectral energy distribution. It was only by adopting this view that Planck was able to reconcile theory with experiment in the study of **black-body** radiation.

Today we are accustomed to thinking of nearly all phenomena in terms of quantized processes. Radiation is supposed to emanate from atoms or molecules in quanta of definite frequency and wavelength as the result of abrupt changes from one quantum state or energy level to another, the frequency being determined by the amount of energy released in accordance with **Planck's law**. But the mechanism whereby these definite frequencies are produced is as yet unknown. In general, there is associated with each quantum state of an atom or a molecule an integral number, whose physical significance is not fully understood but which changes from one value to another whenever there is an accession or a release of energy. These integers, called quantum numbers, appear in the empirical formulae for the series terms in **atomic spectra**, and each exchange of one quantum number for another corresponds to a radiation quantum or a photon of light of definite frequency. Series of spectral lines are thus built up from different combinations of quantum numbers, corresponding to transitions between different pairs of quantum states or levels. Since an atom or a molecule may be quantized as to different **degrees of freedom**, there are different sets of quantum numbers, characterized, respectively, as azimuthal, radial, rotational, vibrational, etc.

Among the outstanding features of the quantum theory may be mentioned the interpretation of the laws of radiation, of the details of atomic, **molecular**, and **x-ray spectra**, of the **Compton** effect and the **Raman effect**, of the **Stern-Gerlach experiment**, of certain **magneto-optical** and **electro-optical** phenomena, and of the laws of **specific heat**. (See also **Quantum Mechanics**.) (L.D.W.)

QUAQUAVERSAL. A term used by structural geologists to describe a dome in which the formations dip outward in all directions. (R.M.F.)

QUARTER-WAVE PLATE. Double Refraction.

QUARTIC EQUATIONS. A quartic (or biquadratic) equation in one unknown is a **polynomial equation** of the fourth degree and has the general form

$$a_0x^4 + a_1x^3 + a_2x^2 + a_3x + a_4 = 0.$$

The quartic equation $y^4 + py^3 + qy^2 + ry + s = 0$ may be reduced by the substitution $y = x - \frac{p}{4}$ to the form $x^4 + ax^2 + bx + c = 0$. Let l, m and n denote the roots of the resolvent **cubic equation**

$$t^3 + \left(\frac{a}{2}\right)t^2 + \left(\frac{a^2 - 4c}{16}\right)t - \frac{b^2}{64} = 0.$$

The required roots of the reduced quartic are then:

$$x_1 = \pm(-\sqrt{l} - \sqrt{m} - \sqrt{n}),$$

$$x_2 = \pm(-\sqrt{l} + \sqrt{m} + \sqrt{n}),$$

$$x_3 = \pm(\sqrt{l} - \sqrt{m} + \sqrt{n}),$$

$$x_4 = \pm(\sqrt{l} + \sqrt{m} - \sqrt{n}),$$

where the upper signs are to be used if $b > 0$, the lower if $b < 0$. (L.L.S.)

QUARTIC FUNCTION. This is a **polynomial function** of the fourth degree and is therefore of the form $ax^4 + bx^3 + cx^2 + dx + e$, where a, b, c, d, e are **constants** (independent of x) and x is the **variable**; it is also sometimes called a biquadratic function. (L.L.S.)

QUARTILE. The quartiles, Q_1, Q_2, Q_3, are the three points dividing a distribution into 4 equal parts. They are determined by this definition in the case of a **serial distribution** and by interpolation in the **cumulative frequency distribution** if a **frequency distribution** has been formed. Sometimes the first quartile refers to all **variates** below Q_1. It should be noted that Q_2 is the same as the **median**. (L.A.A.)

QUARTILE DEVIATION. The quartile deviation, Q.D., is given by the formula

$$\text{Q.D.} = \frac{Q_3 - Q_1}{2},$$

where Q_3 and Q_1 are the third and first **quartiles**, respectively. (L.A.A.)

QUARTZ. The mineral quartz, oxide of the non-metallic element **silicon**, is the commonest of minerals, and appears in a greater number of forms than any other. Its formula is SiO_2. Quartz commonly occurs in prismatic **hexagonal** crystals terminated by a pyramid. This pyramid is due to the equal development of two **rhombohedrons**, as may be observed in cases where one rhombohedron predominates. Cleavage is not observed; the fracture is typically conchoidal; hardness is 7; specific gravity, 2.65; luster, vitreous to greasy or dull; colorless to white, pink, purple, yellow, blue, green, smoky brown to nearly black; transparent to opaque. There seem to be two distinct modifications of quartz, depending upon the temperature at which they were formed. The low-temperature variety is formed below 573° C. and is the more common sort, being found in veins, geodes, etc. It is called low-quartz. The high-temperature modification is formed between 573° C. and 870° C., and is found chiefly in granites and **granite** or **rhyolite porphyries**. This is called high-quartz. Above 870° C. **tridymite** is the stable form of SiO_2. The differences between high- and low-quartz are entirely crystallographic, low-quartz having a vertical axis of three-fold symmetry and three horizontal axes of two-fold symmetry, while high-quartz has a vertical axis of six-fold symmetry and six horizontal axes of two-fold

symmetry. It is usual to separate the many kinds of quartz into (1) crystalline or vitreous varieties, actual crystals or vitreous crystalline masses, and (2) **cryptocrystalline** varieties, mostly compact non-vitreous sorts, but which may show a crystalline structure under the microscope.

(1) Crystalline or Vitreous: Rock crystal, colorless crystals or masses. Amethyst, clear violet or purple, either crystals or masses. Rose quartz, usually massive but rarely in crystals, delicate shades of pink or rose, sometimes red. Citrine or yellow quartz, sometimes called false or Spanish topaz, light to deep yellow. Smoky quartz, smoky brown to almost black, often called cairngorm stone from Cairngorm, Scotland. Milky quartz, often showing delicate opalescence, transparent to nearly opaque, often with a greasy luster. Aventurine quartz incloses glistening scales of mica or hematite. Rutilated quartz incloses needle-like prisms of rutile called "fleches d'amour." Other acicular minerals such as **actinolite, tourmaline, epidote**, etc., may also be thus inclosed; Cat's Eye shows a peculiar opalescence, probably due to inclosed masses of some fibrous mineral. Tiger's Eye is a siliceous pseudomorph after crocidolite of a golden yellow brown color. (2) Cryptocrystalline: the following cryptocrystalline varieties of quartz are treated under their own headings: **agate, basanite, bloodstone, carnelian, chalcedony, chert, chrysoprase, flint, heliotrope, jasper**, moss agate, **onyx, plasma, prase, sard**, and **sardonyx**. Quartz readily forms **pseudomorphs** after various minerals or structures. Silicified wood is a quartz pseudomorph after the organic material of which it originally consisted. Quartz is often pseudomorphic after **calcite, barite, fluorite**, etc. Quartz is an essential constituent of many **igneous rocks**, for example, **granites, granite porphyries**, and **felsites**, as well as quartz **diorites** and their surface equivalents, the **dacites**. In the **metamorphic** rocks quartz figures very largely in the **gneisses** and **schists**, and, of course, in **quartzite**. In the sedimentary rocks most sandstones are composed chiefly of grains of quartz, and quartz forms veins and nodules in limestones. Of the many foreign localities that have yielded fine specimens of quartz, a few only can be mentioned as: the Swiss Alps, the Piedmont of Italy, the Island of Elba, Dauphine in France, Cumberland in England, Banffshire, Scotland, and Madagascar. Fine amethysts come from the Urals, Ceylon, Madagascar, Uruguay, Mexico, and Brazil. In the United States the following localities are well known: Paris, Maine, especially for rose quartz; Herkimer County, New York, for small but very brilliant crystals found in the Cambrian dolomites or in the soil. Amethyst County, Virginia, furnishes amethysts, as do Lincoln and Alexander Counties, North Carolina. Other localities for amethyst and smoky quartz are South Dakota in the Black Hills, the Pike's Peak district, Colorado; Yellowstone Park, Wyoming; Jefferson County, Montana, and in Canada in the Province of Ontario in the Thunder Bay region. The word quartz is believed to have been originally of German origin. Besides the use of the different varieties of quartz for jewelry and other ornamental purposes, this mineral has extensive industrial uses in the ceramic arts, optical and other sorts of scientific instruments (see **Polarized Light**), abrasive, scouring, polishing materials, and for refractories. (E.S.C.S.)

QUARTZ PORPHYRY. One of the **hypabyssal** or effusive rocks chemically related to the **granite** or alkali family but rich in silica, which occurs as **quartz phenocrysts** in a crypto- or microcrystalline ground mass. (R.M.F.)

QUARTZITE. A hard, tough, and compact metamorphic rock composed almost wholly of quartz sand grains which have been recrystallized to form a particularly massive siliceous rock. The term is also used for non-metamorphosed quartzose **sandstones** and grits whose **clastic** grains have been firmly cemented by **silica** which has grown in optical continuity around each grain. (R.M.F.)

QUASI-STATIONARY FRONTS. Fronts.

QUATERNARY. Pleistocene.

QUEBRACHO. Tannins.

QUENCH CIRCUIT. Superregenerative Receiver.

QUENCHING. Immersion of hot metals in liquid baths in order to effect rapid cooling. In steel heat-treating practice quenching oils give slower and brine solutions give faster cooling rates than water. Dilute caustic solutions are sometimes used for rapid cooling rates comparable to brine. These baths are maintained at or near room temperature. For special quenching procedures requiring baths held at moderately elevated temperatures, molten metals, such as lead, and fused salts may be used. (See **Steel, Heat Treating.**)

Quenching of ordinary steel is for the purpose of hardening it. Certain non-hardenable steels, for example austenitic stainless steel, and many non-ferrous metals may be cooled rapidly from elevated temperatures for other reasons. (R.H.H.)

QUEZAL. Trogon.

QUICKLIME. Calcium Oxide.

QUICK-RETURN MECHANISM. Machine tools which cut with a straight stroke in one direction, alternated with non-cutting return strokes, are more efficient of operators' time if the return stroke is performed more rapidly than the forward stroke. The **shaper** offers an example of a machine tool in which the cutting is done by moving the work past a fixed cutting tool which cuts in one direction. The work reciprocates, and in order to save as much time as possible on the non-cutting portion of the cycle, quick-return mechanisms have been developed, one of which is illustrated in the accompanying figure. This is a variation of a slider

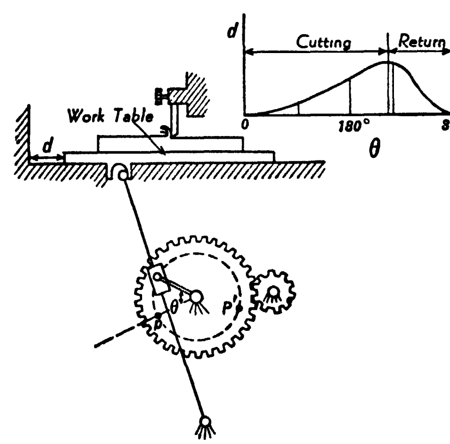


Diagram of the crank shaper.

crank chain, one of the most common of linkages. A pinion engages a large gear to which is affixed a crank arm. The outer end of the crank is pinned to a slider block, which is free to slide on a long swinging arm. As the crank revolves, this arm oscillates back and forth, and by means of a yoke reciprocates a table on suitable ways. The work to be shaped or planed is clamped to this table. The point at which the oscillating arm is **tangent** on either side to the crank pin circle sepa-

rates the cutting from the return stroke. Since the crank arm turns uniformly, time is proportional to crank angle. The return stroke is accomplished in a much smaller crank angle than the cutting stroke, and consequently consumes less time. A typical displacement diagram for return mechanisms is shown. Many quick-return mechanisms which are patented have features superior to those of the crank mechanism, such as more uniform speed on the cutting stroke, larger quick return ratio, etc. These features are obtained at the expense of more complicated mechanism. (F.T.M.)

QUILL. The portion of a feather which bears none of the slender lateral branches. The hollow shaft which is attached to the skin of the bird. Also the thickened and barbed spines of the porcupines, which are modified hairs. (A.W.L.)

QUILLBACK. Pisces, Teleostei. One of the **buffalo fishes,** *Carpioides velifer,* of the Mississippi River system. Also called the carp sucker, a name which belongs more properly to a related species, and skimback or river carp. (A.W.L.)

QUILLWORTS. These curious plants, species of the genus *Isoetes,* grow, as a rule, under water. They have short thick corm-like stems and slender **dichotomously** branching roots. The leaves are slender and somewhat grass-like and are crowded on the upper surface of the short stem. Within the basal portion of the leaf are borne **sporangia** of two kinds. One, containing large **spores** or megaspores, is called a megasporangium. The other is a microsporangium and contains numerous very small spores. The megaspores give rise to small multicellular **gametophytes** on which the **archegonia** are formed. The microspores become minute multicellular bodies in which are formed the small **sperms.** A sperm swims to the egg and unites with it to form a **zygote.** From this a new quillwort is formed. The quillworts are living relics of a once important group. They are of no commercial importance. (R.M.W.)

QUINCE. **Rose family.**

QUINHYDRONE. **Phenols.**

QUININE. The chief alkaloid of **cinchona,** the bark of the cinchona tree which is native to certain regions of South America. It was introduced into Europe in 1639 from Peru, for the treatment of ague. The most important use of the drug has been in the therapy of **malaria,** where it exerts a specific action on the parasite. It is used also for the relief of headache, neuralgia, in the treatment of cardiac arrhythmias, as a sclerosing agent in the treatment of varicose veins, and as a stomachic. Occasionally it is employed to induce labor at term; its popular use as an abortifacient in early pregnancy is unwarranted since it has no effect on the **uterus** except just before delivery. (D.M.H.)

QUINNAT. Pisces, Teleostei. A **salmon** of the west coast of North America, ranging from Alaska to the Ventura River. It is among the most important of the food fishes and is the leading salmon of the Columbia River fisheries. Also known as the chinook or king salmon. This fish attains a maximum weight of 100 lbs. and a length of more than 4′, but most of those taken weigh only ¼ of this amount. (A.W.L.)

QUINOLINE. **Pyridine and Related Compounds.**

QUINONES. **Phenols and Quinones.**

QUINSY. Abscess formation in the tissues around the tonsils, occurring as a complication of acute **tonsillitis.** Symptoms are similar to those of acute tonsillitis. The **lymph glands** in the neck become swollen and tender. Swallowing is extremely painful. Both local and constitutional symptoms are more severe than those in acute tonsillitis. Unless the abscess ruptures spontaneously, incision is required at the proper time. (D.M.H.)

QUINTILE. The 4 quintiles, K_1, K_2, K_3, K_4, are the four points dividing a distribution into five equal parts. They are determined according to the same principles as other **measures of position.** (L.A.A.)

R

RABBET. Dado.

RABBIT. Mammalia, Rodentia. **Rodents** with long ears, large hind legs, and small front legs. Some species burrow and others occupy similar retreats which they do not make for themselves. Many members of the group are called **hares**. There is no sharp distinction between the terms except in their established application to certain species.

Rabbits are found on all continents, although they were introduced into the Australian region. In New South Wales the introduced stock threatened to crowd out even the settlers by its destruction of vegetation. Millions of the animals have been killed per year and the exportation of their hides has somewhat offset their destructiveness.

In North America the common or cottontail rabbit, *Sylvilagus floridanus,* and a few closely related species are widely distributed. One of these species is the brush rabbit, *S. bachmani,* of the Pacific northwest, and two others are the southern marsh rabbit or pontoon, *S. palustris,* and swamp rabbit or cane-cutter, *S. aquaticus.* The large western species are sometimes called hares but more commonly rabbits. The snowshoe rabbit, *Lepus americanus,* also known as the white rabbit or varying hare, lives in the north and in the mountains as far south as Virginia and Colorado. The white-tailed jack rabbit or prairie hare, *L. townsendi,* ranges from the Mississippi River to eastern California. This species becomes white in winter in the northern part of its range. Other species of jack rabbits are found farther west.

The flesh of rabbits is excellent. In the more heavily settled parts of the country they are an important game animal. The fur is thick and soft but the hides are weak, hence they are used chiefly for linings, for cheaper fur garments, and for making felt. After shearing and dyeing rabbit fur reaches the market as northern seal.

Rabbits are bred extensively in captivity as pets, as laboratory animals for use in medicine and bacteriology, to some extent for food, and for the study of heredity. Since they are very prolific they have been among the most useful mammals to the geneticist. (A.W.L.)

RABIES (Hydrophobia). An acute infectious disease of certain animals transmitted to man usually by the bite of an infected dog. Rabies is caused by a **virus** which is present in the saliva of a rabid animal. The disease has been known since 300 B.C. but how it is transmitted was not known until 1804. Pasteur, in 1884, demonstrated that rabies virus is present in the brain of infected animals. Using infected cord and brain tissue he prepared a **vaccine** to be given in repeated injections to individuals bitten by rabid animals. This is the Pasteur treatment which is now widely used in the prevention of the disease.

The period of incubation after a bite from a mad dog is extremely variable, being from 10 days to 2 years; the average is 30–60 days. The nearer the bite to the brain, the shorter is the incubation period. In man, the disease begins with a period of restlessness and depression, followed by gradually developing anxiety, fear, terror, alternating rage and calm. Cerebral irritation may be extreme, and **convulsions** are precipitated by minor noises, lights, or currents of air. The name hydrophobia is derived from the spasmodic contractions of the throat and **larynx** causing agonizing pain when the patient attempts to swallow, or even sees water or hears it mentioned. Extreme thirst and fear of strangling to death drive him to maniacal lengths. Death from cardiac or respiratory failure occurs within a few days.

There is no treatment for rabies. Once the disease develops the patient is doomed to a horrible death. For this reason, preventive treatment with rabies vaccine is imperative whenever an individual is bitten by a rabid animal. If it is not known whether the biting dog is rabid or not, it should be observed for a period of 15 days for signs of the disease, before being released as normal. At the time of a bite from a suspicious animal the wound should be cauterized with pure carbolic acid followed by 95% alcohol. This procedure cannot be relied upon to kill all the virus, but its use does prolong the incubation period and therefore allows more time for adequate vaccine prophylaxis. (D.M.H.)

RACCOON. Mammalia, Carnivora. Stoutly built American animals of moderate size. The head is broad and short, with a sharply pointed muzzle, and the tail is bushy and marked with alternating light and dark rings.

The common raccoon, *Procyon lotor,* ranges over North America east of the Rockies. Two related species live on the Pacific coast and southward into Central America, and one or more additional species have been recorded from South America.

Raccoons are chiefly nocturnal animals. They climb readily and usually nest in hollow trees. In many sections of the country coon hunting at night with specially bred and trained dogs is regarded as among the best sports of the kind.

Raccoon fur is among the better grades, although it is neither very fine nor very beautiful. It is used extensively in making coats. (A.W.L.)

RACE RUNNER. Reptilia, Sauria. Slender **lizards**, reaching a length of about 10", including the long tapering tail. They are found throughout the United States with the exception of the most northern part. One species is known as the swift, *Cnemidophorus sexlineatus.* (A.W.L.)

RACEME. Flower.

RACEMIC ACID. Tartaric Acid.

RACEMIC COMPOUND. Isomerism.

RACHIS. A shaft. The term may be applied to the vertebral column, but its most common use designates the central shaft of a feather. (A.W.L.)

RACK. Spur Gearing.

RACON. The racon, or **radar** beacon, is a device that has been used for some time for the purpose of identifying ships and planes picked up on radar view scopes during military and naval operations. It is now being developed as a standard aid for both air and sea **navigation** that may be used by all navigators supplied with radar.

The amount of energy reflected from an object as small as a navigation **buoy**, or even a lighthouse, is frequently too small to produce a signal on the radar scope. The ordinary radar plan of the terrain below an aircraft does not give sufficient detail to permit positive recognition unless some particularly distinctive feature, such as a shoreline, is available.

The racon is a type of **beacon** that contains the equipment for receiving and transmitting **electromagnetic radiation** of the type used by radar. Whenever a radar pulse from a ship or airborne transmitter arrives at the racon, it "triggers off" a coded pulse of energy. This pulse will arrive at the searching navigator's equipment with sufficient power to set up a signal on the viewing scope. The code characteristic identifies the beacon, and the position of the signal on the PPI gives the bearing and distance of the beacon from the plane. (W.K.G.)

RADAR. Radar (coined from *ra*dio *d*irecting *a*nd *r*anging) is a system for locating reflecting objects by means of radio signals. Anything which will reflect enough energy of a radio signal of high frequency to actuate the **receiver** may be detected and accurately located in space over distances approximating line-of-sight distances from the radar stations. This will be over 100 miles for high-flying planes. Since the radio signals penetrate fog, darkness, rain, and haze, this method of locating planes, ships, and ground objects does not have many of the limitations of the older optical systems. In addition, the ranging by radar means may be much more accurate than that of the optical methods. Although radar was originated a number of years ago, it was not until just before and during World War II that it was brought to the high degree of perfection which permitted its use in detecting enemy equipment and then controlling the gunfire which destroyed that equipment, often without the enemy being visible. Because of the varied reflecting characteristics of many ground installations, bodies of water, types of earth, terrain formations, etc., certain types of radar were used for blind bombing when visual sighting was impossible. These war-developed applications point the way to many obvious peacetime applications such as blind navigation of ships in heavy fogs, blind flying, blind landings, and storm tracking.

Although the details of the various radar systems differ, depending upon the particular type and the use for which it is intended, the basic principles are the same. A series of accurately timed and very short pulses of radio frequency (frequencies range from approximately 100 to several thousand megacycles) are transmitted by a **directional antenna.** Since these pulses represent only a small part of the total time, the power in the pulse may be quite high without the average power (and hence size of equipment) becoming excessive. If these radio signals strike a conducting object some of the energy is reflected. The reflected pulses may then be picked up by the radar receiving system. Basically the direction of the antenna when a reflection is detected gives the direction to the object, and the time between the transmission of the pulse and its return gives the distance (radio waves travel at 186,000 miles per sec.). The details of making the system sufficiently accurate for practical use are very complex, but the principles may be illustrated by considering a unit used for search and fire control against aircraft. Fig. 1 shows a simplified block diagram of the unit. The timing unit or **pulse generator** controls the sequence of operations by supplying a keying pulse to the transmitting system and at the same time a reference pulse to the receiving system. The pulse is shaped and amplified in the modulator unit and is then applied to the **transmitter.** Here it serves to key the pulse of radio-frequency energy, the high-frequency pulse being fed to the antenna. The field to be observed is scanned by the antenna and its radio signal just as it might be scanned by a searchlight and its beam for visual searching. Various types of antenna structures are used, but all are directional, and the direction may be changed at will. Fig. 2 shows one type: a small dipole of a few centimeters' length mounted in a parabolic reflector. When a reflected signal is received by the antenna it is fed through the T-R unit to the receiver. Some radars use separate transmitting and receiving antennas, although most use a common antenna for both functions. The T-R unit is merely an electronic switch which cuts out the receiver circuits when a pulse is being transmitted and then opens them between transmitted pulses so they will be ready for the received pulses. The range of the radar is limited by the distance the signal can travel out and back between transmitted pulses, since one pulse must make its complete trip before the next one starts. The received signal is compared in the receiver with the signal originally generated in the pulse generator, the time difference giving the time of travel of the radio wave and hence the distance. There are various methods of doing this, but **cathode ray oscilloscopes** are used as the comparison indicators. As an elementary example, suppose the signal received from the pulse generator initiates the sweep circuit of the

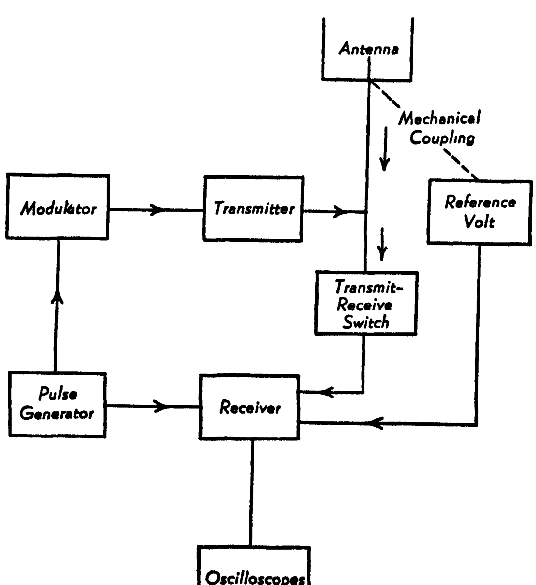

Fig. 1. Block diagram of radar search and control unit.

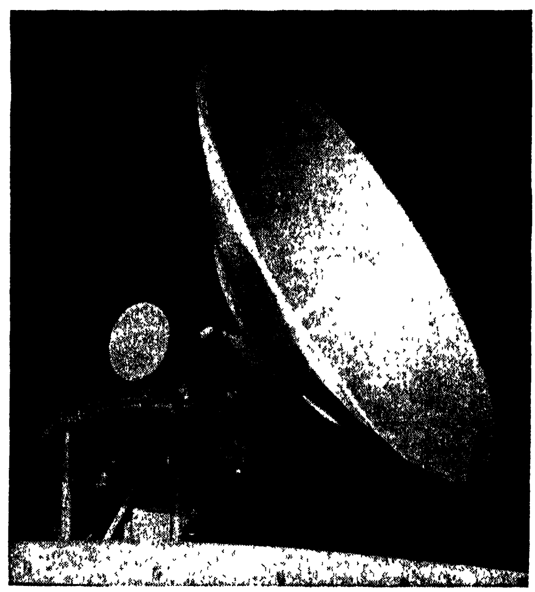

Fig. 2. Radar antenna. (*Electronics.*)

oscilloscope and that the sweep takes a definite and known time to traverse the oscilloscope screen. This may be accurately adjusted by means of the circuit constants of the sweep circuit. If the returned signal from the receiver is fed to the other set of plates of the oscilloscope, it will appear as a hump or "pip" on the trace. If, for example, the sweep time is 100 microseconds and the pip occurs at a point one fourth of the distance across the scope, the time of travel of the radio wave would be $\frac{1}{4} \times 100$, or 25 microseconds, and the distance to the detected object would be $\frac{1}{2} \times 25 \times 10^{-6} \times 186{,}000$, or 2.32 miles. This simple illustration neglects, of course, time delays in the circuits, but these are allowed for easily. In many cases they are adjustable to improve the accuracy of ranging. Connected with the antenna scanning mechanism is a reference voltage generator whose output is also fed into the receiving system to indicate direction to the reflecting plane when a pulse is received. By electronic means this reference voltage may be compared with the received pulse in such a way as to indicate on a scope to the radar operator when he is pointing directly at the target.

In a PPI (plan position indicator) system the movement of the antenna is tracked by the trace of an oscilloscope tube (the PPI scope). Thus, the position of the trace on the scope corresponds to the direction of the beam from the antenna. A reflection then appears as a bright spot on the oscilloscope, the azimuth of the spot being the azimuth of the reflecting object and the distance of the spot from the center indicating the range of the object. The intensity of the spot is a measure of the reflecting efficiency of the target. Thus, when such a radar is used from a plane, the antenna being used to scan the area below, the oscilloscope will show a shaded pattern of the ground since the reflection is affected by changes of terrain, different building materials, bodies of water, etc. As the radar beam sweeps over points with high-reflection coefficients the spot is bright, whereas points with lesser coefficients give less bright regions on the scope. The result on the screen is a picture of the area being viewed, appearing very much like an aerial photograph. Fig. 3 compares a PPI view with a map of the same area. (L.R.Q.)

RADIAL DRILL. Drilling.

RADIAL VELOCITY. That component of the space motion of a star that is directed toward the sun is known as the radial velocity of the star, or the velocity of the star in the line of sight. It is measured by spectroscopic methods, employed the Doppler-Fizeau principle, and is determined directly in linear units (i.e., kilometers per sec., or miles per sec.).

Since a comparison spectrum must be available for measurement of the Doppler displacement of the stellar spectral lines, a slit spectrograph must be used for an accurate determination of radial velocity. This instrument is wasteful of light and only one star can be observed at a time. For these reasons the number of stars for which accurate radial velocities are known is small relative to the total number of stars. The objective prism may be used to determine approximate radial velocities for a large number of stars. In one of the applications of this instrument a comparison spectrum is obtained by interposing a Neodymium screen between the prism and the photographic plate. This produces a few absorption lines on the stellar spectrum relative to which the stellar lines themselves may be measured. Another application of the objective prism to this problem utilizes the fact that the Doppler displacement for a line in the red is greater than that for a line in the violet. Hence the length of the spectrum between these extremes will be changed by an amount proportional to the radial velocity. While the results obtained by the use of the objective prism are only approximate, nevertheless they may be used for statistical study of stellar motions.

From a study of the variations in radial velocity of certain stars, known as spectroscopic binaries, the relative orbits of these objects may be determined. (W.K.C.)

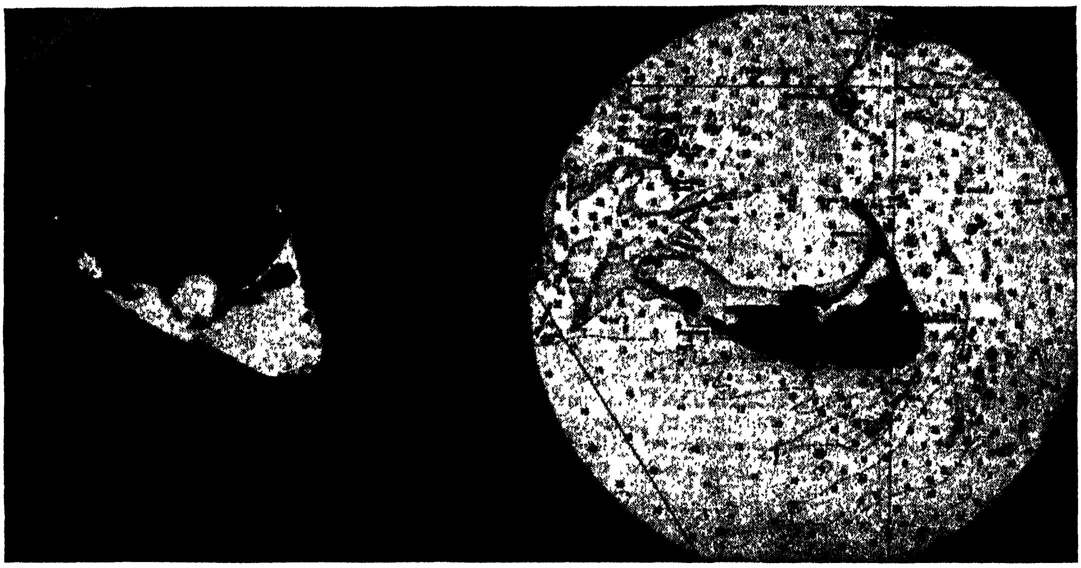

Fig. 3. PPI view compared to map of same area. (*Electronics.*)

RADIAN MEASURE OF ANGLES. For theoretical purposes, angles are generally measured in circular or radian measure. If a circle is drawn with its center at the vertex of an angle, the radian measure of the angle is the ratio of the length of intercepted arc to the radius. The unit angle in this measure is the radian, defined as the angle whose intercepted arc is equal to the radius. The fundamental relation between radian measure and degree measure is given by the equation: π radians $= 180°$. The symbol (^{r}) is often used after the numerical value of the circular measure to indicate radians, but it is often omitted when no misunderstand-

ing can arise. It follows from the fundamental relation above that:

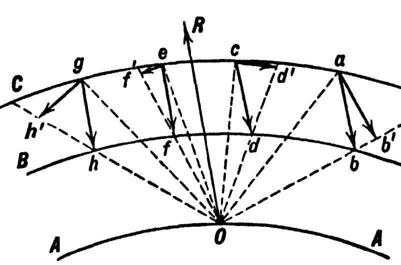
1 radian $= 180°/\pi = 57.29578° = 57° 17' 44.6''$ approximately, or $57.3°$ roughly, and

$1° = \pi/180$ radians $= 0.017453^{(r)}$ approximately, or $0.017^{(r)}$ roughly.

In terms of radian measure, any circular arc intercepted by an angle with vertex at its center is given in length by the formula: $s = r \cdot \theta$, where r is the radius of the circle and θ is the radian measure of the angle. (L.L.S.)

RADIANT POINT. If the paths of all of the meteors observed from a single station on a given night are plotted on a chart of the sky, it will usually be found that a number of them seem to be coming from a certain particular point in the sky. Such a point is known as a meteor radiant point, and the group of meteors associated with the radiant point is known as a **meteor shower.** It will further be noticed that, among the meteors belonging to the shower, those at the greater distance from the radiant point will have the longer trails.

This observed effect is merely due to the perspective view of a number of meteors actually entering the atmosphere of the earth in parallel paths. The accompanying figure represents the cause of the radiant point. The circular segment *AA* represents the surface of the earth with the observer at *O*. *CC* represents the upper part of the atmosphere of the earth where the meteors first become visible, and *BB* the lower atmosphere where the meteors burn out and disappear. *ab*, *cd*, *ef*, and *gh* represent the actual parallel paths of four meteors through this layer of atmosphere, and *ab'*, *cd'*, *ef'*, and *gh'* represent the paths as observed from *O*. Examination of the figure will show that the apparent paths all radiate from a point in the direction *R*, the radiant point, which is a direction parallel to that in which the meteors are actually entering and traveling through the atmosphere. It will further be noted that the meteors more distant from the radiant point, e.g., *ab'* and *gh'*, have apparently longer trails than the nearer ones, *cd'* and *ef'*.



Explanation of radiant point.

The location of the radiant point remains approximately fixed with reference to the **constellations** throughout the duration of the shower and is usually named for the constellation in which it appears, e.g., the **Perseid** shower has its radiant in the constellation of **Perseus**, the **Leonids** in Leo, etc. Occasionally a shower has a name indicating other characteristics, e.g., the Leonid shower is sometimes referred to as the November meteors because the shower occurs during that month each year, and the **Andromedes** are frequently referred to as the **Bielids** because of their established relation with Biela's **Comet.**

The various showers differ from each other, both in the number of members and in the characteristics of the individual members. Probably one of the most famous showers on record is the Leonid shower of November 12, 1833, during which the number of meteors observed from some stations was estimated as 200,000 per hour for several hours.

Many of the showers occur year after year with definite regularity of date. Such periodic showers may be explained by huge numbers of meteors traveling about the **sun** in an orbit which intersects the orbit of the earth. Such a phenomenon has been referred to as a "flying gravel bank," but such a descriptive term is misleading because of the fact that few, if any, of the meteors are large enough to be considered as gravel pebbles. In some cases, the meteors are distributed with fair uniformity all along the orbit, in which case the showers will recur on successive years with approximately the same frequency and appearance. Such is the case with the Perseid shower, which may be observed during the latter part of July and the early part of August each year. In other cases the meteors are concentrated in one or more large swarms with a few scattered members in between along the orbit. This is the case with the Leonid shower.

In a number of cases the orbits of meteor radiant points have been found to agree with orbits of comets. In some cases the comets are still observed as comets, and in other cases the comet itself no longer appears. At present, a large amount of work is being done in this interesting and important field. (W.K.G.)

RADIATION. **Electromagnetic Radiation; Thermal Radiation; Solar and Earth Radiation.**

RADIATION FIELD. When a conductor carries a.c. there are two types of fields set up in the surrounding space. One of these, the induction field, is predominant at low frequencies such as used in power circuits while the other, called the radiation field, predominates at very high frequencies such as used for **radio communication.** The induction field is responsible for the familiar magnetic effects of **coils** and the interference between circuits which are coupled inductively, i.e., the induction field of one links the other. For radio communication over long distances the radiation field is important since it represents the energy which is radiated outward from the **antenna** system and which does not return to the system but spreads out in space. Close to the transmitting station both types of field may be utilized; in fact, certain wireless record players use the induction field, but at appreciable distances (a few wavelengths) the induction field is negligible. The radiation field consists of an electromagnetic wave traveling at the velocity of light (3×10^{10} cm./sec.). It is this wave which cuts across the receiving antenna and induces the signal which is amplified and demodulated in the **receiver.** This radiation goes out from the antenna in various directions, the exact directions and strengths being dependent upon the antenna characteristics. Thus some of the energy may travel along the earth's surface to the **receiver,** some may go upward to the **ionosphere** and be refracted so it is returned to the earth giving long-distance communication. This radiation field is composed of an electric and a magnetic component, mutually perpendicular and perpendicular to the direction of propagation. Upon leaving the antenna the electric field is parallel to the antenna and the magnetic perpendicular to it. Either or both may contribute to the signal induced in the receiving antenna. At extremely high frequencies the polarization or direction of the electric field or vector has an effect on the character of the received signal. (L.R.Q.)

RADIATION PRESSURE. That **electromagnetic radiation** exerts a pressure upon any surface exposed to it was deduced theoretically by Maxwell in 1871, and proved experimentally by Lebedew in 1900 and by Nichols and Hull in 1901. The pressure is very feeble, but can be detected by allowing the radiation to fall upon a delicately poised vane of polished metal. (See **Nichols' Radiometer.**) It may be shown by the electromagnetic theory, by the **quantum theory,** or by ther-

modynamic reasoning, making no assumption as to the nature of radiation, that the pressure against a surface exposed in a space traversed by radiation uniformly in all directions is equal to ⅓ the total radiant energy per unit volume within that space. For **black-body** radiation, in equilibrium with the exposed surface, the energy density is, in accordance with the **Stefan-Boltzmann law**, equal to $\frac{4\sigma}{c}T^4$; in which σ is the Stefan-Boltzmann constant, c is the **electromagnetic constant**, and T is the absolute temperature of the space. One-third of this energy density is equal to $2.523 \times 10^{-15}\ T^4$ (ergs/cm.^{3}), which is therefore the pressure in bars. For example, at the boiling point of water ($T = 373.2°$), the pressure amounts to only 0.00005 dyne/cm.^{2} or about 3 lbs. per sq. mile. Such feeble pressures are, nevertheless, able to produce marked effects upon minute particles like gas ions and electrons, and are of importance in the theory of electron emission from the sun, of **cometary** matter, etc. (L.D.W.)

RADIATION PYROMETER. This instrument, of which there are several commercial designs, is based upon the fact that the intensity of the thermal radiation from a heated body depends in a systematic way upon the temperature of its surface. The essential principle involves the focusing of the radiation upon a thermocouple or some other sensitive thermometric detector by means of a suitable mirror. In one form the mirror is concave, producing a real image of a portion of the heated surface; in another it is a hollow cone, in which the radiation converges in an opening at the apex, where the thermocouple is placed. All instruments of this type must be experimentally calibrated, as temperatures computed theoretically from the **Stefan-Boltzmann law** are, for various reasons, found to be in error. A fundamental difficulty arises from the fact that no actual radiator is an ideal **black body**, and the emissive power of one surface differs from that of another at the same temperature. This gives rise to the term "radiation temperature" as different from the actual temperature of the body under examination.

In addition to the foregoing type, sometimes called the "total radiation pyrometer," the **spectrophotometer** or the spectroradiometer (an infrared spectrophotometer) is used in the case of very high temperatures, and the temperature deduced from the "peak" wavelength in accordance with the Wien displacement law. (See **Wien's Laws.**) In this way the surface temperature of the sun, giving out radiation with a maximum at a wavelength of about 5000 angstroms, has been found to be about 5750° C. (L.D.W.)

RADIATION RESISTANCE. This is a fictitious **resistance** which would absorb the same power which a radio **antenna** radiates. Thus, if we say an antenna has a radiation resistance of 73 ohms we mean that it radiates the same amount of power as a 73-ohm resistor would dissipate if it had the same current as the antenna. (L.R.Q.)

RADIATOR. A radiator is a surface especially heated for the emission of heat energy by radiation. Most persons are familiar with the cast-iron sectional-type radiators which are associated with steam and hot-air building-**heating systems.** The hot water or steam on the inside of these sections produces, by **conduction,** a heated outer surface from which the heat is discharged to the air by radiation, aided by **convection** currents which rise over the heated surfaces. It is possible that the greater part of the heat emission from such radiators is by convection rather than radiation. Less artistic in appearance, but equally suitable for heating, are banks of steam pipes, in which the separate pipes are joined at the ends by U-bends. These are usually hung on the wall or suspended from the ceiling in industrial type buildings. More truly deserving of the name radiator is a domestic electrical appliance consisting of a heater element mounted at the focus of a parabolic reflector. Practically all the heat delivered by this type of radiator is radiant in character. Another type of radiator is the radiant-type gas heater having a number of gas jets producing a flame which heats especially formed fire-clay elements held in it. As a result of the excellent combustion obtained, the fire-clay is heated to incandescence, and emits, radiantly, a great deal of heat **energy.** Of course the products of combustion rising from the heater may deliver a considerable amount of heat by convection, but such heaters are essentially radiators.

On the other hand, there are many devices called radiators in which radiation plays an insignificant part. Outstanding among these, perhaps, is the so-called automobile radiator, by means of which the heat absorbed by the cooling water is dissipated to the atmosphere. If at any time there has been an appreciable amount of heat transfer accomplished by radiation, that is eliminated by recent trends towards enclosed, or nearly enclosed, radiators, in which the radiator core itself is concealed behind polished louvres. The heat transfer in this case takes place mainly by convection, and the design incorporating cellular structure and forced draft is directed towards aiding this type of **heat transfer.** (F.T.M.)

RADICAL AXIS OF TWO CIRCLES. Circle.

RADICAL CENTER OF THREE CIRCLES. Circle.

RADICAL EQUATIONS. A radical equation (or irrational equation) is an **equation** in which the unknown appears under a **radical** sign or with a **fractional exponent.**

Such an equation may usually be solved by squaring both sides of the equation one or more times, or raising both sides to the same other power one or more times, to remove the radicals (or fractional exponents), thus reducing the equation to a **polynomial equation.** Usually one radical should be isolated on one side of the equation before raising to the power.

In this process of solution, **extraneous roots** may be introduced, hence the solution of each radical equation should be checked by substitution in the original equation, and any values not satisfying the equation should be rejected. (L.L.S.)

RADICALS. For chemical radicals, see **Chemical Composition.**

In mathematics, a radical is an indicated **root of a number,** usually a principal root; thus, the radical symbol $\sqrt[n]{a}$ means the principal n^{th} root of a.

Operations with radicals are expressed by the formulae:

$$\sqrt[n]{a \cdot b} = \sqrt[n]{a}\ \sqrt[n]{b},$$

$$\sqrt[n]{\frac{a}{b}} = \frac{\sqrt[n]{a}}{\sqrt[n]{b}},$$

if a and b are positive. (L.L.S.)

RADICLE. Seed.

RADIO. Radio Communication.

RADIO AIDS TO NAVIGATION. Radio is of vital assistance to **navigation** in many ways at the present time. The tremendous amount of research in the general field of **electronics** and **electromagnetic radiation** that has been stimulated by World War II, will undoubtedly bring many new instruments to the aid of the navigator, both sea and air.

The use of radio communication by navigators embraces such **important** fields as determination of **chronometer** correction for use in **celestial navigation,** and

for obtaining information regarding present weather at distant landing fields as well as storm warnings and general weather forecasts.

The loop **antenna** has many applications for assisting the air and sea navigators. These will be found discussed under such topics as **Radio Navigation, Radio Compass, Radio Bearing, Radio Range,** and **Radar.** (W.K.G.)

RADIO BEACON. A radio transmitting station, maintained and operated for the purpose of determination of **radio bearings**, is known as a radio beacon. The transmitting frequency, **latitude and longitude**, characteristic signal, and times of operation of each radio beacon are listed for sea navigators in the Hydrographic Office Publication "Radio Aids for Navigators," and for aviators in a similar publication of the Civil Aeronautics Administration. In one sense of the term, any radio station might be used as a radio beacon since a radio bearing may be obtained from it. However, only stations listed as beacons can be relied upon, since their positions are carefully determined and their signal characteristics are maintained by responsible agents.

Radio beacons are used for determination of radio bearings and also for "homing" purposes. (See **Radio Compass.**) Sea navigators must exert care not to carry the homing operation too far. The notorious case of the sinking of the Nantucket Shoals Light Vessel by an incoming steamer, that was homing on the radio beacon on the light ship, is an example of perfect and too prolonged homing.

Sky-wave reception at night tends to destroy or decrease the directional characteristics of the **loop**, so for greatest accuracy the bearing must be taken in the daytime or the frequency must be kept low enough so the **ground wave** will be large compared with the sky wave. Accuracies of ½ to 2° may be obtained for a few hundred miles at frequencies around 500 kc. and over much greater distances for lower frequencies. More elaborate **antennae** such as the combination of a loop and vertical, or an Adcock antenna, can give somewhat more accurate results. An Adcock antenna allows the use of higher frequencies and increases the range without interference from the sky wave but does not have as large signal pick-up as the loop.

Many coastal radio beacons transmit audible signals, either through the air or underneath the water, which are synchronized with those transmitted by radio. The difference in time of arrival of the radio and audible signal at the receiving ship will give the distance of the ship from the beacon. (W.K.G., L.R.Q.)

RADIO BEAM. Radio Range.

RADIO BEARING. The **bearing** of a radio transmitter, as determined by a **directional antenna receiver**, is known as the radio bearing of the transmitter.

The first application of radio bearing to navigation was the establishment of radio-compass stations. At first a radio-compass station was a receiving station, whose position was accurately known, that was equipped with a **loop antenna.** A ship within radio range could call the station and request for bearing. On receiving a reply from the station the ship would send a set signal, usually a series of K's, and the land station would determine the radio bearing of the ship and transmit it to the ship. Later the radio-compass station developed into an installation of five or more such individual receivers, each equipped with loop antennae and connected with a central station. In case of a call from a ship, each station would obtain the bearing of the ship and telephone it to the central. At the central, each station was indicated on a large chart and the radio bearings of the ship from each station were plotted. The point of intersection of all bearings gave the position of the ship which was then radioed out to the ship.

While this procedure is still available, radio bearings of shore transmitters are usually taken from the ship by means of a loop antenna, or the more modern radio direction-finders or radio compasses. Radio bearings as taken are always relative to the **heading** of the ship, and give the **direction** of the station referred to the bow as zero.

Three corrections must be applied to a radio bearing before it can be used as a **line of position on a mercator chart or small-area plotting sheet.** Loop antennae and radio direction-finders have **deviation** corrections, due to the **magnetic field** of the ship. These must be determined in advance for different headings of the ship and applied to radio bearings as obtained. Then the radio bearing, which is relative, must be changed to true bearing by adding the true heading of the ship. Finally, since radio follows **great circles**, the bearing must be converted from great-circle to mercator, or **rhumb-line**, bearing. Fig. 1 shows two points,

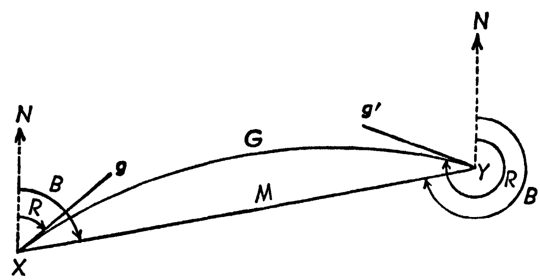


Fig. 1.

X and Y, plotted on a mercator chart, with the rhumb line, XMY, and the great circle, XGY, connecting the two points. The great circle will always be convex toward the nearest pole and we have drawn the figure for the northern hemisphere with true north indicated both at X and Y. The lines gX and $g'Y$ are tangents to the great circle at X and Y respectively, and are the directions in which the signal from Y will arrive at X, and that from X will arrive at Y. Let us consider X to be the receiving station. Then the angle $R(NXg)$ represents the great-circle bearing of Y and the angle $B(NXM)$ the rhumb-line bearing. In this case, it is noted that a correction must be added to the great-circle bearing to obtain the rhumb line. Reversing stations and considering Y the receiver, we see that at this point the correction must be subtracted to obtain rhumb line from great circle.

In case a navigator is working on a **Lambert chart,** as is frequently the case in air navigation, the great-circle bearing is close enough to a Lambert line to be plotted without correction other than for deviation and heading.

The question regarding the value of a fix obtained from radio bearings has long been a matter of much debate. For a number of years the Bureau of Navigation rated a radio fix as of less value than an estimated position obtained by dead reckoning. This may well be a correct evaluation at sea, particularly if the dead reckoning is not extended over more than 48 hours. In the air, when we consider the speed of modern planes, the difficulties in holding heading, and the inaccuracies in predicted winds, there is no question but that a radio fix is of tremendous value. With modern equipment, and under best radio conditions, a radio bearing is accurate to within 3°. To allow for possible peculiarity in the reception from some station, it is always advisable to use three radio bearings to plot for fix. In this case the area of the triangle of intersection will indicate the reliability of the fix. The mercator correction should always be applied if it is

greater than 0°.5. The numerical values of the correction can be quickly obtained from published tables and, if applied with the proper sign, certainly should improve the fix. (See **Radio Navigation.**) (W.K.G.)

RADIO COMMUNICATION. Communication between distant points not directly connected by an electrical conductor may be accomplished by electromagnetic waves radiated through space. Thus radio communication utilizes radiated energy instead of the conducted energy of the wired methods. (See **Radiation field.**) Obvious benefits of the radio method are the elimination of the expense of installation and upkeep of a wire communication system, and the communication between points difficult of access by wired systems. Furthermore, since energy may be radiated in all directions in space, broadcasting to large numbers of persons is simpler. Radiated electromagnetic waves can be used for communication purposes in three ways. First, they may be used to create a monotone signal of dots and dashes comprising a code. This is **radio telegraphy.** It has certain important commercial and governmental uses, but is not suitable for broadcasting, as it must be interpreted by trained operators. Secondly, electromagnetic waves may be modulated so that they carry the electrical equivalent of sound waves. At the receiver they are caused to reproduce the original sound, whether it was voice or music. This is the field of radio telephony and broadcasting, one which more than any other has entered intimately into the life of the average citizen. Thirdly, it is possible to transmit, by means of these waves, electrical pulses which will recreate at the point of reception, a scene which originated at the transmitter. This **television** process is now the subject of considerable experimentation, and its present approach to commercially satisfactory perfection indicates that it may, in the future, be expected to become an important phase of radio.

There are three essentials to radio communication. These are, first, **transmitter,** or source of electromagnetic radiation; second, the radio waves themselves, travelling between the transmitter and receiver; and thirdly, the **receiver,** which can receive and interpret the electrical pulses either as code, sound, or scene. A requisite to radiation of electromagnetic waves is a source of a.c. of high frequency. The radiation of energy from power lines which carry a.c. at 60 cycles per second is negligible because of the comparatively low frequency. When, however, a current oscillates in a wire suitably arranged for radiation (**antenna**) at a frequency of, say, 1000 kilocycles (one "kilocycle," by common usage, is 1000 cycles per second), it is possible to radiate considerable power into space in the form of electromagnetic waves, because radiated power increases as the square of its frequency. Furthermore, since at the higher frequencies a smaller antenna is suitable for radiating the energy, it is natural to expect high frequencies to be employed for all radio communication. In any transmitter there must be this source of high-frequency current. This is the **oscillator** and associated **amplifiers.** The frequency of the oscillator is kept under close control by adjusting the characteristics of the circuit incorporating it, so that there may be little or no interference between the waves sent out by different transmitting systems. That is, at the receiving station the electrical circuit employed may be "tuned" to the frequency of one particular transmitter, thus excluding all other wave trains. Between the oscillator and the radiating **antenna,** the transmitter must have a signalling system. For code this might be as simple as a means for interrupting, at will, the oscillating current. (See **Keying.**) In telephony, there will be provided some way of securing **modulation** of the high-frequency carrier wave with the sound wave. The strength of the electric currents created in a **microphone** by the direct action of the sound waves may be amplified and strengthened before being used to modulate the carrier wave, and the modulated wave itself may be strengthened by amplifying. Ultimately the intensified high-frequency currents are sent into the antenna system where they produce the radio waves. For broadcasting purposes these waves flash off into space in all directions, but for commercial telephony or telegraphy, some degree of directional control is possible by the use of **directional antenna.**

Radio-wave propagation from a simple antenna is an action which is analogous to the waves created by dropping a pebble into a quiet pool. Concentric waves travel outwards from the antenna, decreasing in intensity, very rapidly at first, then more slowly, as they travel further from the antenna. Their speed of travel is the same as the speed of light, and they possess the property of being able to pass through and around most obstacles. Atmospheric conditions, however, can affect their travel, as can also sunlight and water. But while the waves may become successively ever more attenuated, they retain their original frequency.

The third essential to radio communication mentioned above, is the receiver. A receiver consists of an antenna suitably arranged to receive the impressed voltages of the electromagnetic waves which reach it from the transmitting antenna. Then, since the receiver must be selective, so that it will reproduce the output of only one of several possible transmitters, means must be provided to "tune" it to the frequency of the selected transmitter. The received signal is very weak, and it must be strengthened by being passed through one or more stages of radio and audio-frequency amplification. Between the radio and audio amplification occurs the action of **detection,** or demodulation, separating the carried wave from the electrical wave which mirrors the original voice or sound wave. Finally, the amplified voice current is fed into a **speaker** which recreates the original sound.

The above discussion, and the related cross-references, can convey only a faint idea of the electrical complexity of modern radio circuits, and give no hint at all of the problems which have arisen from the widespread commercialization of this form of communication. Although in recent years radio has become an important feature of marine and naval operations (see **Radio Beacon** and **Radio Range**) and it is being relied on to an ever increasing extent to secure safety in aerial transportation (see **Blind Flight and Landing**), and although there has been developed for public use commercial telephonic service between ship and shore, and between continent and continent, and although radio has been employed for many other interesting and useful services, it is proposed here to dwell only on some of the problems associated with the commercialization of radio broadcasting.

The rise of radio broadcasting in the early 1920's was phenomenal. An important new industry mushroomed into existence in this country almost overnight following the initiation of radio broadcasting service by station KDKA in 1920. Hundreds of firms began the manufacture of receiving sets, thousands of retailers opened up stores for sale and distribution of the product, broadcasting stations were set up everywhere, and the principal chain networks were organized. People everywhere purchased receiving sets, and, with adoption by station WEAF of the toll broadcasting policy, the introductory phase of broadcasting by manufacturers of radio equipment in order to stimulate sales was over, and the sponsored program appeared. The commercial possibilities of the radio broadcasting station as an advertising medium attracted a large amount of capital into the field, and soon there was a chaotic condition of interference between stations.

Radio broadcasting developed using long waves, that is waves having frequencies between 550 and 1500 kc. To avoid interference between stations, a clear **channel** of a band of frequencies of 10 kc. should be provided

each station. However, in the broadcast range there are only 96 such channels, and by 1927 there were several hundred broadcasting stations attempting to use them. At that time the situation obviously required more rigid governmental control, and since all radio communication may well be considered interstate, the Government created the Federal Radio Commission to remedy the serious interference which existed among the 600 or more stations. In order to accommodate the large number of stations to the available channels in such a way as to reduce interference, so that the owner of a receiver could obtain satisfactory use from it the Commission had to assign definitely the frequency and power to be used by the different stations, and rigidly control the number of new stations which could be put in service from time to time. Furthermore, it was found necessary where the facilities offered by a station duplicated that of another to cause them to divide their broadcasting time. Also, low-power stations for local broadcasting were frequently required to terminate their activities at sundown.

While the standard broadcast stations still operate on 10 kc. channels in the band from 550 to 1600 kc., much higher frequencies have been developed and are being widely used, both for commercial and entertainment purposes. For commercial services the transmission characteristics of the higher frequencies offer very decided advantages in many cases. In the entertainment field the higher frequencies allow satisfactory international broadcasting and also permit the use of much wider channels than the standard broadcast band. **Television** with its channels of approximately 5 megacycles and frequency modulation with channels of 200 kc. are examples of recent wide-band systems. Obviously these channels would be impractical in the standard broadcast bands because of space limitations. The more or less line-of-sight transmission of very high frequency signals, while a disadvantage for general use, is an advantage for short-range service where the signal is not needed at a distance and is attenuated because of its very high frequency. (F.T.M., L.R.Q.)

RADIO COMPASS. This is probably the most loosely used term in all **navigation.** When the **loop antenna** was first applied to the determination of **radio bearings,** the term radio-compass station was applied to shore installations that would forward, on request, the bearing of a ship from the station. Next the term was applied to a group of shore installations, each equipped with a loop antenna, from which the navigating officer of a ship within range could obtain the **latitude** and **longitude** of his ship. After the loop antenna and receiving sets had been developed to a state where they could be carried by the ships themselves, the term radio compass was applied to the loop. As new and improved radio equipment became available, the term radio compass was successively applied to any radio device that could be used to determine bearing. A glance through any textbook on navigation, particularly those dealing with air navigation, will yield at least two, and sometimes as many as five, different instruments for radio compass.

At the present time the U. S. Naval Aviation service uses the term radio compass for a direction-finding instrument which has a dial on the instrument panel of the plane that looks in many respects like an ordinary **compass,** and which is used for **heading** the ship in much the same manner as is that instrument. Two radio **antennae** are used with this instrument, a loop and a nondirectional antenna. The volume controls for signal intensity are so adjusted that the signal strength from the loop and the nondirectional antenna are the same when the station is in the plane of the loop. The two antennae are then fed into a single receiver and the signal intensity is illustrated in Fig. 1. The resultant signal intensity from any station is shown by a **galvanometer** on the instrument panel. The loop may now be rotated and a pointer swings over a compass card on the instrument panel. When the galvanometer needle is in the zero position the reading on the compass dial gives

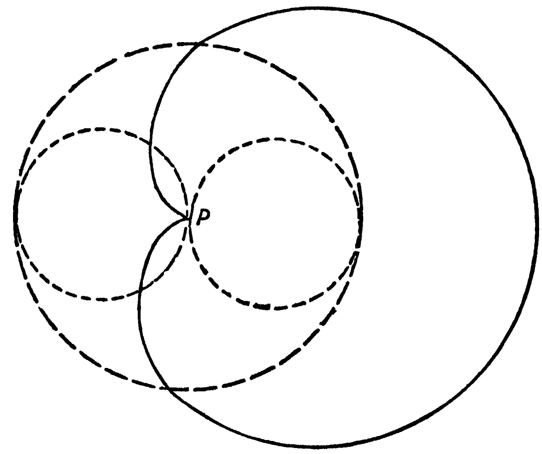

Fig. 1. The length of a line from P to any one of the three curves is proportional to the strength of the signal from a station in the direction toward which the line is drawn. The dotted (figure eight) curve represents the relative intensities in various directions for the loop alone, the dashed (circle) curve the intensity for the nondirectional antenna alone, and the full (catenary) curve that for the combined loop and nondirectional antenna or, in other words, for the radio compass.

the bearing of the transmitting station relative to the ship.

This instrument is frequently used as a "homing" instrument, i.e., an instrument to head a ship toward some selected transmitting station. To be used in this manner the loop is rotated until the compass dial reads zero. The plane is then turned until it is on such a heading that the galvanometer dial indicates zero. The transmitting station is then dead ahead. If the plane remains on this heading it will always be pointing toward the transmitter. However, because of the effect of wind, the plane is not proceeding toward the transmitter, but is spiralling around it. If the wind is known, the loop is turned through the **wind correction angle** and the heading of the plane altered until the galvanometer again reads zero. The plane will then be on **course** toward the transmitter just as long as the galvanometer remains at zero reading and the wind remains constant. If the ship changes heading, the galvanometer dial will show the direction and amount that the plane is off-course, and the pilot can immediately return to proper heading. The pilot must not trust this radio compass too far, for an "off-course" indication may be due to a wind shift. Furthermore, the "homing device" has the pernicious habit of "homing" toward a thunder storm, high-tension line, or some other electromagnetic disturbance, without warning.

New devices, operating on the general principle of **radar,** have been devised which will undoubtedly become known as radio compass when they are available for commercial and private use. (W.K.G.)

RADIO DIRECTION FINDER. **Radio Compass.**

RADIO FIX. **Radio Navigation.**

RADIO FREQUENCY. This is the frequency of the carrier signals used for **radio communication,** and while normally thought of as being quite high (many kilocycles), frequencies as low as a few kilocycles are used. The upper limit is fixed by the state of the art, being at present as high as 30,000 megacycles for certain laboratory equipment. The radio frequencies are often subdivided as follows:

FREQUENCY (KC.)	NAME	SYMBOL
10–30	Very low	VLF
30–300	Low	LF
300–3000	Medium	MF
3,000–30,000	High	HF
30,000–300,000	Very high	VHF
300,000–3,000,000	Ultra high	UHF
3,000,000–30,000,000	Super high	SHF

(L.R.Q.)

RADIO NAVIGATION. The use of radio aids to **navigation** for checking the **dead-reckoning** position of a ship is known as radio navigation. Following a **radio range,** or using a **radio compass,** is included in the general subject of radio navigation. However, neither of these two methods is completely reliable, and positions of the ship should be checked frequently by using radio bearings for **lines of position,** obtaining what is known as a radio **fix.**

The use of radio bearings as lines of position can best be described by solving two numerical problems. 1. A ship is proceeding on **heading** 330° at 12 **knots.** Three **radio beacons,** A, B, and C, are located in the following positions:

Station	A	B	C
Latitude	29° 30′ N	30° 00′ N	28° 40′ N
Longitude	83° 20′ W	81° 40′ W	81° 52′ W.

At 0812 the dead-reckoning position of the ship is L = 28° 32′ N & Lo = 82° 42′ W and at that time radio bearings, corrected for deviation of the radio compass, are $A = 000°$, $B = 063°$, and $C = 117°$. These must be changed to true bearings by adding to each the heading of the ship, obtaining: $A = 330°$, $B = 033°$, and $C = 087°$. Since these are **great-circle** bearings, they must be reduced to **rhumb-line** bearings by applying the correction factors for $A - 0.05$, $B + 0°.2$, and $C + 0°.1$. Then, working either on a **mercator** chart, **mercator plotting** sheet, or **small-area plotting** sheet, the corrected rhumb-line bearings are plotted, and the fix determined as the center of the triangle of intersection of the three lines of position. The position of the fix is L = 28° 37′ N & Lo = 82° 44′ W, and, since the sides of the triangle are less than 3 miles, we can assume that the fix is probably correct to within 1 mile. The complete solution is illustrated in Fig. 1(a) which is drawn on a small-area plotting sheet and labelled in accordance with standard U. S. Navy procedure.

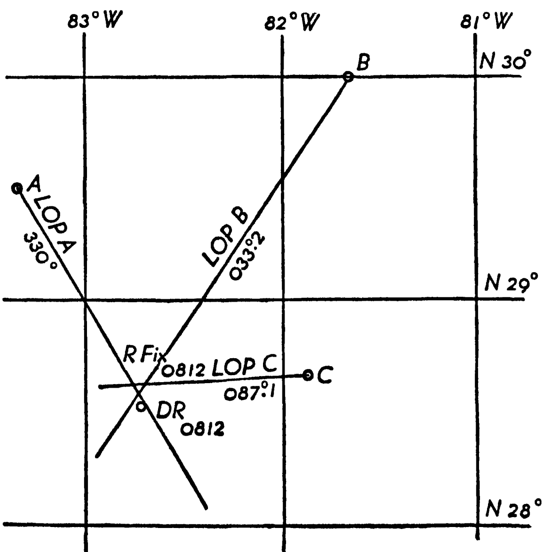

Fig. 1(a). Radio navigation scale diagram.

A plane on routine flight is heading 240° with true air speed of 180 knots. A tail wind of 30 knots is blowing, giving a predicted **course** of 240° and ground speed of 210 knots. The pilot expects that his dead-reckoning position at 1200 will be Latitude 45° 10′ N and Longitude 84° 30′ W. Since he is flying between two layers of overcast, he cannot check his position by either pilotage or celestial navigation. However, there are three radio beacons, A, B, and C, which are available for radio bearings. The positions of the stations are as follows:

Station A, Latitude 44° 17′ N, Longitude 85° 30′ W
Station B, Latitude 45° 24′ N, Longitude 85° 56′ W
Station C, Latitude 44° 15′ N, Longitude 84° 38′ W.

At 1155 the radio bearing of A is found to be 336°. At 1200 the radio bearing of B is 043°, and at 1205 the radio bearing of C is 281°. Correcting the bearings for deviation, heading, and rhumb line we have $A = 215°.5$, $B = 282°.6$, $C = 161°.0$. Because of the rapid motion of the plane the 1155 line must be moved forward parallel to itself through the distance that the plane has advanced in 5 minutes, and the 1205 line must be moved back through the distance that the plane moved in 5 minutes. The fix of the 1200 line with the 1155 and 1205 lines, moved to 1200 by dead reckoning, yields L = 45° 15′ N & Lo = 84° 44′ W. The size of the fix triangle indicates that the position is reliable to within 4 miles. The problem, plotted on a small-area plotting sheet and labelled in accordance with U. S. Navy aviation procedure, is shown in Fig. 1(b). (W.K.G.)

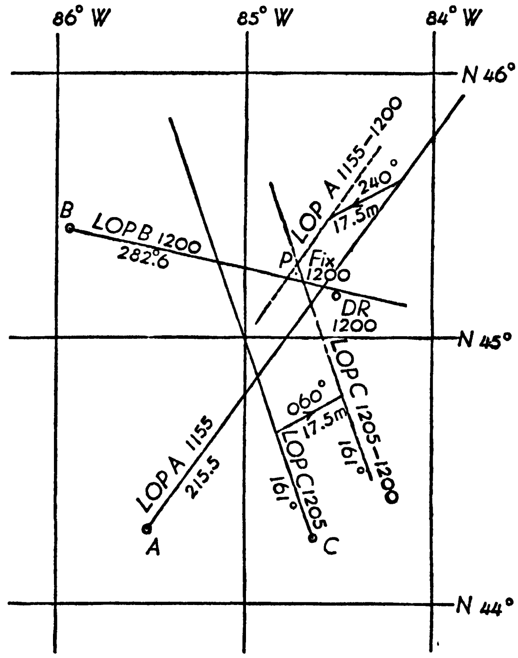

Fig. 1(b). Radio navigation scale diagram.

RADIO RANGE. A radio range is a system of radio signals designed for the purpose of guiding a ship or plane along a designated **track** toward or away from a specified location.

The standard radio range in this country uses relatively low frequency (in the 200–400 kc. band) and, while there are various modifications, the track is indicated by the intersection of two field patterns from the range **antenna** system. The usual antenna arrangement is two pairs of crossed Adcock antennae set 90° in space from one another. This gives two figure-8 field patterns as shown in Fig. 1(a). The patterns overlap in narrow wedge-shaped regions which have their apices at the trans-

mitting station. These overlapping sectors are known as the range or "the beam." Two methods, aural and visible, are used for keeping a ship "on the beam."

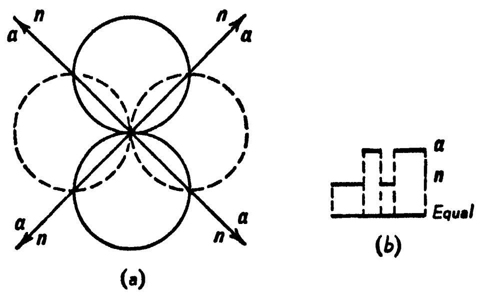

Fig. 1. Radio ranging.

In the aural system the carriers from the two antennae are so **modulated** with some audio note, say 1000 cycles. The code signal (letter a, dot dash) is transmitted from one antenna, and the code signal (letter n, dash dot) from the other, so timed that on the center of the overlapping region the two signals blend together in a continuous note. This is indicated in Fig. 1(*a*), while the time sequence of the code characters is shown in Fig. 1(*b*). To remain directly "on the beam," all that is necessary is for the navigator to head his plane so that the continuous note is heard in his receiver. If he drifts to the right or left of the center, he hears either the a or n signal superimposed on the steady note. This also provides a method for planes proceeding in opposite directions to remain on the proper side of the airway. The range signals are interrupted at frequent intervals to give the name of the station and, when necessary, weather reports and information to aviators or navigators.

In the visual method, the carriers from the two antennae are modulated with different frequencies, say 65 and 85 cycles. The antennae are then excited alternately so that the plane receiver gets first one signal and then the other very rapidly. The demodulated output of the receiver is fed to a tuned reed instrument so if the two signals are received with equal strengths, indicating on course, both reeds will vibrate with equal amplitude, while off-course flight will cause a greater vibration of one or the other depending upon which side of the course the plane is flying.

The exact angular relation of the **courses** laid down by the range station may be altered in several ways. Feeding the two antennae with different strength signals, feeding in different phases, utilization of additional antenna elements, etc., all serve to alter the field pattern so the lines of equal strength can be varied in direction. Where it is desired to rotate the courses after their angular relation has been fixed, a double **goniometer** may be used to feed the antennae. This gives a continuous 360° control of the direction of the beams. Experimental work has been done on ultra high-frequency ranges and in the future there will undoubtedly be other systems put into common use.

There is no way with an ordinary receiving antenna for a pilot to tell in which of two opposite directions the range transmitter is located, unless his **dead-reckoning** position is sufficiently accurate. Several complicated "orientation procedures" are used by aviators to determine the direction of the station. With a modern **radio compass** installation this difficulty is removed.

To further assist aviation pilots who are navigating by radio ranges a system of markers has been established. With the Adcock antennae now in use no signal is transmitted in a vertical direction. Accordingly, above the transmission station there is a cone-shaped region with apex down in which no signal will be heard, and this is known as the "cone of silence." As a pilot, flying a range, passes above the transmitter the signal strength will drop to zero and then increase to normal strength. The time elapsed between this fading and reappearance will be proportional to the width of the cone, and hence, to the altitude at which the plane is passing above the station. Because of the fact that ordinary fading might produce the same effect, many range stations are now equipped with a Z-type marker. This is a transmitter operating on ultra high frequency (75 megacycles) so designed that its transmission cone fills the cone of silence just mentioned. A special receiver is required to pick up this signal, and, as with the cone of silence, the time during which this signal is heard will indicate the altitude of the plane above the transmitter. To warn the pilot that he is approaching a range station, a fan-type marker, operating on the same frequency as the Z-type, is frequently established at a distance from 3 to 5 miles from the range transmitter. The characteristic signal of such a marker, which is indicated on the chart, will give the pilot a positive location. These are particularly valuable in overcast weather when blind-landing procedures may have to be adopted.

At some points of intersection of radio ranges, M-type markers are established. These are non-directional, low-powered, high-frequency radio stations, transmitting a characteristic signal which will inform the pilot that he is approaching the intersection.

The phrase "on the beam" has become a colloquialism for being safe and proceeding correctly. However, in common with all radio equipment, the ranges cannot be relied upon exclusively, and no pilot should ever proceed blindly along the beam without continually checking his dead reckoning and obtaining **fixes** whenever possible by **pilotage, radio navigation,** or **celestial navigation.** For reasons, far from completely understood at present, radio ranges will split up into several components, or the range may bend from its normal direction, may develop a "kink," or do a number of other things which may lead the incautious navigator into serious trouble, rather than safely into his destination. (W.K.G., L.R.Q.)

RADIO TELEGRAPHY. Radio telegraphy is that form of radio communication which utilizes the dots and dashes of the International code to transmit the intelligence.

Basically, the system involves some generator of high-frequency (**radio-frequency**) a.c. which can be interrupted according to the code and which is fed to the transmitting **antenna** where it is radiated into space, and a receiving system for picking up part of this radiated energy and converting it into an audible or visual reproduction of the original dots and dashes. Telegraphy was the first type of wireless communication and was in wide use several years before voice transmission became a practical success. While it is difficult to determine just who was responsible for the invention of radio, or wireless as it was first called, Maxwell is credited with first

showing the possibilities mathematically and Hertz with first verifying this theory. Hughes also did valuable work about the same time, demonstrating as early as 1879 the wireless transmission of signals over distances of several yards. He also later extended this range to several hundred yards and discovered the coherer—a device for receiving radio signals. However, these were laboratory experiments and did not constitute a practical system for communication between distant points. It remained for Marconi to develop and patent the first complete practical system. While there were few, if any, basically new points in his system, he deserves full credit for combining various components into a working system. The art developed rapidly from 1897 when Marconi filed for his first patents to 1901 when he successfully spanned the Atlantic. Modulation was invented by Fessenden in 1902 but the first commercial radio telephone service was not inaugurated for several years. The obvious safety aid involved in ship radio led to its immediate adoption by many vessels and shortly to its enforced adoption by all major passenger-carrying vessels. While these early radio systems were universally **damped wave** installations, practically all present day radio telegraph circuits employ **continuous waves.**

At the lower radio frequencies the alternating currents can be generated by special rotating machines, such as the Alexanderson alternator, and in fact were so generated at first. Now nearly all radio signals are generated by vacuum-tube circuits so we shall confine this discussion to them. Regardless of the size or rating of the transmitting station, the high-frequency a.c. originates in the **oscillator.** In the simplest transmitters the output of the oscillator may be connected directly to the antenna but usually this oscillator output feeds an **amplifier** stage or stages where the power is built up by the amplifying action of vacuum **tubes** and their associated circuits. Not only is the power increased beyond that which can satisfactorily be obtained from oscillators directly, but the character of the transmitted signal is improved. The frequency of an oscillator varies with the voltage, with the load, etc., so by using a **buffer** amplifier the frequency **stability** of the station is improved and this is reflected in more reliable reception and decreased interference between stations. Where it is necessary to operate over a considerable range of frequencies the oscillator is self-controlled, i.e., its frequency may be varied by varying the tuning control just as is done in the familiar broadcast **receiver,** while for fixed-frequency operation the oscillator is preferably **crystal**-controlled. Often where only a few fixed operating frequencies are needed the oscillator is still crystal-controlled with several crystals which may be cut in by a selector switch. A simple radio telegraph transmitter is shown in Fig. 1. Not only must the transmitter

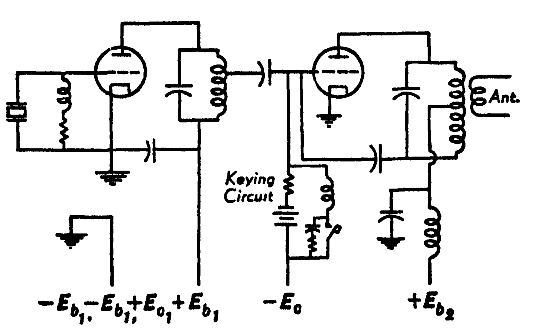

Fig. 1. Simple radio telegraph transmitter.

generate the necessary a-c power for the antenna but suitable means for interrupting this to produce the dots and dashes of the code must be incorporated. While it is necessary in some types of service to stop the oscillation completely for spaces and hence becomes necessary to key in the oscillator, this produces some frequency drift and often an undesirable chirpy signal unless extreme care is taken in the design and operation of the transmitter. As a consequence of this effect on the output signal, the keying is often done in one of the amplifier stages, the oscillator operating continuously but the keyed amplifier preventing the signals from reaching the antenna. The radio-frequency energy is radiated into space by the antenna, the exact spacial distribution depending upon the antenna system which is often designed for the particular type of service. Many telegraph stations employ **directional antennae** as most of their work is with fixed stations and does not require general coverage.

The receiving antenna intercepts the radio wave and hence has a very small voltage induced in it. This voltage is fed into the receiver which involves some sort of selective circuit for tuning in the desired station, usually one or more stages of amplification, a **detector** and an audio **amplifier.** The reception of continuous wave signals by ear requires some means of converting the high radio frequencies into an audible frequency. This is accomplished by heterodyning the incoming signal with a slightly different frequency of locally generated a.c. to produce an audible beat. This beat, upon **detection,** becomes an **audio-frequency** current which can operate the diaphragm of the headphones or **speaker** to give a sound. This, of course, responds to the keying of the original radio wave. (See **Heterodyne** and **Detection.**) Fig. 2 shows the wave forms produced in this detection process.

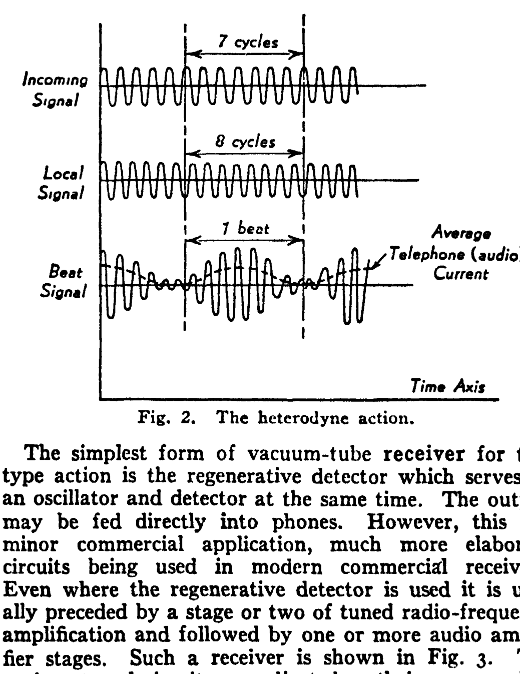

Fig. 2. The heterodyne action.

The simplest form of vacuum-tube **receiver** for this type action is the regenerative detector which serves as an oscillator and detector at the same time. The output may be fed directly into phones. However, this has minor commercial application, much more elaborate circuits being used in modern commercial receivers. Even where the regenerative detector is used it is usually preceded by a stage or two of tuned radio-frequency amplification and followed by one or more audio amplifier stages. Such a receiver is shown in Fig. 3. The various tuned circuits are adjusted so their response is a maximum at the frequency of the station desired. This gives the needed selectivity. After detection the audio signal is built up by the amplifiers to drive a head-set or speaker. Much of the present day reception is done with **superheterodyne** receivers, a beat-frequency oscillator being added to the basic circuit. This oscillator is fix-tuned to the intermediate frequency plus, let us say, 1000 cycles and its output mixed with the intermediate frequency output at the detector. The result is the 1000-cycle beat **note.** Other refinements include crystal filter circuits to cut out interference from stations on almost the same frequency as the desired one.

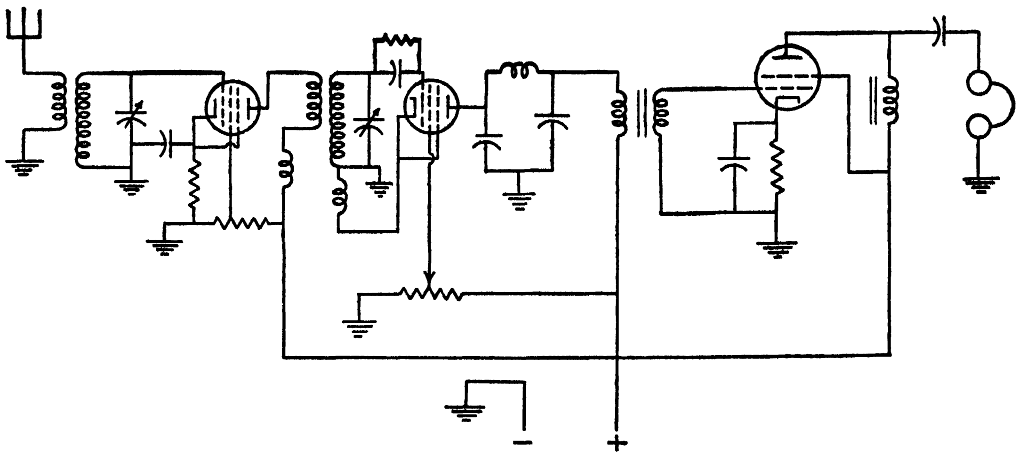

Fig. 3. Commercial radio telegraph receiver.

Manual operation of the radio telegraph employing a hand-operated key at the transmitting end and earphones at the receiver, is satisfactory for a great many services. However, there are instances where limitations in speed of transmission of messages, caused by the inability of even trained and competent operators to receive more than approximately 40 words per min., do not fully develop the possibilities of either the investment or of the channel allotment. Particularly, in point-to-point commercial wireless telegraphy automatic transmitting and receiving equipment is justified. In one system the message is typed out on a machine having a keyboard similar to a standard typewriter. Operation of this machine perforates a roll of paper which is then fed into an automatic transmitter, in which the perforations in the tape create an action which takes the place of the manual keying of the hand-operated transmitter. Since the perforation of the tape and its use occur in two different machines, there need not be any equality of the speed of perforating the roll and the speed with which it is then fed through the automatic transmitter. Several perforating machines might be employed to supply messages to one automatic transmitter, so the limitations imposed by an operator's speed of typing need not affect the transmitter. As a result, the latter can be made to transmit over 200 words per min. This greatly increases the use to which a point-to-point wireless telegraph system may be put. Naturally, reception of such high-speed signals must also be the function of a machine. A commonly used system has an ink recorder in which movement of the pen is controlled by the incoming signal, and a record of dots and dashes is made upon a continuous roll of paper. Operators may then transcribe this ink record into the original message. (L.R.Q.)

RADIOACTINIUM. Symbol: RdAc. A radioactive element of the **actinium** series. (See **Radioactive Changes.**) (R.K.S.)

RADIOACTIVE CHANGES. The phenomenon of radioactivity was discovered by Becquerel in 1896 by the effect produced on a photographic plate by **pitchblende** (**uranium**-containing mineral) while wrapped in black paper in the dark. Soon after this, it was found that uranium minerals and uranium chemicals are radioactive, and strangely the minerals showed more radioactivity than could be accounted for by the uranium content. About the same time there was discovered radioactivity of **thorium** minerals and thorium chemicals. Uranium and thorium are the previously known chemical elements to which is attributable the phenomenon of radioactivity. Later, it was found that **potassium** and **rubidium** possess a mild degree of radioactivity. There is sufficient thorium element in the oxide of a gas mantle so that, if it is treated as Becquerel treated pitchblende, an image of the mantle web is obtained on the photographic plate.

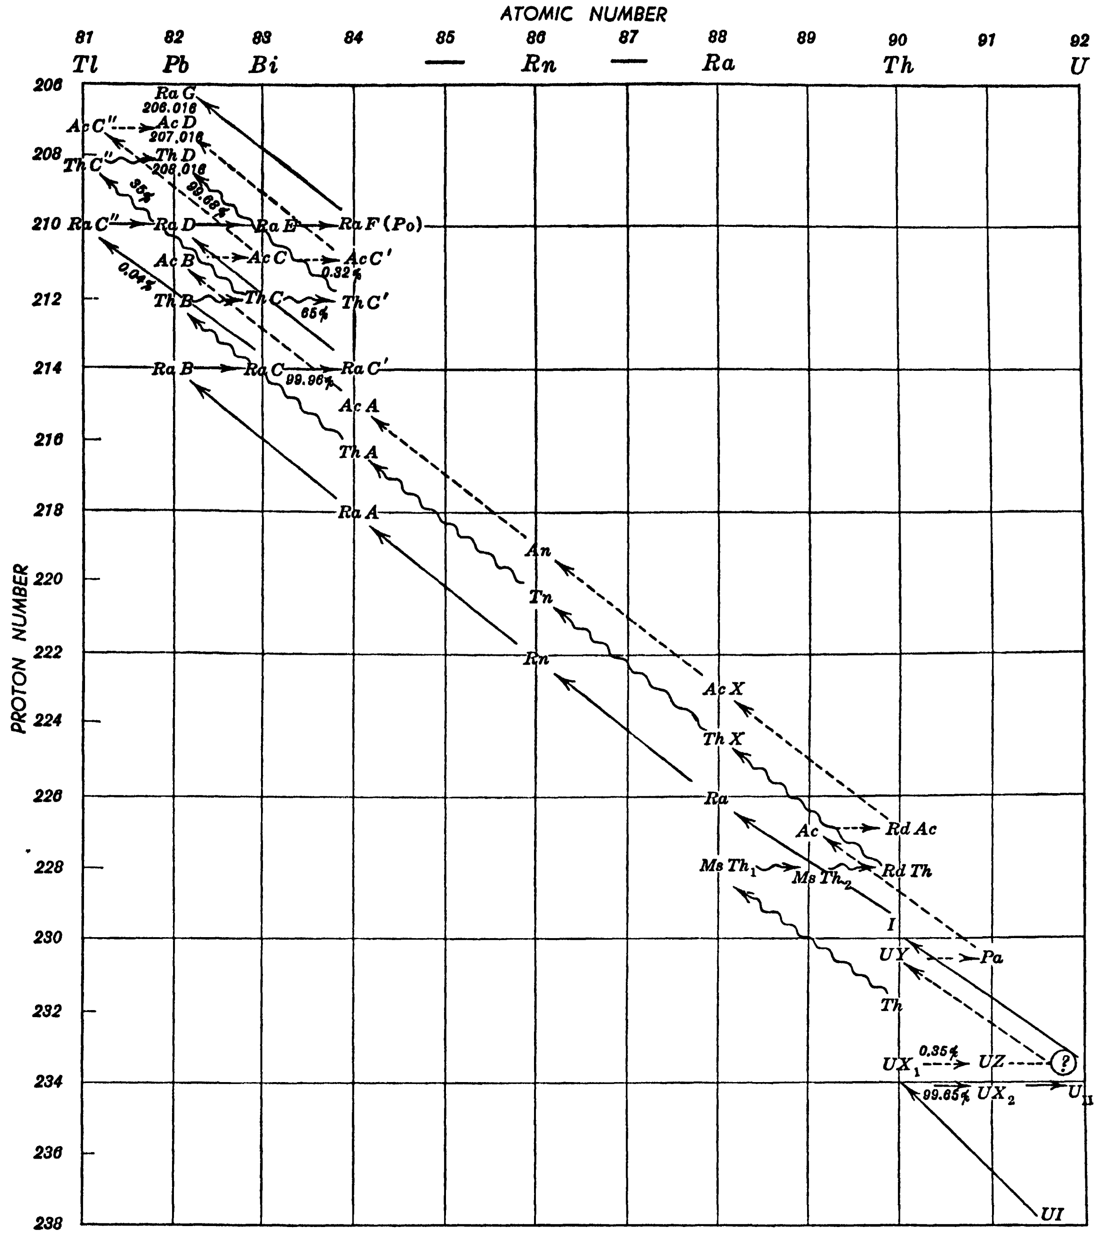
The excess radioactivity of mineral over chemical uranium led P. and Mme Curie to experiment with the mineral. For detecting the presence of radioactive substance a method was found in the discharge of a charged gold-leaf electroscope, which method also serves for the quantitative estimation of radioactivity by observation of the rate of drop of the gold-leaf. By separating into fractions and examining each fraction by the electroscope, they found in the **bismuth** element fraction the first new radioactive element to be discovered. It was named **polonium** (1898). They found that polonium disappeared rapidly, half of its radioactivity vanished in about six months. The fraction containing **barium** element was also found by them to be radioactive. Repeated fractional crystallizations of the chloride and bromide solutions made possible the recovery by them of practically pure salt of the second new radioactive element. It was named **radium** (1898).

Radium is chemically similar to barium; displays a characteristic **spectrum;** its salts exhibit **phosphorescence** in the dark, a continual evolution of heat taking place sufficient in amount to raise the temperature of 100 times its own weight of water 1° C. every hour; and many remarkable physical and physiological changes have been produced. Radium shows radioactivity a million times greater than an equal weight of uranium, and unlike polonium, suffers no measurable loss of radioactivity over a short period of time (in 1600 years the activity diminishes to one-half of the original). From solutions of radium salts, there is separable a radioactive gas, radium emanation, **radon,** which is a chemical element similar to **xenon** and disappears at a characteristic rate (in 3.8 days the activity diminishes to one-half of the original) with the simultaneous formation of another radioactive element, Radium A.

The series of radioactive transformations are displayed in graphical form on page 1191, and the constants of the radioactive elements in tabular form on page 1192.

Of the various properties possessed by radioactive substances, the emitted radiations merit special attention. The radiations are of three types, alpha, beta, and gamma. In kind they resemble **anode rays, cathode rays, x-rays,** respectively. In this behavior towards **electrical and magnetic fields,** the resemblance is qualitatively complete: 1. Alpha rays are positively charged particles of mass 4 and slightly deflected by electrical and magnetic fields. 2. Beta rays are negatively charged **electrons** of mass 1/1800 of that of the **hydrogen atom,** and largely deflected by electrical and magnetic

TRANSFORMATIONS OF RADIOACTIVE ELEMENTS



fields. 3. Gamma rays are undeflected by electrical and magnetic fields, and of **wavelength** of the order of 10^{-8} to 10^{-9} cm.

Alpha rays consist of particles shot off from the interior of the atoms of certain **elements** with a definite velocity and a definite range for each element. The velocity is from 5–7% that of **light**. The range is the distance traversed in a homogeneous medium before **absorption**, and is proportional to the cube of the velocity (Geiger and Nuttall, 1911). The penetrating power is the smallest of the three kinds of rays, the beta being of the order of 100 times, and the gamma rays 10,000 times more penetrating. The alpha rays are particles of **helium** carrying two unit positive charges (He^{++}). Ramsay and Royds (1909) experimentally demonstrated that accumulated alpha particles, quite independently of the matter from which they have been expelled, consist of helium. They sealed radon in a glass tube with wall so thin that the alpha particles passed through the wall into a surrounding vessel and after six days the whole spectrum of helium was observed. Helium itself does not diffuse through such a wall. Therefore alpha particles on losing their charge become ordinary helium. This is the first instance of the *production of a known element* during radioactive transformation. The loss of a single alpha particle by an atom leaves the residual atom four units less in **atomic weight** and two positive charges less in **valence** (Fajans, 1913). The shooting of alpha particles may be visibly registered by Crooke's spinthariscope, in which the tip of a wire, coated by a tiny amount of radium salt, is placed near a screen coated with **zinc** blende. Viewed in the dark with a magnifying eyepiece, each alpha particle striking the zinc blende target emits a visible scintillation. It is *as if* one were seeing atoms. The detection and counting of single alpha particles was

SOME CONSTANTS OF RADIOACTIVE ELEMENTS

accomplished by Rutherford and Geiger (1908) by the deflection of an electrometer needle upon the arrival of each alpha particle in a gas at low pressure in an electric field somewhat below the sparking point.

Beta rays are electrons shot off from the interior of the atom of certain elements with velocities varying almost up to that of light. The loss of a single beta particle by an atom leaves the residual atom the same in atomic weight and one negative unit less in valence. (Soddy, Russell, Fleck, Fajans, 1913.)

Gamma rays are like x-rays but more penetrating. The presence of gamma rays from 30 milligrams of radium can be observed in an electroscope after passing through 30 cm. of iron (Rutherford). For the protection of the operator, radium is kept in lead outer containers or screened by lead sheets. Gamma and beta rays usually accompany each other, and seem to be related in much the same ways as x-rays and cathode rays. The wavelength of gamma rays has been determined by diffraction through crystals, and ranges from about 10^{-8} cm. for the *soft* gamma rays of radium B to 0.7×10^{-9} cm. for the *hard* penetrating rays of radium C.

The end-product of the uranium series indicates lead of atomic weight 206. Actually, uranium lead (RaG) has an atomic weight of 206.016 (from uranium I, 238.14, by loss of 8 alpha particles). The end point of the thorium series indicates lead of atomic weight 208. Actually thorium lead (ThD) has an atomic weight of 208.016 (from thorium 232.12, by loss of 6 alpha particles). The end point of the actinium series indicates lead of atomic weight 207 (stated as 207.016). Atomic weight determinations by Richards (1916) showed lead of North Carolina uranite of atomic weight 206.40, from Colorado carnotite 206.59, and from Joachimsthal pitchblende 206.57.

Radioactive Isotopes. Mesothorium 1 and radium are chemically identical. It is possible to distinguish by chemical methods only 10 different radioactive elements, numbers 81, 82, 83, 84, 86, 88, 89, 90, 91, 92, while from radioactive evidence it appears that there are about 39. All of the elements in each of the 92 possible places of the Mendeleeff-Moseley classification of elements exhibit identical chemical properties. Such elements—isotopic elements—are abundant among the radioactive elements.

Artificial Disintegration of the Elements. In 1919, Rutherford disintegrated the atom of nitrogen by bombardment with alpha particles fired off from radium-C. By means of advancements since then the artificial disintegration of practically any element is possible. The results of these studies have lead (1) to fundamental knowledge of the structure of the atom, and (2) to the application of this knowledge (a) to produce new atoms and atomic particles and (b) to create or absorb energy. All of these results are radically novel and apparently at variance with previous scientific beliefs. Most radical to the layman is probably the annihilation of some of the mass of reactants with the simultaneous creation of a relatively enormous amount of energy. **The disappearance of 1/100 atomic mass unit** (where the "ordinary" oxygen atom is 16.0000 atomic mass units) **results in the appearance of 9.3 million electron volts (MEV),** of energy, and conversely the appearance of 1/100 atomic mass unit in the disappearance of 9.3 million electron volts. In the disintegration studied by Rutherford, wherein nitrogen was bombarded with **alpha particles** (helium atoms, atomic mass 4, atomic number 2, electrical charge 2 units +), the result is as follows:

Atomic mass: Atomic number:	${}^{14}_{7}N$	+	${}^{4}_{2}He$	→	${}^{17}_{8}O$	+	${}^{1}_{1}H$
Exact mass:	14.0075		4.0039		17.0045		1.0081
Mass sum:	18.0114				18.0126		

Appearance of mass: 18.0126 − 18.0114 = 0.0012 unit

$$\text{Disappearance of energy: } 9.3 \times \frac{0.0012}{0.0100} = 1.1 \text{ MEV}$$

Curie and Joliot found further, in 1933, that boron, magnesium, or aluminum, when bombarded with alpha particles from polonium, emit positrons (β^+) and the emission continues after the polonium is removed. The half-life of this positron emission from aluminum (after the polonium is removed) is 3.25 minutes, and the average energy of ejected positrons is approximately 2.2 MEV by absorption measurements. Radioactive isotopes of many of the chemical elements have been obtained, and some 60 or more eject positrons, some having quite a long half-life. This phenomenon of produced radioactivity is called artificial radioactivity, not because there is anything artificial in the radioactivity itself but simply because it is produced artificially. In alpha-particle bombardment the alpha particle is first captured by the atom bombarded and then either a proton (${}^{1}_{1}H$) or a neutron (${}^{1}_{0}n$) is ejected. The same kind of atom may eject *both* protons *and* neutrons simultaneously from different individual atoms; thus for sodium atoms it is found:

Atomic mass:
Atomic number:

$${}^{23}_{11}Na + {}^{4}_{2}He \rightarrow {}^{26}_{12}Mg + {}^{1}_{1}H$$

$${}^{23}_{11}Na + {}^{4}_{2}He \rightarrow \underset{\text{radioactive}}{{}^{26}_{13}Al} + {}^{1}_{0}n$$

Besides (1) alpha particles (${}^{4}_{2}He$), it is found that (2) protons (${}^{1}_{1}H$), (3) neutrons (${}^{1}_{0}n$), and (4) deuterons (${}^{2}_{1}H$) serve as projectiles for (a) the transmutation of elements, (b) the production of artificial radioactivity, and (c) nuclear fission. Also, (5) photon ($h\nu$) bombardment is effective in a few cases.

In 1932, Cockcroft and Walton bombarded lithium with *protons* having energies of 100 to 700 thousand electron volts (KEV) and found that alpha particles were ejected, as evidenced (a) by scintillations on a fluorescent screen, (b) by photographing the tracks of the particles in a Wilson cloud chamber, and (c) by electrical methods of detection.

Atomic mass: Atomic number:	${}^{7}_{3}Li$	+	${}^{1}_{1}H$	→	${}^{4}_{2}He$	+	${}^{4}_{2}He$
Exact mass:	7.0182		1.0081		4.0039		4.0039
Mass sum:	8.0263				8.0078		

Disappearance of mass: 8.0263 − 8.0078 = 0.0185 unit

$$\text{Appearance of energy: } 9.3 \times \frac{0.0185}{0.0100} = 17.2 \text{ MEV}$$

Other disintegrations produced by proton bombardment are:

$${}^{7}_{3}Li + {}^{1}_{1}H \rightarrow {}^{8}_{4}Be + h\nu$$

$${}^{9}_{4}Be + {}^{1}_{1}H \rightarrow {}^{6}_{3}Li + {}^{4}_{2}He$$

$${}^{9}_{4}Be + {}^{1}_{1}H \rightarrow {}^{8}_{4}Be + {}^{2}_{1}H$$

$${}^{11}_{5}B + {}^{1}_{1}H \rightarrow {}^{4}_{2}He + {}^{4}_{2}He + {}^{4}_{2}He$$

Since protons with energies as low as 20 KEV are effective in producing some disintegrations, it is believed that there are certain responsive or "resonance" values of energy at which the proton can enter the atomic nucleus readily when its own (proton) energy is relatively small.

When beryllium is bombarded with alpha particles it became clear, after Chadwick (1932) had recognized the neutron as a particle of zero electrical charge and of mass equal to the hydrogen atom or proton, that the reaction involved is:

Atomic mass:
Atomic number:

$${}^{9}_{4}Be + {}^{4}_{2}He \rightarrow {}^{12}_{6}C + {}^{1}_{0}n$$

wherein a neutron (${}^{1}_{0}n$) was ejected. Due to its bearing no electrical charge, the neutron can readily penetrate the

nuclei of atoms, even those that are highly charged and heavy, and accordingly more disintegrations have been produced with neutrons than with any other particle. The disintegrations by neutron bombardment are varied and may result in the ejection of one or more neutrons, of an alpha particle, of a proton, or of a photon, and practically all of the elements have been disintegrated by this method. The following examples are illustrative:

$${}^{1}_{1}H + {}^{1}_{0}n \rightarrow {}^{2}_{1}H + h\nu$$

ordinary hydrogen into heavy hydrogen

$${}^{6}_{3}Li + {}^{1}_{0}n \rightarrow {}^{3}_{1}H + {}^{4}_{2}He$$

production of rare ${}^{3}_{1}H$ possessing radioactivity

$${}^{10}_{5}B + {}^{1}_{0}n \rightarrow {}^{7}_{3}Li + {}^{4}_{2}He$$

$${}^{23}_{11}Na + {}^{1}_{0}n \rightarrow {}^{20}_{9}F + {}^{4}_{2}He$$
radioactive

$${}^{24}_{12}Mg + {}^{1}_{0}n \rightarrow {}^{24}_{11}Na + {}^{1}_{1}H$$
radioactive

$${}^{27}_{13}Al + {}^{1}_{0}n \rightarrow {}^{27}_{12}Mg + {}^{1}_{1}H$$
radioactive

$${}^{27}_{13}Al + {}^{1}_{0}n \rightarrow {}^{24}_{11}Na + {}^{4}_{2}He$$
radioactive

$${}^{27}_{13}Al + {}^{1}_{0}n \rightarrow {}^{28}_{13}Al + h\nu$$

$${}^{39}_{19}K + {}^{1}_{0}n \rightarrow {}^{38}_{19}K + {}^{1}_{0}n + {}^{1}_{0}n$$
radioactive

Some disintegrations require the use of neutrons of high energy, called fast neutrons, and some require those of low energy, called slow neutrons. Slow neutrons are usually obtained by allowing fast neutrons to pass through some substance containing hydrogen. In the examples cited above, the disintegration by neutron bombardment results in products of decidedly unequal masses, but the neutron bombardment of uranium (1939) splits this atom into two products of almost equal masses. This phenomenon of "equal splitting" is called fission.

By bombardment with *deuterons* (${}^{2}_{1}H$) the lithium atom absorbs deuteron and ejects two alpha-particles, thus:

Atomic mass: Atomic number:	${}^{6}_{3}Li$	+	${}^{2}_{1}H$	$\rightarrow$	${}^{4}_{2}He$	+	${}^{4}_{2}He$

$$\text{Exact mass:}\quad \underbrace{1.0169 \qquad 2.0147}_{8.0316} \qquad \underbrace{4.0039 \qquad 4.0039}_{8.0078}$$

Mass sum: 8.0316 8.0078

Disappearance of mass: 8.0316 − 8.0078 = 0.0238 unit

$$\text{Appearance of energy: } 9.3 \times \frac{0.0238}{0.0100} = 22.1 \text{ MEV}$$

Also:

$${}^{6}_{3}Li + {}^{2}_{1}H \rightarrow {}^{7}_{3}Li + {}^{1}_{1}H$$

$${}^{7}_{3}Li + {}^{2}_{1}H \rightarrow {}^{4}_{2}He + {}^{4}_{2}He + {}^{1}_{0}n$$

$${}^{7}_{3}Li + {}^{2}_{1}H \rightarrow {}^{8}_{3}Li + {}^{1}_{1}H$$
radioactive

Two disintegrations by the bombardment of deuterium (heavy hydrogen, ${}^{2}_{1}H$) by deuterons are specially interesting:

$${}^{2}_{1}H + {}^{2}_{1}H \rightarrow {}^{3}_{2}He + {}^{1}_{0}n$$
rare, stable

$${}^{2}_{1}H + {}^{2}_{1}H \rightarrow {}^{3}_{1}H + {}^{1}_{1}H$$
rare, radioactive

The deuterium target is usually "heavy water" frozen on a surface that is cooled by liquid air, or it may be some other solid deuterium compound, say hydrocarbon. Other disintegrations by deuteron bombardment are:

$${}^{10}_{5}B + {}^{2}_{1}H \rightarrow {}^{4}_{2}He + {}^{4}_{2}He + {}^{4}_{2}He$$

$${}^{12}_{6}C + {}^{2}_{1}H \rightarrow {}^{13}_{6}C + {}^{1}_{1}H$$

$${}^{12}_{6}C + {}^{2}_{1}H \rightarrow {}^{13}_{7}N + {}^{1}_{0}n$$

$${}^{23}_{11}Na + {}^{2}_{1}H \rightarrow {}^{24}_{12}Mg + {}^{1}_{0}n$$

$${}^{23}_{11}Na + {}^{2}_{1}H \rightarrow {}^{24}_{11}Na + {}^{1}_{1}H$$
radioactive

$${}^{27}_{13}Al + {}^{2}_{1}H \rightarrow {}^{25}_{12}Mg + {}^{4}_{2}He$$

$${}^{196}_{78}Pt + {}^{2}_{1}H \rightarrow {}^{197}_{78}Pt + {}^{1}_{1}H$$
radioactive

In the last reaction ${}^{197}_{78}Pt$ is radioactive, with a half-life of 18 hours, and is transformed into gold ${}^{197}_{79}Au$ plus an electron. (R.K.S.)

RADIOACTIVE MINERALS. Strutt, one of the earliest workers in radioactive minerals, discovered that a specimen of **thorianite** which he tested contained 280 million times as much helium as the same mineral could generate in a year; thus he assumed that the **igneous** rock in which thorianite formed must be 280 million years old. **Uranium,** another radioactive substance, has been found to break up into **helium** and lead, one atom of uranium yielding eight atoms of helium and one atom of lead. Since these stable atoms of helium and lead can be measured and compared with the amount of uranium which has not disintegrated, it is possible to determine how long it has been since the mineral was formed. Analysis of radioactive minerals, by this method, collected from the oldest known granites of the **Archeozoic** intimate that the age of these rocks is approximately 1 billion, 800 million years old. One of the chief arguments in favor of the "radioactive method" for determining the age of the earth is that it checks when applied to the radioactive minerals collected from successively younger formations. (R.M.F.)

RADIO-FREQUENCY HEATING. **Electric Heating.**

RADIOGRAPHY. Photography by x-ray radiation or by the gamma rays of radium or **radioactive substances.**

In making radiographs, the x-rays emitted from the anode of the tube (see **X-Rays**) are directed towards the subject to be examined. Upon reaching the subject some pass through while others, meeting parts of the subject which offer greater resistance, are absorbed wholly or partially. Thus a shadow of those parts of the subject which are more opaque to the passage of the rays is cast on the photographic film and, upon development, a shadow image of the variations in the transparency of the subject to x-ray radiation is obtained. This photographic image is termed a radiograph.

While all photographic materials are sensitive to x-ray radiation, special x-ray emulsions are available which are more sensitive, thus permitting shorter exposures, and have the high contrast necessary to differentiate between slight variations in the absorption of x-rays by different parts of the subject. Such films differ from those used in the camera in having much thicker emulsion coatings; sensitivity to x-ray radiation depending largely upon the amount of silver halide present for the formation of an image and not, as with light, on the sensitivity of the different grains of silver halide in the emulsion.

When the exposure must be kept as short as possible as, for example, in photographing organs of the body which cannot be immobilized, or thick sections, intensifying screens are used. These are screens coated with a fluorescent substance, such as calcium tungstate, which convert some of the x-ray energy into ordinary light and so reduces the exposure. Placed in contact with the photographic emulsion an intensifying screen may reduce the exposure to 1/25 the exposure required by direct exposure to x-ray radiation. With thick metallic castings the reduction in exposure may in some cases reach 1/100.

Radiographs may also be made by photographing the image on the intensifying screen with an ordinary camera. Since this procedure requires a longer exposure, it is used only when a small image is acceptable. These small radiographs, which may vary in size from 4 x 5" to 1 x 1½" do not show as much detail as the larger direct radiograph, which is much better for diagnostic purposes, but meet the requirements of a "screening" examination the object of which is to locate outstanding cases.

This is also the simplest method of making x-ray motion pictures although it is often difficult to obtain sufficient exposure even when using (1) intensifying screens of the highest efficiency, (2) lenses with apertures of f/1.5 to f/1.9, and (3) emulsions of the highest available speed.

Micro-radiography is the term applied to the radiography of small objects where the detail is too fine to be seen by the unaided eye and the radiograph must either be examined with a low-power microscope or an enlargement must be made by projection. It is a relatively new field and one which is rapidly assuming considerable importance in the study of sections of tissue, leaf structure, insect anatomy, seeds, spray materials, textiles and artificial fibers and even the distribution of the constitutents in an alloy. For this latter the material must be in the form of a thin section. Soft, i.e , low-voltage, x-rays are used and single-coated, fine-grain, high-resolution films or plates. The resulting radiograph may be enlarged from 10 to 100 times, depending on the subject, the film or plate, and the voltage used in exposing the radiograph.

Stereoradiographs are necessary when the distance of an object or malformation below the surface must be determined. They are made by making two radiographs in succession, shifting the position of the tube between exposures a distance equal to the normal interpupillary distance. After processing, the radiographs are placed in a modified Wheatstone type of stereoscope in which the two images are combined to produce a three-dimensional (**stereoscopic**) image. Stereoradiography is not often used in industrial radiography but at times is of considerable value. (C.B.N.)

RADIOLARIA. **Plasmodroma.**

RADIOLARIAN OOZE. **Oceanic Deposits.**

RADIO-METEOROGRAPH. **Meteorological Instruments.**

RADIOMETER. An instrument for detecting, and usually also for measuring, thermal radiation, especially **infra-red**. Radiometers are of several different types.

1. *Crookes Radiometer.* The apparatus devised by Sir William Crookes consists of pairs of light vanes mounted at the ends of opposite spokes of a very light, horizontal wheel poised on a pivot like a compass needle. It therefore resembles a miniature paddle-wheel. One side of each vane is a polished metal surface, these surfaces being all directed the same way around the wheel; the other side is blackened. The whole apparatus is mounted inside a glass or quartz bulb from which the air is partially exhausted. When **radiation** from the sun or other hot source falls on the vanes, the wheel revolves in the direction toward which the polished surfaces are directed. This motion is explained by the higher absorptivity of the blackened surfaces, which causes them to become warmer than the polished surfaces. This, in turn, causes a creeping of gas molecules, known as "thermal transpiration," around the edge of the vane from the polished to the black face, thus building up an excess of pressure against the latter. If a similar vane system is suspended by a fine quartz fiber and provided with a small mirror, the torque caused by the inequality of pressure is made observable and may be used to measure the intensity of the incident radiation.

2. *Nichols Radiometer.* The apparatus used by Nichols and Hull for the measurement of **radiation pressure** (1901) consisted of a pair of small, silvered glass mirrors suspended, in the manner of a **torsion balance**, by a fine quartz fiber within an enclosure in which the air pressure could be regulated. The torsion head to which the fiber was attached could be turned from outside the enclosure by means of a magnet. A beam of light was directed first on one mirror and then on the other, and the opposite deflections observed with mirror and scale. By turning the mirror system around so as to receive the light on the unsilvered side, the influence of the air in the enclosure could be ascertained. This influence was found to be a minimum, and to have an almost negligible value, at an air pressure of about 16 mm. of mercury. The radiant energy of the incident beam was deduced from its heating effect upon a small, blackened silver disk, which was found more reliable than the **bolometer** at first used. With this apparatus the experimenters were able to obtain an agreement between observed and computed radiation pressures within about 0.6 of 1%.

3. Instruments operating on either the Crookes or the Nichols principle, according to the pressure of the residual gas in the enclosure, are in use under the name "vane radiometer." They are more sensitive if the radiation beam is allowed to fall on only one vane, the rest of the vane system being carefully shielded.

4. In addition to these, the **pyrheliometer**, the **bolometer**, the **radiomicrometer**, and the thermopile (see **Thermel**) may be properly classed as radiometers. (L.D.W.)

RADIOMICROMETER. A very sensitive **thermel**, adapted to the detection of feeble thermal radiation; devised by C. V. Boys (1889). It consists of a small bismuth-antimony thermocouple short-circuited by a narrow, oblong loop of copper wire and suspended by a quartz fiber between the poles of a strong permanent magnet. The couple is surrounded by a thick housing of soft iron to shield it from magnetic disturbances and stray radiation. The radiation to be measured is admitted through an opening in this shield and falls on a tiny copper disk soldered to the couple. A very small amount of radiation communicates heat enough to generate a current in the loop and cause it to turn in the magnetic field. The deflection is observed by means of a mirror attached to the loop, which reads on a scale like a **galvanometer**. By using a large lens to concentrate the rays, Boys was able to detect the radiation from a candle more than 2 miles distant. (L.D.W.)

RADIOTHORIUM. Symbol: RdTh. A radioactive element of the **thorium** series. (See **Radioactive Changes.**) (R.K.S.)

RADIUM. Symbol: Ra. Atomic number: 88. Atomic weight: 225.97. Melting point: 960° C.

Radium metal is white, rapidly oxidized in air, decomposes water, and in the metallic state is a curiosity. Radium is usually handled as the chloride or bromide, either as solid or in solution. Its most remarkable property is its radioactivity, which decreases about 1%

in 25 years. Radium element evolves heat continuously, 0.132 calories per hour per milligram of radium when the decomposition products are retained, and the temperature of radium salts remains about 1.5° C. above the surroundings. Discovered by P. and Mme Curie in 1898. (See **Radioactive Changes.**)

Radium occurs in **pitchblende,** and in **carnotite** along with **uranium.** Radium was first obtained from the uranium residues of pitchblende of Joachimsthal, Czechoslovakia, later from carnotite of southwestern Colorado and eastern Utah. Richer ores have been found in Belgian Congo and in the Great Bear region of northwestern Canada.

Radium is formed by the radioactive transformation of uranium—about 3,000,000 parts of uranium being accompanied in nature by 1 part of radium—and spontaneously generates **radon** gas—about 100 cu. mm. of radon per day per gram of radium.

Chemically related to **barium,** radium is recovered from its ores by addition of barium salt, followed by treatment as for recovery of barium, usually as the sulfate. The sulfates of barium and of radium are insoluble in most chemicals, so they are transformed into **carbonate** or **sulfide,** both of which are readily soluble in **hydrochloric acid.** Separation from barium is accomplished by fractional crystallization of the chlorides (or bromides, or hydroxides). Dry, concentrated radium salts are preserved in sealed glass tubes, which are periodically opened by experienced workers to relieve the pressure. The glass tubes are kept in lead shields.

Radium chloride ($RaCl_2$) and radium bromide ($RaBr_2$) are less soluble and radium hydroxide ($Ra(OH)_2$) more soluble than the corresponding barium compounds.

Radium causes serious flesh burns due to its radioactivity, but under proper control is used in the treatment of certain forms of **cancer.** (R.K.S.)

RADIUS. In zoology, the term radius has two common meanings. 1. It is a principal radiating division of the body of an **echinoderm.** In the starfishes and other forms with projecting arms, the arm or ray is the most conspicuous part of a radius. In more compact forms like the sea urchins each radius is a segment of the body. 2. It also denotes a bone of the forearm or lower foreleg of **vertebrates.**

For the use of the term radius in mathematics, see **Circle** and **Polar Coordinates.** (A.W.L.)

RADIUS OF CURVATURE. In mathematical terms the radius of curvature of a curve is the reciprocal of the curvature k, that is $\frac{1}{k}$, in which k is equal to the change in the direction of a curve per unit length of arc. The radius of curvature of a straight line is infinite. The radius of a **circle** is the radius of curvature of the circular curve. The radius of curvature of an **ellipse, parabola, hyperbola,** etc. (all mathematical curves), is a variable which depends upon the sharpness (curvature) at a particular point on a curve. If these curves are assumed to be made up of a number of infinitely short, connected, circular arcs, the radius of curvature might be defined, in simple terms, as the radius of an infinitely short, circular arc located at the point where the radius of curvature is desired. (See also **Curvature of a Plane Curve.**) (C.W.C.)

RADIUS OF GYRATION. The radius of gyration of an area in respect to a particular axis is the square root of the quotient of the **moment of inertia** divided by the area. It is the distance at which the entire area must be assumed to be concentrated in order that the product of the area and the square of this distance will equal the moment of inertia of the actual area about the given axis. The numerical value of the radius of gyration, k, is given by the following formula in which I is the moment of inertia and A, the area.

$$k = \sqrt{\frac{I}{A}}.$$

The radius of gyration of a **mass** is similar except that the moment of inertia of the mass is involved. (C.W.C.)

RADIUS VECTOR OF A POINT. Polar Coordinates in a Plane.

RADON. Symbol: Rn. Atomic number: 86. Atomic weight: 222. Density: 9.72 grams per liter, 0° C., 760 mm., or 7.5 when air equals 1.00. Melting point: −110° C.

Radon is a colorless gas, radioactive, and formed by **radioactive** transformation of radium. Radon, **thoron** and actinon are isotopes. Discovered by Dorn in 1900 in the radioactive transformation of **radium,** and thoron by Rutherford in 1900 in the radioactive transformation of thorium. Radon decays to ½ its radioactivity in about 4 days. Radon is obtained by bubbling air through a radium salt solution, and collecting the gas plus air. (See **Radioactive Changes.**) (R.K.S.)

RADULA. A horny strip in the floor of the mouth of a **snail.** It bears many rows of minute teeth and is used for scraping up food. The radula is developed in a ventral pouch of the oral cavity known as the radula sac. (A.W.L.)

RAFFIA. *Raphia Ruffia.* Palmaceae. This African **palm** tree has leaves of great length, sometimes as much as 25′. The leaf epidermis may be removed in strips. These strips, known as raffia, have been used in basketwork and for tying up plants. (R.M.W.)

RAFINESQUINA. Invertebrate Paleontology.

RAGLANITE. A term proposed by Adams and Barlow, in 1910, for a **facies** of **nepheline-syenite** also containing abundant **oligoclase feldspar** and the accessory minerals, **mica, calcite, apatite and magnetite.** (R.M.F.)

RAGWEED. *Ambrosia artemisiifolia.* **Composite Family.**

RAIL. Aves, Gruiformes. Long-legged marsh birds (**Aves**) of wide distribution. They have moderate to long and slender beaks, rather small wings, and a short tail. North America has several species, including the clapper, *Rallus longirostris,* Virginia, *R. limicola,* and sora rail, *Porzana porzana.* The corncrake, *Crex crex,* is a Eurasian species which reaches North America occasionally. In New Zealand the group is represented by the large weka rails which do not fly, although they have wings. (A.W.L.)

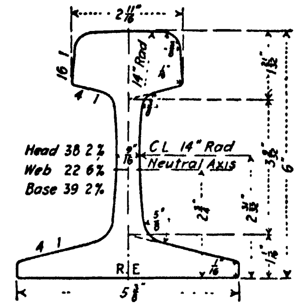
RAILS. Steel.

RAILWAY. The railway is a transportation agency which, in spite of the growing importance of other transportation systems (bus, truck, aircraft), is the principal method of transporting goods over long distances. The activities connected with the operation of railways constitute one of the leading industries of the United States by virtue of the services rendered, the capital invested, and the personnel employed. The operation of the railway, furthermore, may and does affect practically all persons living in its sphere of influence, because of the dependence upon transportation for the distribution of goods under the system of manufacture used in a progressive and mechanized civilization such as ours. The services of the railway consist of the movement, for a

price as expressed by the current rate, of freight or passenger traffic. From the standpoint of total receipts, freight is the more important. The speed with which a railway can transport goods with a small expenditure of energy means that manufacture can be specialized geographically. Large-scale production, and a considerable division of labor, are possible. These things have contributed in a large degree to making many commodities available at costs which would not be possible under any other system of production. The carrying of passengers is of greater importance to the nation than the net receipts of passenger traffic to the railway would indicate. The availability of definite scheduled transportation to the people as a whole, which transportation is rarely affected by season or weather, has an important economic and political connotation. Suburban passenger railway facilities have grown to be essential to the life of a metropolis, the housing facilities of which are entirely inadequate to its workers, who therefore, by necessity or choice, reside in suburbs which are swiftly and surely connected with the metropolis by the railway. Mobility of labor, rapid transportation of the mail, and carrying of commodities at a premium rate by the express business, are further important branches of railway activity. The railways of the United States are privately owned under the supervision of the Federal body for the control of interstate commerce. Although there are nearly 2000 separate companies divided into three classes by the range of their annual revenue, practically all of the transportation based on ton or passenger mileage is controlled by the class 1 companies, of which there are about 175 organizations. A class 1 railway is that having an annual revenue in excess of $1,000,000.

The railway proper consists of a continuous strip of ground called the right of way, varying from 60 to 150′ in width, which extends, with a minimum of curves and departures, in a direct course between centers of population, business, or industry which it serves. On this right of way there is a smooth graded base called the subgrade, upon which is laid **ballast** consisting of cinders or crushed stone. The cross ties which support the rails are usually laid on the subgrade, and afterwards lifted into position when the ballast has been placed. The gradient employed in rolling or mountainous country is, of necessity, a compromise between cost of construction and cost of operation. The steeper the ruling gradient of a line, the more powerful the tractive equipment must be, or the smaller the train size. On the other hand, the cost of reducing the gradient may, in rugged country, become extremely high. One cut-off constructed by a railway company which was able to reduce its ruling gradient from 1.2 to 0.7% is said to have cost approximately $300,000 per mi. This expenditure was justified since it reduced the grade and distance between termini on a trunk line which carried heavy traffic.

The wooden cross tie has become standard in this country, although substitutes in the form of concrete or steel have been tried. New wooden ties are usually creosoted to lengthen their life, and are approximately 7″ x 9″ x 8′ 6″ long. They are spaced a little under 2′ on centers, and on them are laid two parallel steel rails which are firmly spiked to each tie. The hard smooth way provided by the steel rail and the minimum rolling friction of steel wheels on these rails accounts for the extremely low haulage costs per ton mile on railways. The T-rail is the standard for open track work. These rails are rolled in steel rolling mills to standard sections the size of which is denoted by the weight per yd. of run. A 60-lb. rail is a relatively light one, and most of the trackage of this country will be found from this weight upwards to 150 lbs. The present standards of the American Railway Engineering Association are 100-, 110-, and 131-pound rails. The rails are manufactured in lengths of between 30 and 40′, and are coupled together by splice plates of several different designs. These couplings permit **expansion** and contraction of a sufficient amount at each joint.



Rail section.

Where the rails bear on the cross ties, there will be wear. When treated ties having a long life expectancy are used, steel tie plates are installed to relieve the cross tie of rail wear. The plate is held securely to the tie and the relative motion, caused by traction or expansion and contraction of the rails, is taken up between the plate and the rail.

Principal routes are nearly all double tracked. The rapid movement of trains, operation of automatic **block signalling**, and freedom from collision hazards, are so superior with the double-tracked arrangement that the additional expense is justified where a large amount of traffic is carried over the railway. Feeder and branch lines are largely single-track, although in many cases where it is thought that a large traffic will eventually develop, the subgrade of the right of way is prepared in sufficient width for double-tracking. Standard practice on double-tracked roads is for the train to advance on the right-hand track. In a few instances trunk lines have triple or quadruple tracks.

Necessary features of the right of way are those structures which are required to carry the railway over obstacles or depressions such as highways, rivers, streams, valleys. The use of **bridges** and trestles, tunnels, **culverts**, and other auxiliary structures, is inevitable in a railway having the trackage implied by membership in the class 1 railway group. Such structures are independently treated in this work.

The railway just described is served by terminal facilities and intermediate stations. The facilities of the intermediate stations will depend upon the importance of the stop. Usually this may be gauged roughly by the population of the locale. The facilities provided consist ordinarily of a station house and side track to which cars may be shunted for unloading or loading of bulk freight, such as sand, lumber, coal, etc. Packaged and crated commodities are handled in a portion of the station set aside for that purpose, or in a separate freight warehouse. The intermediate station contains a waiting room for passengers, and an office from which passenger tickets are dispensed, and which often serves as the base for freight, express, and telegraph services, all of which are concentrated in the hands of one station agent in the small, unimportant stops, but which may be divided among a larger personnel in the case of a city. Express and mail handling facilities and conveniences for passenger loading are also part of the station equipment. Under the head of terminal facilities come also those mentioned for the intermediate stops, although greatly increased and amplified in service to the general public. Larger passenger stations offering diversified services, greater division of labor, and more attention to architectural embellishment, characterize the terminal passenger station. Space is provided also for the executive branch. Long railways are subdivided into divisions with termini intermediate between the divisions as well as at

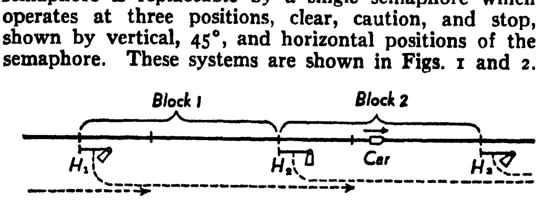
the ends of the line. These termini are important servicing points for the mobile equipment. From the standpoint of the rolling stock, the railway terminal is a "yard" in which the passenger and freight cars may be stored, and an engine house to perform a similar function for the locomotives. The yard is an area of ground covered by long parallel lines of track as close together as is possible, and equipped with switches and cross-overs so that all tracks may be connected with the main railway. The rolling stock not in use, or awaiting use, can be shunted to these yards. Car maintenance and overhaul shops are located alongside. The engine house is provided with stalls for the locomotives and shop facilities for normal repair work and servicing facilities for coaling, cleaning, inspection, and oiling. These houses are either rectangular in form, having a transfer table which rolls the entire length of the house and thus can serve a long line of parallel stalls. Or more frequently they are constructed in circular form; hence the name roundhouse. In a roundhouse the stalls are ranged radially from a central point at which is located a turntable. The incoming **locomotive** is rolled onto this turntable, which is then turned until the turntable track aligns with the short section of track leading to the stall.

The economic operation of a railway system is a very complex affair, reaching into practically all walks of life. The technical maintenance and operation are subjects more appropriate to the nature of this work. This activity consists of the scheduling of trains and the maintenance of them on schedule; servicing of the equipment, both stationary and mobile, so that it will be available for use when needed; and the operation of the physical system, safely and reliably, yet with train speeds as high as possible, for one of the essentials of the service rendered by the railway is fast transportation, whether it be that of freight or of passengers. The activities of technical maintenance must be carried out in a manner to maintain the system against the continuous tendency to deteriorate through such factors as floods, washouts, rust, dirt, rot, snow, friction, wear. It also will include the installation and operation of signalling systems, which have been found necessary, even on double-tracked roads, if heavy traffic schedules are to be maintained. The subject is discussed in more detail under **railway signalling.** Rolling stock must be periodically serviced, at which time work like greasing of bearings, cleaning of upholstery, repair and cleaning of box cars, painting of steel cars, replacement of wheels and brakes, etc., is done. A steam **locomotive,** consisting, as it does, of an entire steam power plant on wheels, is a complicated piece of equipment having many points of wear and many requirements of adjustment. The vibratory nature of its motion when in use, coupled with the presence of high temperatures, high pressures, ash, and smoke, make for expensive but necessary periodic overhauls, and for close inspections at the end of every run. The constant pounding of heavy loads over the track may loosen spikes, crack rail joints, loosen bonds, and these defects can, if unattended, lead directly and rapidly to a serious accident. Hence it is necessary to have a large force going over the right of way constantly, for inspection and repairs. Certain auxiliary services of a special nature are exemplified by the special ballast cleaner trains and by cars fitted with apparatus to detect "rail cancer." Special snow-handling equipment is necessary on railways which are not located in a warm climate. (F.T.M.)

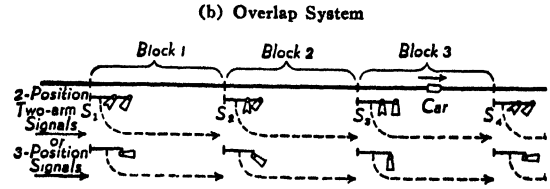
RAILWAY SIGNALLING. The momentum arising from the velocity and mass of a train requires a signalling system for the safety and convenience of operation of a railway train. Railway signalling, which displays signals designed to prevent more than one train occupying a certain section of track at a time, permits the operation of rolling stock at much higher speeds than would be possible, with safety, if the presence of other trains had to be detected visually by the engineman. Furthermore, passenger trains may be operated more smoothly if the engineman has the information given by the signalling system. The railway automatic **block signal** system has become standard equipment on the railways of this country.

Railway signalling embodies many functions besides the automatic block, but except for the following brief mention, these other classes of signalling are not treated here. A railway system employs signals for advising the engineman when orders from train dispatchers are ready for him. Special signals are employed for controlling railway traffic at junctions, grade crossings, drawbridges, etc., and other fixed or manually operated signals, such as signs along the right of way, indicate yard limits or speed limits. The trainmen make use of torpedoes, flags, or lanterns as signalling devices. Block signals are not always automatic, since many street-car systems have used manually operated block signals for suburban lines. With the disappearance of these extended street railways before the competition of buses, the examples of manually operated block signals have dwindled.

The block signal itself is the physical mechanism employed to signal the condition of the track ahead to the engineman. This it does by a mechanism which conveys the information visually. A pole or tower having a semaphore arm and lights is mounted alongside the track on the right of way, in clear view of the engineman. The trackage of the railway is divided electrically into blocks of from 1 to 5 miles in length. On descending grades the blocks are made longer than on rising grades, since a greater distance is required in which to stop a train. The shorter the block the more trains the system can handle, but the signalling system becomes more expensive, and the average speed of operation may be curtailed. The system used for dividing the line into blocks may be (a) simple blocks (not shown), one beginning where the other ends, each block covered by one block signal, (b) an overlap system, in which the blocks overlap by a distance equal to the space required for a train to stop after application of brakes, (c) the double-semaphore system, in which the condition not only of the block being entered is being shown, but that of the one next ahead. The semaphores in this system are known as the home and distant signals. They are distinguished during the daytime by the position and painting of the semaphore arm, and at night by the relative position of the lights on the pole. The double semaphore is replaceable by a single semaphore which operates at three positions, clear, caution, and stop, shown by vertical, 45°, and horizontal positions of the semaphore. These systems are shown in Figs. 1 and 2.



(b) Overlap System



(c) Home and Distant Signal System

Fig. 1. Block signal systems.

The basis of the automatic block-signal system is the track circuit, by means of which the train automatically operates the signals by electricity. As shown in Fig. 3, the block is a section of track in which the rails are insulated from those in the adjoining block by insulating track joints. The rail joints within the block are bonded

electrically by bridging them with galvanized wire. For steam roads the track circuit is low-voltage d.c., but in the case of electric railways, in which the track forms a return circuit for the power current, it is not possible to insulate the blocks, and alternating track circuits must be used for automatic block signalling. In the case of a-c electric railways, the blocks must be laid

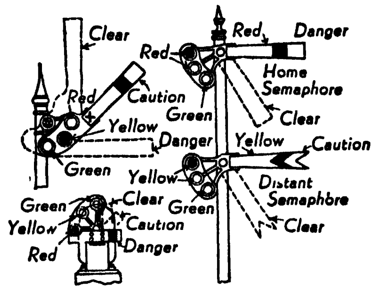


Fig. 2.

out with the use of a-c track circuits of much higher frequency than the power current. Fig. 3 illustrates automatic block signal connections for a steam road. A track circuit battery *B* maintains a current through the track relay *R*. The armature of this relay closes the semaphore circuit so that the battery *B* holds the semaphore arm clear. When a train enters the block the

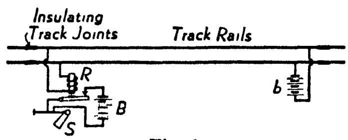

Fig. 3.

wheels and axle short-circuit the relay coil and the battery *B* is disconnected from the semaphore holding solenoid, causing it to drop to horizontal position. Electrically the track circuits are more complicated when the home and distant signalling is used, and polarized relays are used to distinguish between the impulses received from the two blocks. (F.T.M.)

RAILWAY TRACK. A railway track consists of steel rails which are laid on cross ties. (See **Tie, Railway.**) The rails which are usually separated from the ties by steel tie plates are held in position in the case of wooden ties by hook-headed spikes which are driven into the latter through holes in the plates. The ties are embedded in a material called **ballast**, usually broken stone. The ballast spreads the load of the train over the earth, holds the track in position and acts as a drainage system. The gauge of the track is the distance measured from inside to inside of rails as shown in Fig. 1. The standard gauge in this country is 4′ 8½″.

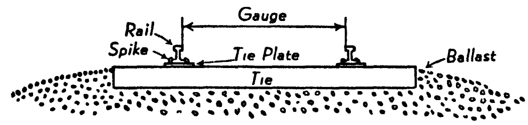

Fig. 1. Railway track.

Railway tracks are divided into main and secondary tracks. The secondary system is subdivided into branch, side and spur tracks. A branch is a track for general traffic leading from the main line to communities which are at some distance from the main line. A siding is a track for storing cars at a station or a yard. Side tracks may be located between stations, in which case they are used by slow trains to allow the passing of fast trains. Spur tracks are used for access to quarries, construction projects, mines or industrial plants.

A turnout is a curved track connecting two other tracks. A cross-over is a turnout connecting two parallel tracks which are either straight or curved. The essential features of a turnout are a switch, frogs and guard rails. The switch is a device which causes the train to turn from one track to the other. Where one rail of the turnout crosses a rail of the main track, a device known as a frog is used to allow the flange of the car wheels to pass the intersection. Guard rails are short pieces of rail placed opposite the frog to prevent the flange of the wheels from bearing against the point of the frog and also to prevent them from going in the wrong direction at the point.

Fig. 2 shows a diagrammatic illustration of a turnout with a split switch, which is the most common type, in the open and closed position. One rail of the turnout and one rail of the main track are continuous. The transition from one track to the other is made by means of a pair of switch rails which are connected by **tie rods** and pivot about one end. The tie rod at the free end of the switch rails is connected to a switch stand or interlocking tower where the switch is activated.

A stub switch is shown diagrammatically in Fig. 3. The switch rails are free to move as a unit at one end

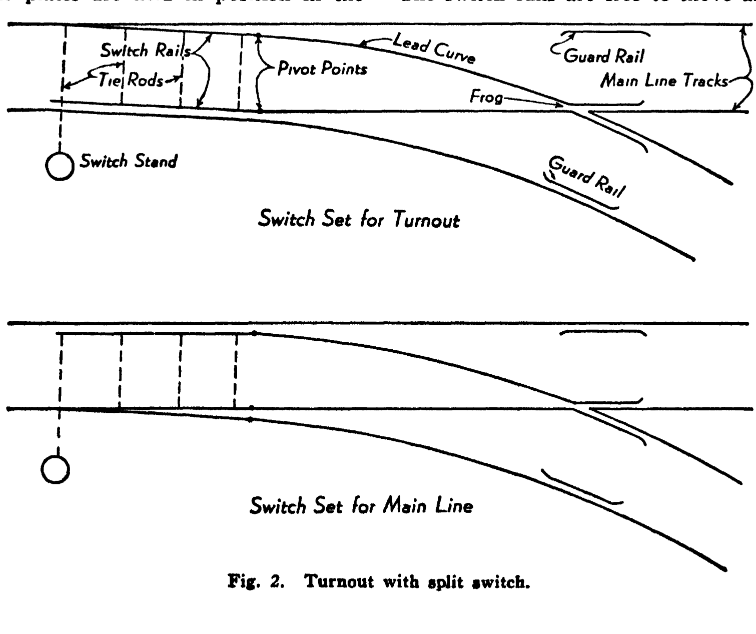

Fig. 2. Turnout with split switch.

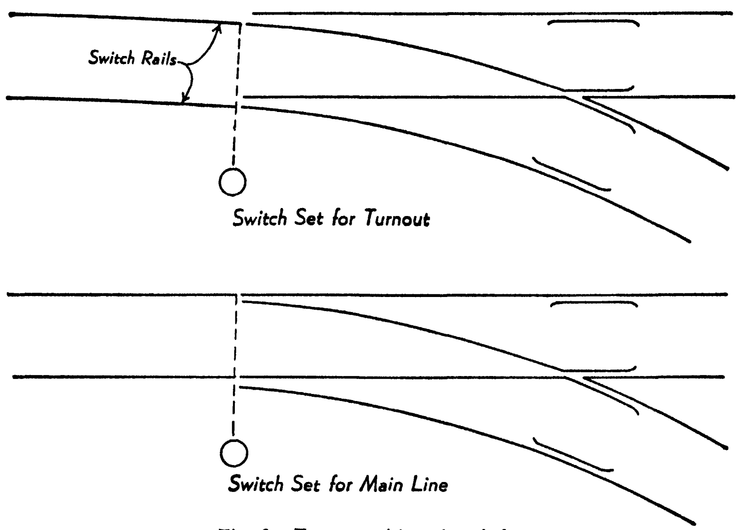

Fig. 3. Turnout with stub switch.

so that they can be shifted from one track to the other. The free end of the switch rails is connected to the switch stand by a tie rod.

The arrangement of rails where two tracks cross each other is called a crossing. The tracks may be straight or curved but, in any case, four frogs are required. Fig. 4 shows a typical crossing for straight tracks. (C.W.C.)

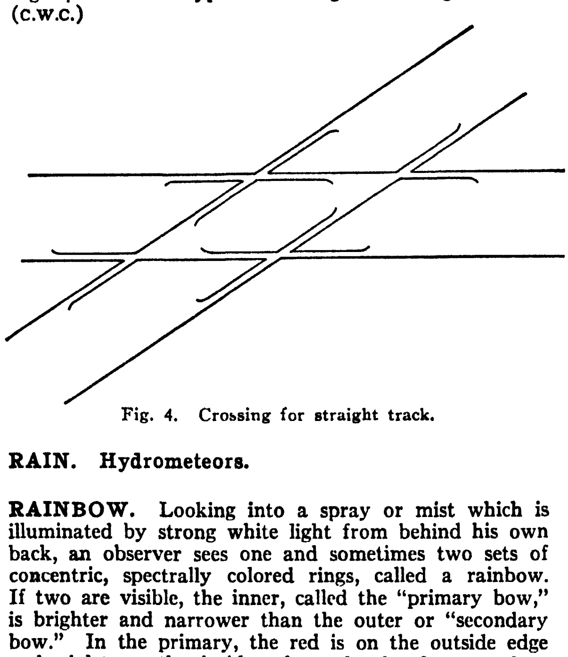

Fig. 4. Crossing for straight track.

RAIN. Hydrometeors.

RAINBOW. Looking into a spray or mist which is illuminated by strong white light from behind his own back, an observer sees one and sometimes two sets of concentric, spectrally colored rings, called a rainbow. If two are visible, the inner, called the "primary bow," is brighter and narrower than the outer or "secondary bow." In the primary, the red is on the outside edge and violet on the inside; the order in the secondary being the reverse of this. The colors are not so pure as in a **spectrum**, because each wavelength extends over a wide radial range, the rainbow itself being made up of the fairly pronounced intensity maxima.

The colors of the rainbow are caused by the refractive **dispersion** of the spherical water drops. Figs. 1 and 2 show, respectively, the dispersion composing the primary and the secondary bow. The figures also explain why the order of colors is reversed, and show that only the highest drops in the primary and the lowest in the secondary refract red light to the eye. The two internal reflections, with consequently greater loss of light, explain why the secondary bow is fainter. The center of the ring system is exactly opposite the source of light; so that natural rainbows are seen only when the

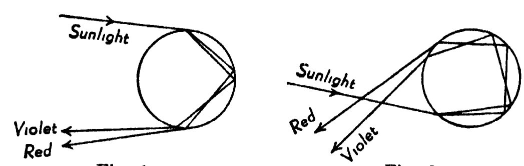

Fig. 1. Fig. 2.
Formation of primary bow (left) and secondary bow (right). Circles represent raindrops.

sun is near the horizon, unless the observer is elevated high above the surrounding country and can look obliquely downward into the rain. (L.D.W.)

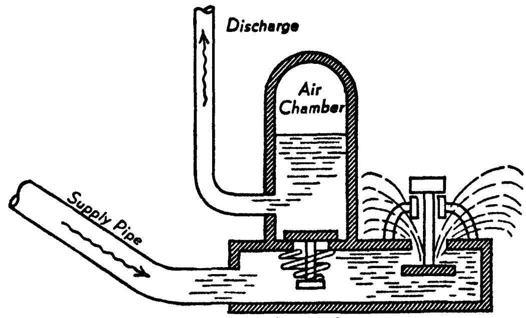
RAKE. Cutters.

RAM. The male sheep. (See **Press Working; Planer.**)

RAM, AIR. If the carburetor air scoop of an aeronautical spark ignition engine is faced upstream the air caught in it and brought partially to rest will increase in pressure on account of the "ramming" of the air into the scoop. If the air could be ideally and completely brought to rest the ram would be $\frac{\rho}{2} V^2$ (see **Dynamic Pressure**). An airplane travelling at 200 m.p.h. ($V = 294$ ft. per sec.) at sea level, having a ram of one-half the theoretical amount, would receive a supercharge from this source of $1\frac{1}{2}''$ of mercury. (F.T.M.)

RAM, HYDRAULIC. The hydraulic ram is a form of water pump. It is self-actuated, but of no very great efficiency. It derives its power from the flow of the water being pumped, of which it must necessarily waste a considerable amount. However, where more water is available than that needed at the pump discharge, the hydraulic ram is a simple, inexpensive, and relatively reliable means for pumping water. The greatest application of these devices is to be found in the supply of water to farmhouses and other dwellings not served by central water supply systems, and where, of course, a spring or some other source of potable water exists. The operation of the ram may be understood by reference to the figure. The body of the ram

is connected with the source of water by a supply pipe, and should be set well below the source so that water will flow rapidly from the supply to the ram. This requirement, of course, rules the ram out as a device for pumping water from wells. The figure shows the ram with its atmospheric valve open. This



Hydraulic Ram

lets the water flow through the ram at increasing speed until the water flow suddenly drags the valve upwards into the closed position. The momentum of the rapidly moving water in the supply pipe then builds up pressure in the ram sufficient to open the discharge valve and surge some water into the air chamber. After subsidence of the pressure wave, the pressure acting in the discharge closes the discharge valve, and the atmospheric valve drops into open position under the action of its dead weight during the minimum pressure phase of the surge. Flow is resumed through the atmospheric valve, and another cycle of operations begins. Meanwhile the surplus pressure existing in the air chamber due to the incoming surge of water acts to discharge that water into the discharge pipe leading to the water supply system.

In its simplest form the ram is not self-starting; hence it is desirable for the source of water to yield sufficient flow to operate the ram continuously. Where this is not possible, the flow is stored in a reservoir and the ram operated from that periodically. (F.T.M.)

RAMAN EFFECT. A phenomenon involved in the **scattering** of light from the molecules of transparent gases, liquids, and solids; discovered by the Indian physicist, C. V. Raman, in 1928. It consists in the appearance of extra spectrum lines in the vicinity of each prominent line of the spectrum of the incident light. For example, if light from a **mercury arc** shines into carbon tetrachloride (CCl_4, a liquid), some of the violet lines in the scattered light, especially the one at 4358 angstroms, have associated with them a fairly distinct "Raman spectrum," consisting of several lines, some of which are of longer, some of shorter, wavelength than the much brighter, unaltered line. The shorter, usually faint, are called "anti-Stokes" lines, because they violate the law of Stokes (see **Luminescence**).

The Raman spectrum for a given line is characteristic of the scattering substance, and is made up of lines somewhat more diffuse, or "broader," than the corresponding incident line. Water gives broad bands. The phenomenon extends into the x-ray region, and is somewhat analogous to the **Compton effect**, in which, however, the scattering particles are electrons instead of molecules. The Raman effect is explained as due to the absorption or contribution of energy from or to the quantum of incident radiation by the scattering molecule, the result being a decrease or an increase in the frequency of the quantum, with corresponding change of wavelength. The phenomenon was predicted by Kramer 4 years prior to its discovery. (L.D.W.)

RAMIE. **Boehmeria nivea.**

RANDOM FLUCTUATION. A random fluctuation is a variation due to chance or to random sampling. (L.A.A.)

RANDOMIZED BLOCK. A randomized block is a design in which there are two sources of variation. Usually it is desired to eliminate one of the sources of variation, either that of rows or columns. We consider s blocks consisting of r treatments in each block forming an rxs table of r columns and s rows. The **analysis of variance** then would be

Mean square among column **means**

$$\frac{r\Sigma(\bar{X}_c - \bar{X})^2}{c - 1} = V_c$$

Mean square among row means

$$\frac{c\Sigma(\bar{X}_r - \bar{X})^2}{r - 1} = V_r$$

Mean square due to error

$$\frac{(rc - 1)V_T - (r - 1)V_r - (c - 1)V_c}{(r - 1)(c - 1)} = V_e$$

Total mean square

$$\frac{\Sigma\Sigma(X_{ij} - \bar{X})^2}{rc - 1} = V_T$$

To test for equality of column means we compute Snedecor's F, $F = \frac{V_c}{V_e}$ with $n_1 = c - 1$ **degrees of freedom** and $n_2 = (r - 1)(c - 1)$ degrees of freedom. To test for equality of row means, $F = \frac{V_r}{V_e}$ with $n_1 = r - 1$, $n_2 = (r - 1)(c - 1)$. Randomized blocks are used in agriculture and in industry. It is assumed that the variates are distributed normally and independently with the same **variance** σ^2. Here $\bar{X}$ = mean of all rc items, $\bar{X}_c$ = mean of a column, $\bar{X}_r$ = mean of a row and X_{ij} is the item in the ith row and the jth column. (See **Latin Square.**) (L.A.A.)

RANG. The term for a subdivision of the **igneous** rocks according to their classification by Cross, Iddings, Pirrson and Washington. (R.M.F.)

RANGE. This term is used in two senses. The range is a measure of **dispersion** and equals the difference between the largest and the smallest **variate** in a distribution. The range is used in another closely related sense when we say a **variable** has a range from $x = a$ to $x = b$. (L.A.A.)

RANGE AND ENDURANCE, AIRPLANE. The range of an airplane is the distance it can fly in calm air before the fuel supply is exhausted. Its endurance is the time it can remain in flight before its fuel is exhausted. This should be distinguished from **refueling** endurance, where the airplane is refuled from another while in flight and endurance depends on pilot fatigue or mechanical endurance of the airplane.

The range at a specified speed is somewhat simpler to compute than the maximum range and would be merely the $\frac{\text{fuel-carrying capacity}}{\text{specific fuel consumption}}$ multiplied by the air speed, if it were not for the fact that the specific fuel consumption may decrease slightly as fuel is consumed during the flight. The maximum range requires adjustment to the most economical (i.e., maximum $\frac{\text{airspeed}}{\text{specific fuel consumption}}$) speed during the entire flight. This can be done either for increments of the flight, assuming fuel consumption constant during each incre-

ment, and flight at maximum $\frac{\text{Lift}}{\text{Drag}}$, or one of several formulae developed for this purpose may be used.

Diehl's formula for maximum range is

$$R\ (\text{miles}) = 625\,\frac{\eta_0}{C_0}\left(\frac{L}{D}\right)_{\max}\left[1 - \left(\frac{W_1}{W_0}\right)^{0.6}\right].$$

η_0 = Initial propulsive efficiency (approximately propeller efficiency).
C_0 = Initial engine fuel consumption, lb./hp. hr.
W_0 = Initial gross weight, lbs.
$W_1 = W_0$ − weight of fuel consumed.

The practical maximum range may be more or less than the theoretical, depending on wind conditions. Conservative viewpoint of the pilot will further reduce the practical maximum range as he allows for (1) unexpected headwinds, (2) time required to search for terminus after long navigational flight over unknown territory, (3) unknown but possible adverse weather conditions, (4) need for circling airport terminus while waiting for landing clearance, (5) small inaccuracies in fuel gauges, (6) inability to pilot continuously at maximum L/D attitude, at constant altitude, and in a direct line between termini, and (7) length of time taken to climb to flight altitude.

Maximum endurance could be of use in estimating time an airplane might stay aloft over a fog-bound airport when meteorological data had indicated a definite time for re-establishment of landing visibility. (F.T.M.)

RANGE OF STRESS. **Cycle of Stress.**

RANGE MARKS. Two prominent objects, either natural or artificial, which are located along a line which has some particular value for navigators, are known as range marks. Range marks are used for so many different purposes in **navigation** that it would be futile to attempt to list them all. However, one example may be of interest. A channel is entered on **track** 200°, followed for 1100 yards, then the channel turns and track must be altered to 296°. The turning point is marked by a black and white striped **buoy.** A lighthouse on shore is so placed that its **bearing** from the buoy is 200°. Accordingly, when a ship has the lighthouse and the buoy in line, the bearing of the buoy from the ship is 200°, and to follow the first leg of the channel the ship simply keeps the lighthouse "ranging" on the buoy. As the ship approaches the buoy the pilot watches the shore and when a red and white striped target ranges on a white church spire, he alters heading and holds the target on the spire to follow the 296° leg of the channel. Currents may force the pilot to head quite differently from the directions of the channel as given on his chart, but the range marks give a **line of position** and, so long as the ship is on the proper line, the pilot knows he is proceeding in safe water. (See **Radio Range.**) (W.K.G.)

RANGE, MAXIMUM. **Range and Endurance; Airplane.**

RANK CORRELATION. Consider N pairs of ranked **variates** $(x_1, y_1), (x_2, y_2) \cdots (x_N, y_N)$ $1 \le x_{iN} \le N$, $1 \le y_{iN} \le N$, the rank coefficient of correlation ρ^1 is defined

$$\rho^1 = 1 - \frac{6\sum_{i=1}^{N}(x_i - y_i)^2}{N(N^2 - 1)}.$$

The range of variation for ρ^1 is $-1 \leqq \rho^1 \leqq 1$. Tables have been constructed to test the hypothesis that the population value ρ^1 is zero without any assumption as to the distribution of the **variates** (x_i, y_i). It has been shown by H. Hotelling and M. Pabst that as $N \to \infty$, the distribution of ρ^1 approaches normality with **mean** zero and **variance** $\frac{1}{N-1}$. If $N > 10$, the normal approximation seems quite adequate, using $\sigma_{\rho'}{}^2 = \frac{1}{N-1}$. These results have brought ρ' into favor again particularly when $N < 100$ since in such cases the computation of ρ' is simpler than the usual **coefficient of correlation.** (L.A.A.)

RANKINE CYCLE. Rankine's modification of the Carnot cycle is the basis of the modern steam plant cycle even though the Rankine cycle itself has been modified and changed with the passing of time. The elements of the Rankine vapor cycle are shown in Fig. 1(a). It consists essentially of a **boiler** which receives

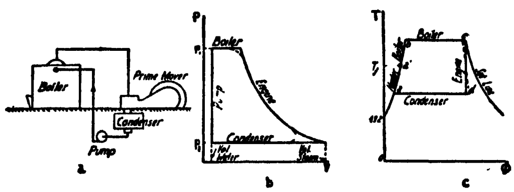


Fig. 1.

feed water from a **pump,** a prime mover to expand the steam **adiabatically,** a **condenser** to receive the exhaust steam from the **engine** and reduce it to water, and a pump to overcome the pressure difference between boiler and condenser. Figs. 1(b) and 1(c) show this cycle on the pressure-volume and temperature-entropy planes. In Fig. 2 is shown a common form of application of the Rankine vapor cycle. This plant is char-

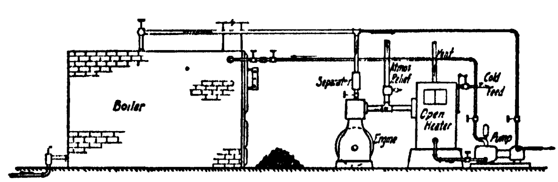

Fig. 2.

acterized by atmospheric exhaust, use of a portion of the exhaust for feedwater heating in an open heater, and a reciprocating steam-driven boiler feed pump, also exhausting to atmosphere. The efficiency of such a plant is necessarily very poor, yet for small amounts of power it represents a type of plant that has the advantage of a minimum investment and can be operated by the nontechnical man in a semi-successful manner.

The Rankine vapor cycle efficiency is (see Fig. 1(c)).

$$E_{rv} = \frac{H_c - H_d}{H'_c - h_{a'}} \quad \text{or} \quad \frac{2545}{S(H'_c - h_{a'})}.$$

where H_c = heat per pound of steam entering prime mover.
H'_c = heat per pound of steam leaving boiler.
H_d = heat per pound of steam leaving prime mover.
$h_{a'}$ = heat per pound of boiler feed water.
S = the steam rate in pounds per horsepower hour

This equation is exact for complete expansion cycles such as may be had by the use of the steam turbine, but is a slightly optimistic approximation for steam engine type of expansion since release pressure is somewhat higher than exhaust. (See **Steam Engine.**) (F.T.M.)

RAOULT'S LAW. The **vapor pressure** of a substance in **solution** is proportional to its **mole fraction.** (See **Solutions and Solubility, Distillation.**) (R.K.S.)

RAPE. **Brassica.**

RAPESEED OIL. **Esters.**

RAPFEN. Pisces, Teleostei. A fish (**Pisces**) of northern and eastern Europe, related to the carps. It lives in quiet waters in lakes and slow streams. (A.W.L.)

RARE EARTH METALS. **Cerium; Yttrium.**

RASCHIG RING. **Gas Absorption.**

RASH. A skin eruption of temporary nature which may be caused by sensitivity to **drugs**, to **protein** substances (**allergy**), to chemicals, or may be part of a disease picture. The so-called "exanthems"—**measles, german measles, chicken pox, smallpox,** and **scarlet fever**—have distinct and characteristic rashes which are important in differential diagnosis. (R.S.M.)

RASP. **File.**

RASPBERRY. **Rose Family.**

RASPBERRY FRUIT-WORM. Insecta, Coleoptera. The **larva** of a small **beetle**, *Byturus unicolor*, which lives on the inside of the fruit on raspberries. It eats the receptacle but is often found in the fruit itself. Since the adults eat the foliage and buds the pest can be held in check by spraying with **lead** arsenate. (A.W.L.)

RASPBERRY-CANE BORER. Insecta, Coleoptera. The **larva** of a **beetle** which bores in the canes of raspberry plants, ultimately killing them. The adults girdle the tender growth and cause it to wilt. If wilted canes are removed to a few inches below the girdling the development of the larvae is prevented. (A.W.L.)

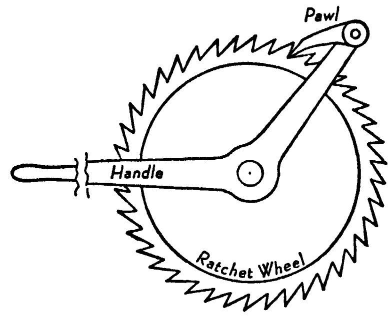
RASSE. Mammalia, Carnivora. A civet of the Oriental region. (A.W.L.)

RAT. Mammalia, Rodentia. In the strict sense an animal of the genus *Rattus*, this term is much more widely applied to many small gnawing animals. The true rats are dull-colored animals with long scaly tails, short legs, small ears, and a pointed muzzle. The common brown rat, *R. norvegicus*, is a typical example. This species was introduced from Europe in Colonial times and has since become a troublesome and sometimes dangerous pest over the entire country. It is much more aggressive than the related black rat, *R. rattus*, and has almost crowded the latter out. The roof rat, *R. alexandrinus*, is a third species found in the southern United States. Still other species of the genus are found in other continents.

Some of the closely related genera include the bandicoot rats, bush rats, bamboo rats, kangaroo rats and cane rats. The name American pouched rats is sometimes applied to a group containing the pocket **gopher.**

Less closely related members of the order are the **Philippine rats, fish-eating rats, wood rats, African crested rat,** and **muskrat.** (A.W.L.)

RATCHET AND PAWL. The ratchet and pawl together comprise an intermittent type of mechanism in which motion derived from a reciprocation or oscillation is converted into intermittent circular motion, constant in direction. This mechanism finds considerable use in lifting **jacks, windlasses,** and similar mechanisms. The ratchet wheel has a circumference covered with ratchet teeth. As shown in the accompanying figure, these are designed to receive a forceful pressure in the counterclockwise direction only. When a ratchet must be reversible, the shape of the teeth necessarily must be modified from that shown in the diagram. The pawl on the oscillating arm slips freely over the teeth in the clockwise direction, but engages and rotates the ratchet when it moves in the anti-clockwise direction. If the ratchet wheel is under a torque it will rotate backwards when



Ratchet and pawl.

the pressure of the driving pawl is released unless a holding pawl is provided. The pawls are held against the ratchet wheel either by dead weight or by spring pressure. (F.T.M.)

RATE OF CHANGE OF A FUNCTION. **Derivative of a Function of one Variable.**

RATE OF CLIMB, AIRPLANE. When an airplane is in horizontal unaccelerated flight at less than maximum level speed for its altitude, the engine is necessarily throttled somewhat below rated power. If desired, some or all of this unused power could be applied to the airplane without accelerating it if the airplane were directed into a climb. Rate of climb is defined as the vertical component of the velocity of an airplane in a steady unaccelerated climb. If full available engine power is used the rate of climb will become maximum intermediate between minimum and maximum climbing air speeds. If the power required to overcome drag in level flight at various speeds and the thrust power available at full throttle are plotted against air speed, the power intercept between the two represents power available for producing the rate of climb. The maximum rate of climb may thus be discovered since it equals

$$\frac{550 \text{ (Maximum excess horsepower available)}}{\text{Airplane weight, lbs.}} \text{ ft./sec.}$$

A high rate of climb is sought in the design of interceptor and fighter military aircraft and in special commercial photographic mapping airplanes. In the military field superiority in rate of climb gives important tactical advantages; in the photographic field it allows the mapping party to reach their working altitude quickly and make maximum use of the occasional superior atmospheric conditions which are necessary for some of this work.

A tangent drawn from the origin to a rate of climb curve (rate of climb vs. air speed) shows the air speed for maximum angle of the flight path. This is the optimum speed for climbing flight to clear fixed obstacles. (F.T.M.)

RATE OF FALL OF RAIN DROPS. Rain drops are commonly accepted as those whose diameter is greater than 0.5 mm. The rate of fall of these drops ranges from about 3 meters per sec. for the smallest to about 8 meters per sec. for the largest. (P.E.K.)

RATEL. Mammalia, Carnivora. A short-legged animal, *Mellivora ratel*, with a broad depressed body and head, resembling the badgers in form. The ratels live in India and Africa. They are nocturnal burrowing animals which eat other animals and insects. From their love of honey they have received the name honey badger. (A.W.L.)

RATING. Mechanical and electrical apparatus is rated on different bases, the particular method being associated with the conditions of usage, or with the historical development of the apparatus. The rating of electrical apparatus is almost always based upon the temperature at which the apparatus may be operated continuously. Usually the limiting condition is the temperature to which the **insulation** may be continuously subjected without its rapid deterioration. The rated horsepower of an electric motor, then, would be the power at which the current which was drawn caused the maximum permissible temperature rise in the windings. A common basis of rating where rubber insulation is employed is a 40° C. temperature rise above room temperature.

A few examples of the determination of rating in the mechanical field will show how varied the picture is, and demonstrate that technical equipment is not subject to uniform systems of rating. Steam **boilers** are rated by a unit based on their heating surface, but progress in the art of generating steam in boilers, and in the field of combustion engineering, has so increased the steam production possible from a given area of heating surface that the actual performance of steam boilers can nowadays be related to their ratings only by the use of a term "per cent rating." A boiler operating at 300 per cent rating would not necessarily be considered overloaded.

The power rating of a **steam engine** depends upon the extent to which steam is used expansively in the engine. The less the expansion, the greater the power rating of a given cylinder volume, and the less economical the engine is of steam. Common practice rates the power as that derived when the **ratio of expansion** is 4, but an engine may, by advancing the cut-off, derive more than this rating, at the expense of steam consumption. A steam turbine has its nozzles, blades, and passages designed for a certain full load at which steam consumption will be minimum. Loads above this can be carried by admitting some high-pressure steam into low-pressure sections of the casing by overload valves. Naturally the **generator** to which the **turbine** is connected is provided with sufficient capacity to absorb this power. Common practice is to rate a turbine at the maximum capacity that can be produced without using overload values, then provide for carrying about 20% overload by secondary or tertiary overload valves. The generator will be rated to absorb the turbine rated power at 80% power factor. To load the turbine over its normal rating the power factor of the generator must be raised. (F.T.M.)

RATIO. The ratio of two numbers is their indicated **quotient**, frequently expressed as a **fraction**. The ratio of a to b is indicated by the notation $a : b$, or frequently a/b or $a \div b$. (L.L.S.)

RATIO OF EXPANSION. This ratio of certain volumes in the **piston** and **cylinder** engine is of considerable importance, since it is indicative of power output, and other important characteristics of engines. This is also the same as "compression ratio," a term frequently used in describing the modern **Otto cycle engine**. However, ratio of expansion will first be defined for the **steam engine**. In a steam engine, when the piston is at the inner end of its stroke and ready to do work on an outward stroke, there is a small clearance volume created by the necessity for avoiding mechanical contact between piston and cylinder head. As the piston moves under the influence of inflowing steam, the pressure remains nearly constant until the steam is cut off by the **valve action**. Beyond this point the steam expands with **decreasing** pressure. The ratio of expansion is the number of times steam is expanded in volume after the point of cut-off. It is equal to the ratio,

$$\frac{\text{volume of the cylinder at the conclusion of a stroke}}{\text{the volume at point of cut-off}}.$$

The greater the ratio of expansion, the smaller the amount of power developed by a cylinder of given size, but the power produced is obtained more efficiently than with small ratios. A common ratio of expansion for steam engines is four.

The cycle of the gasoline engine includes a compression of the charge from maximum cylinder volume into the clearance volume, with a corresponding rise of pressure. After an explosion, the charge re-expands to the maximum volume, so that whether we consider the ratio taken along the compression or expansion portion of the cycle, numerically it will be the same. In the Otto cycle, the ratio of expansion is

$$\frac{\text{The piston displacement} + \text{the clearance volume}}{\text{the clearance volume}}.$$

Since the efficiency of the Otto engine is dependent to a great extent on the ratio of expansion, it is seen that the clearance volume is an important dimension in these engines. Modern engines have "compression ratios" of six or slightly over, as compared to ratios of four obtained in earlier engines. The use of high compression ratios has incurred the problems and results discussed under the head of **detonation.** (F.T.M.)

RATIONAL FUNCTION. A rational function is a **function** which involves the **variable** in only the rational operations of addition, subtraction, multiplication, division and raising to powers with constant integral exponents.

Rational functions are divided into two sub-classes: rational integral functions or **polynomial functions**, and rational **fractional functions.** (L.L.S.)

RATIONAL INTEGRAL EQUATIONS. Polynomial Equations.

RATIONAL INTEGRAL FUNCTION. Polynomial Function.

RATIONAL NUMBERS. Number.

RATIONAL ROOTS OF POLYNOMIAL EQUATIONS. Polynomial Equations.

RATTANS. Species of *Calamus*. Palmaceae. The various **palms** known as rattans are all climbing plants of the Old World tropics. The genus *Calamus,* with its 280 species, contains the greater number of these palms, especially those of commercial importance. As a group the rattans are found in low altitudes, growing in the forests. Many are leaf-climbers, in which the main axis or outer ends of the **pinnae** of the pinnately compound leaves bear stout downward projecting spines. These spines prevent the plants from sliding from any support on which they may rest. The stems are slender (1/8–2½" in diameter) and very long. Many are from 250–600′ in length, and of uniform diameter throughout this length. The outer portion of the stem is very hard and tough; the inner, softer and rather porous.

In gathering, these stems are cut off close to the base and pulled from their supports. The leaves are then removed and the stem cut into sections 10–20′ long. These may be bent double and thus bundled for shipment. Sometimes they are split before shipping. The outer layer, removed in long narrow strips, is used in weaving mats, making baskets, and for the cane-seats of chairs. The central portion remaining after the cane is stripped off is used in making reed furniture. Coarse brushes are also made from this central portion. Many other minor uses are made of these plants in the eastern countries and islands where they are native. (R.M.W.)

RATTLESNAKE. Reptilia, Sauria. A poisonous **snake** with a series of loosely attached horny **rings** at the tip of the tail which constitute the rattle. When

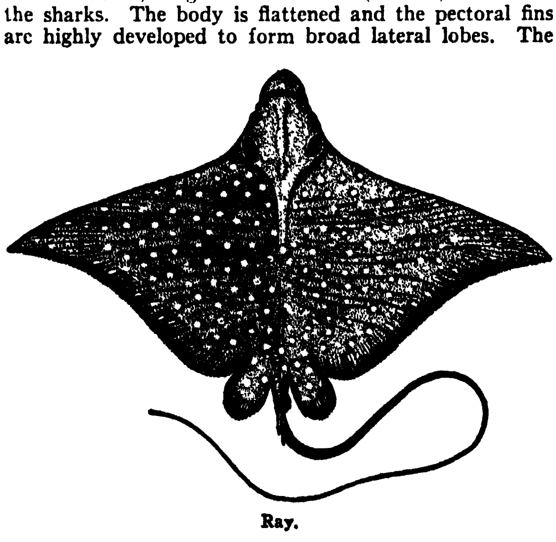
aroused the snake vibrates its tail, producing a sound between a rattle and a buzz. These snakes have a thick body, tapering at the neck toward the broad triangular head. They are **pit vipers**.

Rattlesnakes occur only in the New World, chiefly in North America. They are most abundant in the warmer parts of the United States. The little massasauga, *Sistrurus catenatus*, which reaches a length of only thirty inches, is the most widely distributed species, ranging from New York to South Dakota and southward into Mexico. It still persists in wild spots, especially swamps, even in heavily settled areas. The ground rattler, *S. miliarius*, of the southeastern coastal area and southern Mississippi Valley is still smaller. These small species are less dangerous than the large rattlesnakes, but even they are not to be disregarded. The common rattlesnake, *Crotalus horridus*, is distributed from Maine to Florida, east of the plains. Another eastern species, the diamond-back rattlesnake, *C. adamanteus*, is found on wet ground from the Carolinas to Louisiana. It is the largest species, with a length of 6′, and is correspondingly dangerous. In the western United States several species are found in the plains area and the deserts. Of these the sidewinder, *C. cerastes*, and prairie rattler, *C. confluentus*, are the best known. The latter is found from Canada to Texas over the entire western half of the United States.

These snakes have been ruthlessly destroyed and are now rare except in wild country. Their virulent poison has been the chief cause of economic importance, but the skins and rattles have been attractive as curios in some parts of the country, and in Florida one enterprising snake fancier makes canes of the spinal column and cans the flesh for the market. It is more than probable that filets of rattlesnake will also remain in the class of curios. (A.W.L.)

RAVEN. Aves, Passeriformes. Large **black birds** with more or less iridescent luster. They are closely related to the common crow. The common raven, *Corvus corax*, is found in Europe, Asia, and North America. One variety, the American raven, extends from Canada to Guatemala and from the Rockies to the Pacific. Another, the northern raven, is found from Alaska to Greenland, southward into the northern tier of states, and in the mountains to Carolina. Two species of white-necked ravens are known, one in the southwestern deserts of the United States and the other in Africa. All of these birds eat carrion, eggs, insects, small animals, and to a limited extent vegetable matter. (A.W.L.)

RAY. Pisces, Plagiostomi. Fishes (**Pisces**) related to the sharks. The body is flattened and the pectoral fins are highly developed to form broad lateral lobes. The tail is slender. Rays are typically marine, but some species ascend rivers and some fresh-water species occur in tropical America. Among the different forms the electric rays (*Torpedo*) and eagle rays (*Myliabatis*) or devil-fishes are noteworthy. The former have electric organs formed of modified muscle tissue and are said to kill their prey by electrocution. The latter attain great size, up to a weight of 800 lbs., and are said to be dangerous to divers. Some of the rays are also known as skates. (A.W.L.)



Ray.

RAYNAUD'S DISEASE. A vascular disorder characterized by paroxysmal **cyanosis** of the fingers in response to cold or to emotional stimuli. Toes, ears, chin, may also be affected. The disease appears most commonly in women in the third decade of life, and familial cases have been described. The cyanosis is due to interference with the blood supply through constriction of the vessels—vasospasm, resulting from abnormalities of the nervous control of the vessel walls. The cause of these abnormalities is not known. Attacks begin gradually, with mild symptoms, but later there is severe pain, numbness, and discoloration of the affected parts. The attack may last for minutes or hours. In the advanced disease, the fingers may become dark blue or black and gangrenous. Sometimes, a mild chronic form exists, never progressing to **gangrene**.

Treatment is directed toward avoiding the precipitating factors—cold, emotional upsets, etc. Nicotine has a deleterious effect on the vessels, and smoking should be eliminated. Vasodilation may be accomplished with drugs, or surgically by interrupting the sympathetic nerves (see **Autonomic Nervous System**) which carry impulses resulting in vascular constriction. (D.M.H.)

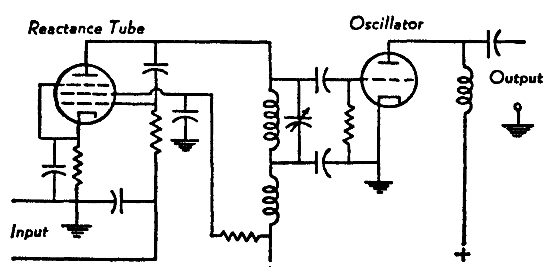
RAYON. **Carbohydrates; Cotton.**

RAZORBACK. 1. Pisces, Teleostei. One of the less common species, *Xyrauchen texanus*, of **buffalo fishes** of the Mississippi basin. 2. Mammalia, Artiodactyla. Feral hogs of the southern states. (A.W.L.)

RAZORBILL. Aves, Charadriiformes. A moderately large ocean bird (**Aves**), *Alca torda*, found on both sides of the northern Atlantic. It has a large compressed beak with deep furrows. The species is related to the extinct great auk and to the murres, puffins, and guillemots, and is also known as the razor-billed auk. A number of other vernacular names are indiscriminately applied to various members of this group. (A.W.L.)

REACTANCE. **Alternating Currents; Impedance.**

REACTANCE TUBE. This is a vacuum **tube** operated in such a way that it presents the characteristics of a reactance to the rest of the circuit. As reactance takes



a current which is essentially 90° out of phase with the voltage it is necessary that the tube do the same. Reference to the circuit will indicate one method of connecting it to accomplish this. The **grid** is excited by a voltage obtained from the plate voltage by the resistance-condenser circuit (the condenser connected to the cathode is merely a d-c blocking condenser and is a value which

produces no other appreciable effect). The resistance-condenser circuit applies a voltage to the grid which is nearly 90° out of phase with the plate voltage. Since, in a pentode, the plate current is in phase with the grid voltage, this means that the plate current (a-c component) is 90° out of phase with the plate voltage, thus the plate circuit has the desired reactance characteristics. The advantage of the tube over a conventional reactance is that the magnitude of its reactance effect may be easily varied by adjusting the d-c bias applied to the grid. The circuit shows the tube connected as part of the tuning capacity of an **oscillator.** By varying the grid bias (hence the gain) of the tube the tuning of the oscillator is varied. This is used in many frequency-**modulation** transmitters to give the frequency modulation. In this application a suitable audio signal is fed to the grid of the reactance tube so its reactance effect will vary with the audio and hence frequency modulate the oscillator. It is also used in frequency-stabilizing circuits where the deviation from the desired frequency is made to vary the grid bias of the reactance tube and hence correct the oscillator frequency. (L.R.Q.)

REACTION. Apart from the chemical usage of this term (see various **Reactions**; and **Chemistry**), its technical meaning is associated with mechanical action. The reaction force is that which is produced as the result of an **acceleration** of some **mass**, be it a solid or fluid. The recoil of a gun is a reaction force set up by the acceleration of the projectile. In a certain class of **turbine**—both hydraulic and steam—the machines obtain the principal part of their actuating forces by the reaction created when, in the one case, water, and in the other, steam, is accelerated under conditions controlled by the mechanism of the turbine. (See **Jet Propulsion.**)

In structural engineering the term reaction refers to the forces exerted by the supports of a **structure** to counteract the effects of applied loads. (F.T.M.)

REACTIONS INVOLVING OXIDATION-REDUCTION. Originally oxidation referred to the reaction of a substance with **oxygen gas**. The elucidation by Lavoisier of the burning of substances with oxygen is considered by some to mark the beginning of chemistry as a science. When **carbon** burns in excess of oxygen or air, **carbon dioxide** is formed with the accompanying liberation of a definite amount of heat. When **hydrogen** and oxygen of air are burned or subjected to an electric spark, water is formed with the accompanying liberation of a definite amount of heat. When substances containing carbon and hydrogen are similarly burned, carbon dioxide and water are formed with accompanying liberation of a characteristic amount of heat in each case. **Fuels** are burned for the sake of the heat liberated upon oxidation. **Foods** are consumed in part for the sake of the heat liberated in the oxidation reactions of digestion. **Iron** rusts in moist air or oxygen, forming hydrated forms of ferric oxide by oxidation. **Magnesium,** when ignited, burns in air with the formation of white magnesium oxide solid and the liberation of heat and an intense light of high actinic value and used for this purpose in photography.

In all cases, the weight (**mass**) of the substance burned plus the weight of oxygen consumed equals the weight of the products of oxidation. This was demonstrated by Lavoisier in the case of the substances with which he experimented.

Oxidation is a reciprocal process. Oxygen is the oxidizing agent; the substance reacting with oxygen is called the reducing agent. Besides the kinds of simple reactions given in the examples above, there are many others more complex. But the reciprocal principle of oxidation-reduction applies in all cases. Oxidation-reduction, as now understood, includes:

I. Reactions involving oxygen, **chlorine,** and substances supplying such elements on the one hand, with carbon, hydrogen, metals, and other similar substances on the other hand.

II. Reactions taking place in an **electrolyte** wherein a change of electronic charge of an ion occurs. Compare **Reactions Involving Recombination of Ions.**

I. Reactions involving oxygen, etc., with carbon, etc., are illustrated as follows:

Reducing Agent	Oxidizing Agent	Resultant	
carbon hydrogen sulfur phosphorus	oxygen, excess	carbon dioxide water sulfur dioxide phosphorus pentoxide	
hydrogen, excess	copper oxides lead oxides tin oxides iron oxides (but not magnesium oxide, aluminum oxide, zinc oxide)	copper lead tin iron	water
magnesium aluminum zinc iron tin lead copper (but not mercury, silver, gold, platinum)	oxygen-furnishing substance	magnesium oxide aluminum oxide zinc oxide ferric oxide or ferroferric oxide stannic oxide lead monoxide cupric oxide	
arsenic antimony aluminum iron copper	chlorine	arsenic trichloride antimony trichloride aluminum chloride ferric chloride cupric chloride or cuprous chloride	
carbon carbon monoxide	copper oxides lead oxides tin oxides iron oxides	copper lead tin iron	carbon dioxide or carbon monoxide or both
aluminum *	iron oxides silicon oxide boron oxide manganese oxides chromic oxide	iron silicon boron manganese chromium	aluminum oxide, glass
silicon	iron oxides	iron	silicon oxide
magnesium zinc iron lead	sulfur	magnesium sulfide zinc sulfide ferrous sulfide lead sulfide	
magnesium (in ether; Grignard's reaction)	aldehydes	secondary alcohols	
	ketones	tertiary alcohols	

Other oxidizing agents:
Metallic nitrates
Metallic chlorates
Metallic perchlorates
Metallic bromates

* Goldschmidt thermit reaction.

II. Reactions taking place in an **electrolyte,** wherein a change of electronic charge of an **ion** occurs, are brought about (A) by an impressed electric **direct current** *in an electrolyte,* (B) by the transfer of **electrons** between ions, either (1) where spatially separated *and* electrically connected, or (2) by contact in an electrolyte. (See **Electrochemistry** for (A) and (B) (2) in more detail.)

(A) *Oxidation-Reduction Reactions Due to Impressed Direct Current*

In an Electrolyte. In the electrolytic refining of copper a cell is arranged containing the impure copper casting as **anode,** copper sulfate as **electrolyte,** and a

thin pure copper sheet as **cathode.** Upon the impression of d.c. of low **electromotive force** in the proper direction, copper of the anode passes into the electrolyte as cupric ion (Cu^{2+}) and pure copper is deposited from the electrolyte onto the cathode. The reaction may be represented thus:

Copper (Cu°) of anode → Cupric ions (Cu^{2+})
of electrolyte → copper (Cu°) of cathode

In a similar manner, the electrolysis of fused **sodium** chloride yields sodium metal at the cathode and **chlorine** gas at the anode (Downs process for sodium, 1920). The reaction may be represented thus:

Sodium cation (Na^{+}) of electrolyte →
Sodium metal (Na°) at cathode

Chlorine (Cl_2°) at anode
← Chlorine anion ($2Cl^{-}$) of electrolyte

In all such reactions, there is a *change of charge,* that is, oxidation or reduction, of ions *at* cathode *and* anode. The electrolysis of sodium sulfate solution will clarify this, thus:

Hydrogen ions ($2H^{+}$) (turning litmus red) plus	Sodium cations ($2Na^{+}$) of electrolyte →	Hydroxyl ions ($2OH^{-}$) (turning litmus blue)
oxygen gas (O_2^{0}) 1 volume, at anode	← Sulfate anions (SO_4^{--}) of electrolyte	plus hydrogen gas (H_2^{0}) 2 volumes at cathode

Sodium ions and sulfate ions when discharged react with water at the cathode and anode, respectively, yielding the above products. The total amount of sodium and sulfate ions in the electrolyte remains the same after as before passing the current, the *net* effect (upon stirring the electrolyte) being the decomposition of water to form 1 volume of oxygen at the anode and 2 volumes of hydrogen at the cathode.

Sodium chloride solution electrolyzed with accompanying stirring of the electrolyte yields sodium **hypochlorite** (NaOCl).

Aluminum metal is produced by electrolysis of aluminum oxide dissolved in fused **cryolite** (Na_3AlF_6), and **magnesium** metal by electrolysis of fused magnesium chloride anhydrous ($MgCl_2$).

The charging of a lead storage cell (**Accumulator**) involves reactions in this category, thus:

Lead sulfate ($Pb^{2+}SO_4^{--}$) paste of the anode, in contact with the electrolyte, is changed into lead dioxide ($Pb^{4+}O_2^{0}$), brown solid *in situ.* Sulfate ion (SO_4^{--}) passes into electrolyte	←Sulfuric acid-water electrolyte (concentration of sulfuric acid increases with the amount of charging→	Lead sulfate ($Pb^{2+}SO_4^{--}$) paste of the cathode, in contact with the electrolyte is changed into lead metal (Pb^{0}) *in situ.* Sulfate ion (SO_4^{--}) passes into electrolyte

(B) 1. *Oxidation Reduction Reactions by the Transfer of Electrons Between Ions,* where the latter are spatially separated *and* electrically connected. In the Daniell **cell,** one of the oldest known wet batteries, the chemical setup is:

Zinc metal (Zn°) in zinc sulfate ($Zn^{2+}SO_4^{--}$) electrolyte.

Copper sulfate ($Cu^{2+}SO_4^{--}$) electrolyte containing copper metal (Cu°).

The two electrolytes in contact *in the cell.*

The two metals electrically connected *outside the cell* by a metallic conductor.

Results: 1. An electromotive force (1.1 volts) is generated.

2. Simultaneously, chemical reaction occurs:

Zinc metal is dissolved into the electrolyte as zinc ions at the electrode		Copper ions are precipitated from the electrolyte as copper metal at the electrode
$Zn^{0} \rightarrow Zn^{2+}$	$\longrightarrow$ Direction of positive current *in* the cell	$Cu^{2+} \rightarrow Cu^{0}$

As thus arranged, (1) the chemical reaction generates a definite **electromotive force,** namely, 1.1 volts. The direction of the positive current is from zinc to copper *in* the cell, through the electrolyte, and from copper to zinc *outside* the cell through the metallic conductor. (2) The *amount* of electric current generated is proportional to the *amount* of chemical reaction taking place, namely, 96,500 coulombs per equivalent weight (see **Chemical Composition**) of change. Of zinc, $\frac{65.38}{2} = 32.69$ grams changed from metallic to ionic; and of copper, $\frac{63.57}{2} = 31.79$ grams changed from ionic to metallic in generating 96,500 coulombs of electricity.

The discharging of a lead storage cell involves reactions in this category, thus:

Lead dioxide (PbO_2) electrode in **sulfuric acid** electrolyte

Sulfuric acid electrolyte containing lead metal (Pb^{0}) electrode

The two electrodes electrically connected *outside* the cell by a metallic conductor

Results: 1. An electromotive force (about 2.2 volts) is generated.

2. Simultaneously, chemical reaction occurs:

Lead dioxide transformed into lead sulfate ($Pb^{2+}SO_4^{--}$) at the electrode		Lead sulfate ($Pb^{2+}SO_4^{--}$) formed from lead at the electrode
$Pb^{4+} \leftarrow Pb^{2+}$	$\longleftarrow$ Direction of positive current *in* the cell	$Pb^{2+} \rightarrow Pb^{0}$

As thus arranged, (1) the chemical reaction generates a definite electromotive force, namely, about 2.2 volts when fully charged to about 1.9 volts when almost discharged, the concentration of sulfuric acid *decreases* with the amount of discharging. The direction of the positive current is from lead to lead dioxide *in* the cell through the electrolyte, and from lead dioxide to lead *outside* the cell through the metallic conductor. (2) The amount of electric current generated is proportional to the *amount* of chemical reaction taking place, namely, 96,500 coulombs per equivalent weight (see **Chemical Composition**) of change. Of lead dioxide, $\frac{239}{2} = 120$ grams changed to lead sulfate, $\frac{303}{2} = 152$ grams; of lead, $\frac{207}{2} = 104$ grams changed to lead sulfate, $\frac{303}{2} = 152$ grams; and of sulfuric acid $\frac{98}{2} \times 2 = 98$ grams removed from electrolyte as lead sulfate in generating 96,500 coulombs of electricity.

Reading down: Each **element** *above loses* **electrons** more readily than any element below. Accordingly, each element above has a higher *reducing* power than any element below.

Reading up: Each element *below gains* electrons more readily than any element above. Accordingly, each element below has a higher oxidizing power than any element above.

Therefore, any *metal above* will displace, from the salt solution of any metal below, the metal of the latter from its own cation.

(B) 2. *Oxidation-Reduction Reactions by the Transfer of Electrons Between Ions,* where the latter are in contact in an **electrolyte.** Instead of arranging the **electrodes** and electrolytes of the Daniell cell described above wherein the electrode compartments are separated in space and electrically connected through the electrolyte *in* the cell and through the metallic **conductor** *outside* the cell, the materials may be placed in direct contact. To make it still simpler, when zinc metal is placed in copper sulfate solution, a reaction occurs—copper metal is displaced from the solution and an equivalent amount of zinc metals goes into solution as zinc ions. This part of the reaction is identical with that in the Daniell cell. But to generate an electromotive force the conditions laid down for the Daniell cell must be followed.

Reactions of this type may, therefore, be brought about either (1) by the cell method, wherein the electromotive force of each half-cell may be measured by balancing against the electromotive force of a standard half-cell, e.g., a hydrogen electrode, or a calomel (mercurous chloride) electrode, or (2) by placing the substances in contact, as in a test tube or a beaker. The resulting transformation of materials, that is, the chemical reaction, is the same in each case. The difference in the electromotive force of the component half-cells is a measure of the tendency to react.

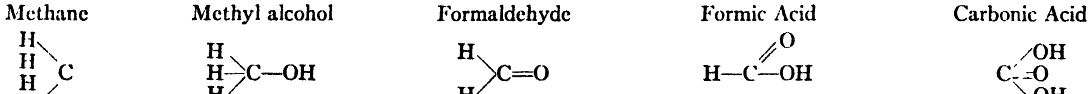
Latimer and Hildebrand "Ref. Book of Inorg Chem," Macmillan.

Reactions not in solutions of electrolytes but oxidation-reduction in character are of wide scope and of fundamental importance in organic chemistry. They comprise such reactions as transformations (horizontally, not vertically) among the following typical groups of compounds:

Methane | Methyl alcohol | Formaldehyde | Formic Acid | Carbonic Acid



Carbon Monoxide C=O | Carbon Dioxide O=C=O

Hydrocarbons, primary	Alcohols, primary	Aldehydes	Acids, carboxylic
" secondary	" secondary	Ketones	
" tertiary	" tertiary		
" quarternary			

(See **Hydrocarbons; Alcohols; Aldehydes** (ketones included); **Acids, Carboxylic.**)

Benzene C_6H_6	Phenol $C_6H_5 \cdot OH$	
	Hydroquinone $C_6H_4(OH)_2(1,4)$	Benzoquinone $C_6H_4(O)_2(1,4)$

(See **Phenols and Quinones.**)

Ethane	Ethyl amine	Acetamide	Urea
$CH_3 \cdot CH_3$	$CH_3CH_2 \cdot NH_2$	$CH_3 \cdot CONH_2$	$C\begin{array}{l}\diagup NH_2\\ {=}O\\ \diagdown NH_2\end{array}$
		Methyl cyanide	
		$CH_3 \cdot CN$	

(See **Amines and Amides; Amination.**)

Benzene	Phenylamine (aniline)	Phenylhydrazine	Beta-Phenyl-hydroxylamine	Nitrosobenzene	Nitrobenzene
C_6H_6	$C_6H_5 \cdot NH_2$	$C_6H_5 \cdot NHNH_2$	$C_6H_5 \cdot NHOH$	$C_6H_5 \cdot NO$	$C_6H_5 \cdot NO_2$

(See **Hydrazines; Hydroxylamines; Nitro and Nitroso Compounds.**)

Benzene	Phenylamine	Hydrazobenzene	Azobenzene	Azoxybenzene	Nitrobenzene
C_6H_6	$C_6H_5 \cdot NH_2$	$C_6H_5 \cdot NHNH \cdot C_6H_5$	$C_6H_5 \cdot N{:}N \cdot C_6H_5$	$C_6H_5 \cdot N{:}\underset{\ddot{O}}{N} \cdot C_6H_5$	$C_6H_5 \cdot NO_2$
		Benzidine			
		$(4)H_2N \cdot C_6H_4 \cdot C_6H_4 \cdot NH_2(4)$			

(See **Azo- and Related Compounds.**)

Benzene	Thiophenol	Benzene sulfinic acid	Benzene sulfonic acid
C_6H_6	C_6H_5SH	$C_6H_5 \cdot SOOH$	$C_6H_5 \cdot SO_2OH$
	Carbon disulfide	Carbonyl sulfide	
	CS_2	COS	
	Diphenyl sulfide	Phenyl sulfinyl benzene	Phenyl sulfonyl benzene
	$(C_6H_5)_2S$	$(C_6H_5)_2SO$	$(C_6H_5)_2SO_2$

(See **Thioalcohols and Related Compounds.**)

Methane	Methyl chloride	Methylene chloride	Chloroform	Carbon tetrachloride
H_4C	$H_3C \cdot Cl$	$H_2C \cdot Cl_2$	$HCCl_3$	CCl_4

(See **Chlorine, Organic Compounds.**)

Methyl phosphine $CH_3 \cdot PH_2$	Methyl phosphinic acid $CH_3PO(OH)_2$
Dimethyl phosphine $(CH_3)_2PH$	Dimethyl phosphinic acid $(CH_3)_2POOH$
Trimethyl phosphine $(CH_3)_3P$	Trimethyl phosphine oxide $(CH_3)_3PO$
Tetramethyl phosphonium hydroxide $(CH_3)_4POH$	

(See **Phosphines and Related Compounds.**)

CLASSIFICATION OF CERTAIN REACTIONS FROM THE STANDPOINT OF OXIDATION-REDUCTION

Reduction	Oxidation
Hydrogenation	Dehydrogenation
Deoxygenation	Oxygenation
Dechlorination	Chlorination
Chloride-formation	Chlorate-formation
Debromination	Bromination
Bromide-formation	Bromate-formation
Nitrite-formation	Nitrate-formation
Amino-formation	Nitro-formation
Cyanide-formation	Cyanate-formation
Sulfide-formation	Sulfate-formation

(R.K S.)

REACTIONS INVOLVING RECOMBINATION OF IONS. Reactions of acids, bases, salts in water solution are usually reactions of **ions** in one of the following ways:

1. Recombination of **anions** and **cations.**
2. Formation of complex anions or cations.
3. Change of the electronic charge of anions or cations or a component part of either.

The third type of reaction is discussed under **Reactions Involving Oxidation-Reduction.** The first two types are considered here.

1. Recombination of anions and cations.

a. Those reactions in which there is *no change of state* involved, that is, no gas and no solid separating from or entering into the solution.

Of these reactions the most common is the neutralization of an acid and a base.

In dilute solution (say 1/20 molar—see **Concentration**) the electrolytic dissociation data for a few substances is as follows:

Substance	Formula	Percentage Electrolytic Dissociation at M/20
Hydrochloric acid...	H^+Cl^-	100%
Acetic acid..........	$H^+Ac^-(HC_2H_3O_2)$	4%
Sodium hydroxide....	Na^+OH^-	100%
Sodium chloride......	Na^+Cl^-	100%
Sodium acetate.... ..	Na^+Ac^-	100%
Water.......... . .	H^+OH^-	0.00001%

The following outline represents graphically the state of affairs in two pairs of solutions before mixing and after mixing—in the latter case recombination of ions occurs. *C/* is the original number of each entity *before* mixing, and */C* the final or equilibrium number of each entity *after* mixing and recombination of ions has taken place.

Example 1. Taken: 100 mols M/20 HCl
100 mols M/20 NaOH

$$\begin{array}{ccccc}
HCl & \rightleftarrows & H^+ & + & Cl^- \\
0/ & & 100/0.00001 & & 100/100 \\
 & & + & & + \\
NaOH & \rightleftarrows & OH^- & + & Na^+ \\
0/ & & 100/0.00001 & & 100/100 \\
 & & \downarrow\uparrow & & \downarrow\uparrow \\
 & & HOH & & NaCl \\
 & & /100 & & /0
\end{array}$$

Example 2. Taken: 100 mols M/20 HAc
100 mols M/20 NaOH

$$
\begin{array}{ccccc}
HAc & \rightleftarrows & H^+ & + & Ac^- \\
96/ & & 4/0.00001 & & 4/100 \\
 & & + & & + \\
NaOH & \rightleftarrows & OH^- & + & Na^+ \\
0/ & & 100/0.00001 & & 100/100 \\
 & & \downarrow\uparrow & & \downarrow\uparrow \\
 & & HOH & & HaAc \\
 & & /100 & & /0
\end{array}
$$

In the first example the real chemical reaction is essentially $H^+ + OH^- \rightleftarrows HOH$; in the second, $HAc + OH^- \rightleftarrows HOH + Ac^-$.

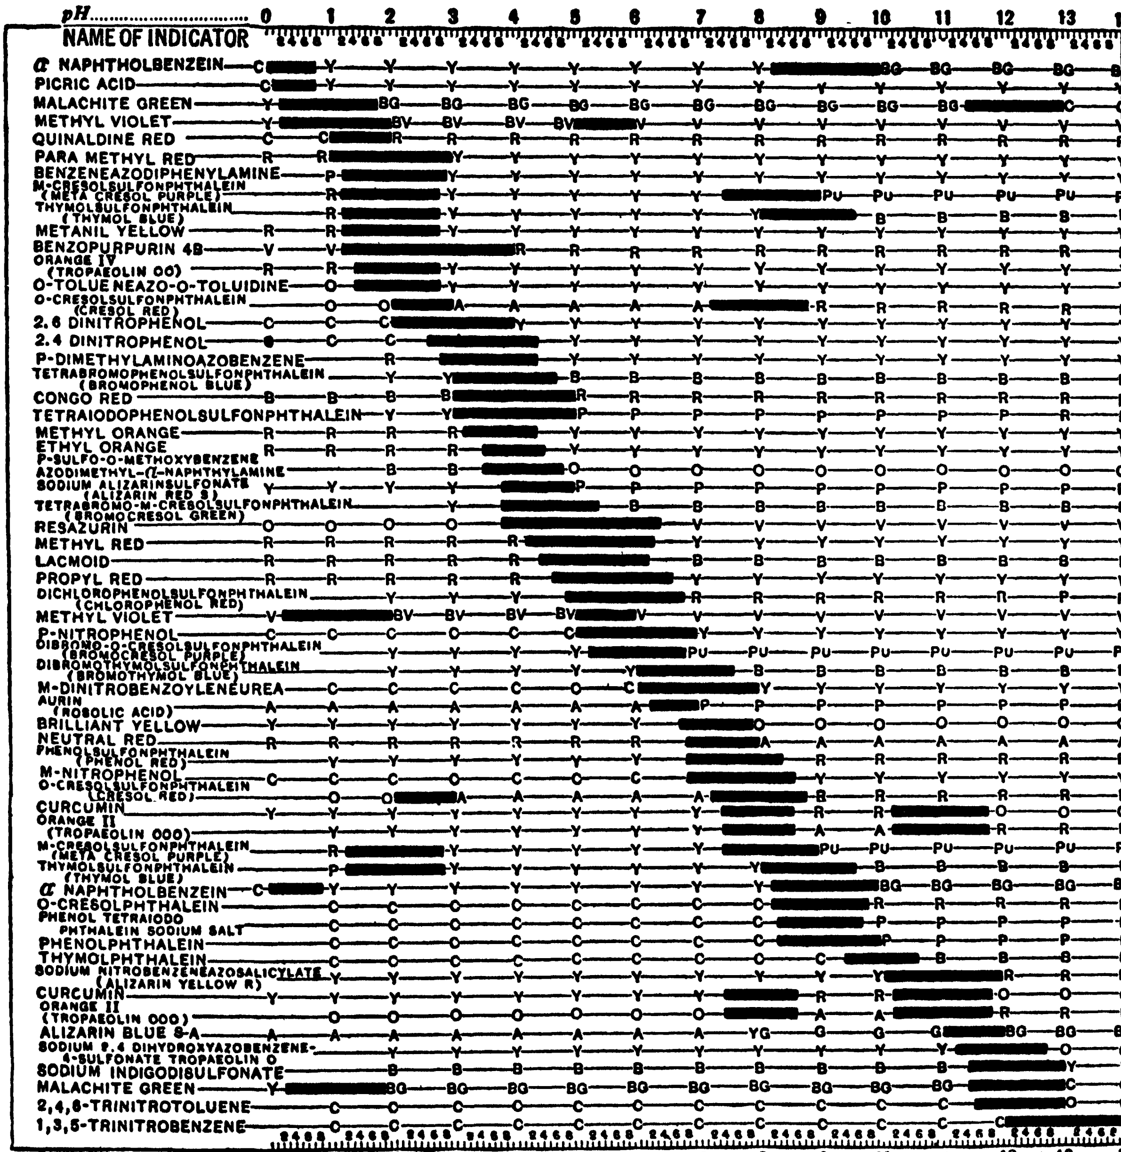
In support of this, data from another source is available, namely, the heat of the reaction, which is, per 1 mol of water formed, in example 1, 13,700 calories, and in example 2, 13,400 calories, thus showing that the reactions are not identical. The net *difference* between the two is the ionization of acetic acid

$$HAc \rightleftarrows H^+ + Ac^-$$

which evidently absorbs 300 calories.

Acids and bases which are ionized to the degree of hydrochloric acid and sodium hydroxide, e.g., hydrobromic acid, nitric acid, potassium hydroxide, give the same heat of reaction, namely, 13,700 calories. The

HYDROGEN ION CONCENTRATION RANGES (pH) AND COLOR CHANGES OF INDICATORS



A—Amber	BV—Blue Violet	Pu—Purple
B—Blue	G—Green	R—Red
C—Colorless	O—Orange	V—Violet
BG—Blue Green	P—Pink	Y—Yellow

The pH ranges shown are approximations and are intended to aid in selecting the proper indicator. (*Eastman Kodak Co.*)

heat of reaction of hydrochloric acid and **ammonium** hydroxide (electrolytic dissociation comparable with that of acetic acid) is 12,200 calories—the heat of ionization of ammonium hydroxide is evidently 1500 calories absorbed. The heat of reaction of acetic acid and ammonium hydroxide is 11,900 calories (13.700 − (300 + 1500)).

When solutions of **salts** that are completely ionized are mixed, e.g., **sodium** chloride plus **potassium** nitrate, there is no heat change. No chemical reaction has occurred.

The cases converse to the above are interpreted similarly. Thus, when sodium chloride solution is tested for acidity or alkalinity, it is found to be neutral, while sodium acetate solution, as would be expected from an examination of the above, displays alkalinity, that is, excess of hydroxyl ion (OH^-):

$$Na^+Ac^- + HOH \rightleftharpoons HAc + Na^+OH^-$$

and, therefore,

$$Ac^- + HOH \rightleftharpoons HAc + OH^-$$

Hydrogen Ion Concentration. In pure water and in a solution of a salt of highly ionized acid and highly ionized base, the **concentration** of hydrogen ion (H^+) and of hydroxyl (OH^-) is equal, and the actual concentration numerically 10^{-7} mols each. But in a solution such as **sodium** acetate or **aluminum** sulfate, where the acid (HAc) or the base ($Al(OH)_3$), respectively, is *slightly* ionized, the concentration of H^+ and OH^- is not equal, and therefore not 10^{-7} mols. There is excess of OH^- in sodium acetate solution, and excess of H^+ in aluminum sulfate solution, when equivalent amounts (see **Chemical Composition**) of cation and anion of the salt are present in solution. Hydrogen ion concentration may be ascertained by the use of indicators or by the electrometric method (see **Electrochemistry**).

Indicators. Substances are known which indicate by their color or change of color various concentrations of H^+ and OH^-. These indicators, of which litmus is a familiar example, are of great importance when it is desired to know the acidity or alkalinity of a solution and when that solution is not itself too markedly colored. (See chart on page 1211.)

pH. More commonly used as a measure of hydrogen-ion concentration than molar concentration above, is the expression pH, which equals the logarithm of the reciprocal of the **hydrogen ion** concentration:

$$pH = \log \frac{1}{[H^+]}.$$

When the concentration of hydrogen ion is 10^{-7}, symbolized $[H^+] = 10^{-7}$, the concentration of **hydroxyl** ion is also 10^{-7}, symbolized $[OH^+] = 10^{-7}$, as in pure water. When $[H^+] = 10^{-1}$, $[OH^-] = 10^{-13}$, and so on, since the ion product constant $[H^+] \times [OH]$ equals 10^{-14}.

pH *of Various Materials.* Of special importance in the applications of hydrogen and hydroxyl ion concentrations is the pH of various media in nature, for example, natural waters, soils, animal secretions, and in industry, for example, the **colloidal** state and many solutions. Acidity is produced in soils, and solutions by the addition of acids (e.g., **sulfuric acid**), acid salts, (e.g., **sodium** hydrogen sulfate, **calcium** dihydrogen phosphate), or hydrolyzable salts of a strong acid and a weak base—see **Acids, Bases, Salts**—(e.g., **aluminum sulfate, ferrous** or ferric sulfate). Alkalinity is similarly produced by addition of bases (e.g., **calcium hydroxide**), or salts (e.g., calcium carbonate, sodium carbonate, sodium hydrogen carbonate, trisodium phosphate, sodium silicate).

pH OF VARIOUS MATERIALS

Material	pH
Sea water	7.75 to 8.25
Soils	3 to 10
Plant tissues and fluids	About 5.2
Animal tissues and fluids	About 7.0 to 7.5
Blood	7.35–7.5
Urine	5.0–7.0
Milk	6.5–7.0
Gastric juice	1.7
Pancreatic juice	7.8
Intestinal juice	7.7
Internal tissue fluids:	
Minimum, below which acidosis ensues	7.0
Maximum, above which tetany ensues	7.8

pH OF SOIL FOR SPECIFIC CROPS

Crop	pH Desired	Crop	pH Desired
Wheat	6.0–8.0	Onion	6.0–8.0
Corn	6.0–8.0	Spinach	6.0–8.0
Oats	6.0–7.0	Apple, pear, cherry, peach, plum	6.0–8.0
Barley	6.0–8.0	Orange, lemon	5.0–7.0
Rye	6.0–8.0	Grape	6.0–8.0
Potato	6.0–8.0	Strawberry, raspberry	5.0–6.0
Peanut	5.0–6.0	Tomato	6.0–8.0
Cotton	6.0–8.0	Rose	6.0–8.0
Flax	6.0–7.0	Pea, sweet	6.0–8.0
Tobacco	5.0–8.0	Hydrangea	6.0–8.0
Clover	6.0–8.0	Hollyhock	6.0–8.0
Alfalfa	6.0–8.0	Foxglove	6.0–8.0
Red top	6.0–7.0	Tulip	6.0–8.0
Timothy	6.0–8.0	Rhododendron	5.0–6.0
Bluegrass	6.0–8.0	Oak	5.0–8.0
Pea	6.0–8.0	Maple	5.0–8.0
Bean	6.0–8.0	Elm	6.0–8.0
Sugar cane	6.0–8.0	Holly	4.0–6.0
Beet, common and sugar	6.0–8.0	Spruce, pine, fir	5.0–6.0
Carrot	6.0–8.0	Douglas fir	6.0–7.0

VARIOUS SUBSTANCES HAVING (IN 0.01M SOLUTION) A pH VALUE WITHIN THE COLOR TRANSITION RANGE OF INDICATORS

0.01 Molar Solution	pH Approximate	Indicator	Color Point Acidic–Basic
Hydrochloric acid	2	Thymol blue	Red–yellow
Acetic acid	3	2,6-Dinitrophenol	Colorless–yellow
Ammonium chloride	5	Methyl orange	Red–yellow
		Congo red	Blue–red
Sodium chloride	7	Bromthymol blue	Yellow–blue
Sodium acetate	10	Phenolphthalein	Colorless–pink
Ammonium hydroxide	11	Orange II	Amber–red
Sodium hydroxide	12	Sodium indigo sulfonate	Blue–yellow

Titration of Acids and Bases. An indicator does not change color from the purely acidic to the purely basic side at a point, but rather, it will be noted, over a narrow measurable band or range of pH—the color change interval. The selection of an indicator for the titration of a given slightly ionized acid or slightly ionized base depends upon the **ionization constants.** The ionization constant is, for slightly ionized acids, practically the product of the hydrogen ion concentration and of the

anion concentration. The following data are in all cases stated for the *first* hydrogen ion dissociation only, thus:

$$\frac{[H^+] \times [Anion^-]}{[Non\text{-}ionized\ acid]} = \text{Ion product constant of acid.}$$

IONIZATION CONSTANTS OF ACIDS (FIRST HYDROGEN IONIZATION) AT 25° C., EXCEPT AS OTHERWISE STATED

Tartaric	1×10^{-3}
Thiosulfuric	1×10^{-2}
Trichloracetic (18° C.)	2×10^{-1}
Uric	1.5×10^{-6}

For ionization constants of **nitrogen** bases and nitrogen acids see Amines.

$$\frac{[Cation^+] \times [OH^-]}{[non\text{-}ionized\ base]} = \text{Ionization product of base.}$$

Common Ion Effect. When **sodium** acetate (Na^+Ac^-, ionization large) solution is added to **acetic acid** (H^+Ac^-, ionization small) solution, the concentration of acetate ion is greatly increased with equivalent decrease of hydrogen ion. When **ammonium** chloride (NH_4^+ Cl^-, ionization large) solution is added to ammonium hydroxide ($NH_4^+OH^-$, ionization small) solution, the concentration of ammonium ion is greatly increased with equivalent decrease of hydroxyl ion. This may be demonstrated in such cases by the use of the proper indicator, e.g., methyl orange in the case of acetic acid, phenolphthalein in the case of ammonium hydroxide. The principle is not confined to cases of acids and bases, but is of general application to **electrolytes**. This may be visibly demonstrated by the use of **cupric** bromide solution. The addition of either cupric chloride solution on the one hand, or **potassium** bromide solution on the other hand, causes increase in the cupric and bromide ions, respectively, with resultant color change from the predominant blue of cupric ion to predominant green to brown of non-ionized cupric bromide.

b. Those reactions in which there is *a change of state* involved, that is, a gas or a solid separates from or enters into the solution.

Of these reactions, the most common is the precipitation or the solution of a solid and the evolution or the solution of a gas. In principle, precipitation of solid and evolution of gas are the same, in that in each case the given substance is insoluble (more or less) in the medium (Examples 3 and 4, below). Solution of a solid or of a gas in the medium is the converse of the above in simple cases (Examples 5 and 6, below).

Example 3. Taken: 100 mols M/20 $AgNO_3$
100 mols M/20 HCl

$AgNO_3$	⇄	Ag^+	+	NO_3^-
o/		100/o 0013		100/100
		+		+
HCl	⇄	Cl^-	+	H^+
o/		100/o 0013		100/100
		⇅		⇅
		AgCl		HNO_3
		/o		/o
		⇅		
		AgCl		
		(Solid)		
		/100		

Result: AgCl solid separates as precipitate.

Example 4. Taken: 100 mols M/20 Na_2CO_3
200 mols M/20 HCl

				H_2O	+	CO_2 (gas)
				/large prop.		/large prop
				⇅		
		2NaCl		H_2CO_3		
		/o		/small prop.		
		⇅		⇅		
Na_2CO_3	⇄	$2Na^+$	+	CO_3^{--}		
o/		200/200		100/small prop.		
		+		+		
2HCl	⇄	$2Cl^-$	+	$2H^+$		
o/		200/200		200/small prop.		

Result: Na_2CO_3 decomposed, CO_2 gas given off.

Example 5. Taken: 100 mols $BaCrO_4$ solid
200 mols M/20 HCl

$BaCrO_4$ (solid)	⇄	$BaCrO_4$	⇄	Ba^{++}	+	CrO_4^{--}
100/		o/		o 015/100		o 015/100
				+		+
		2HCl	⇄	$2Cl^-$	+	$2H^-$
		o/		200/200		200/200
				⇅		⇅
				$BaCl_2$		H_2CrO_4
				/o		/o

Result: $BaCrO_4$ dissolved.

Example 6. Taken: 100 mols CO_2 gas passed into NaOH solution
100 mols M/20 NaOH

CO_2 (gas)	⇄	H_2CO_3	⇄	H^+	+	HCO_3^-
Large/ prop./		Small/ prop./		Small/Small prop./prop.		Small/Large prop./prop.
				+		+
		NaOH	⇄	OH^-	+	Na^+
		o/		100/Small prop.		100/Large prop
				⇅		⇅
				H_2O		$NaHCO_3$
				/100		/Small prop

Result: CO_2 dissolved, and $NaHCO_3$ formed.

2. Formation of Complex Anions or Cations.

The formation or disappearance of complex ions is similar in principle. New combinations are formed without change of electronic charge of the fundamental element.

Example 7. Taken: $Zn(OH)_2$ Solid
Excess NaOH Solution

$$\begin{array}{cccccc} & & \nearrow & Zn^{++} & + & 2OH^- \\ \underset{\text{(solid)}}{Zn(OH)_2} \rightleftarrows Zn(OH)_2 & & & & & \\ & & \searrow & 2H^+ & + & ZnO_2^{--} \\ & & & + & & + \\ & 2NaOH \rightleftarrows & & 2OH^- & & 2Na^+ \\ & & & \updownarrow & & \updownarrow \\ & & & 2H_2O & & \underset{\text{(solution)}}{Na_2ZnO_2} \end{array}$$

Result: $Zn(OH)_2$ dissolved. Similar cases: $Na_2Pb^{2+}O_2$, $Na_2Sn^{2+}O^2$, $NaAl^{3+}O_3$, complex zincate anion (ZnO_2^{--}) containing Zn^{2+} formed.

Example 8. Taken: $Zn(OH)_2$ solid.
Excess NH_4OH solution.

$$\begin{array}{cccccc} & & \nearrow & 2H^+ & + & ZnO_2^{--} \\ \underset{\text{(solid)}}{Zn(OH)_2} \rightleftarrows Zn(OH)_2 & & & & & \\ & & \searrow & Zn^{++} & + & 2OH^- \\ & & & + & & + \\ & & \nearrow & 4NH_3 & + & 4H_2O \\ & 4NH_4OH & & & & \\ & & \searrow & 4OH^- & + & 4NH_4^+ \\ & & & \updownarrow & & \updownarrow \\ & & & (NH_3)_4Zn^{++} & + & 2OH^- \end{array}$$

Result: $Zn(OH)_2$ dissolved, complex ammonio-zinc cation ($(NH_3)_4Zn^{++}$) containing Zn^{2+} formed.
Similar cases: $(NH_3)_2Ag^{1+}OH$, $(NH_3)_4Cu^{2+}(OH)_2$, $(NH_3)_2Cu^{1+}OH$, $(NH_3)_4Cd^{2+}(OH)_2$. (R.K.S.)

REACTIONS INVOLVING WATER. The length of the present discussion is not in proportion to the importance of the subject for the reason that several aspects have conveniently and necessarily been discussed elsewhere. The following articles should be consulted: **Chemical Changes, Reactions Involving Recombination of Ions.**

Reactions involving water are classified as follows:

1. Consumption of water.
2. Production of water.
3. Water as catalyzer.

1. Consumption of Water. This topic is concerned with all reactions in which water is a reactant—hydrolytic and hydration reactions.

a. **Salts** are hydrolyzed in solution to an extent depending upon the strength of the acid of the **anion** and the strength of the base of the **cation**. **Sodium** chloride, a salt of a highly ionized base and a highly ionized acid, is, practically, not hydrolyzed in solution. **Ammonium** acetate, a salt of a slightly ionized base and a slightly ionized acid, is hydrolyzed in solution with the consequent presence of some ammonium hydroxide and some **acetic acid**. One-sided hydrolysis is frequently encountered, e.g., **sodium** carbonate, a salt of a highly ionized base and a slightly ionized acid, is basic (contains excess hydroxyl ions (OH^-)) in solution; **aluminum** chloride, a salt of a slightly ionized base and a highly ionized acid, is acidic (contains excess hydrogen ions (H^+)) in solution.

b. Some salts crystallize from water solution with definite ratios of water called water of **crystallization**, composing the crystal. Water of crystallization is an integral part of such crystals. Spontaneous evolution of water (in cases of efflorescent crystals) or loss of water upon heating, causes change in the crystal form and composition.

c. Some salt crystals, those containing water of crystallization and where the salt is of a slightly ionized nonvolatile base and a highly ionized volatile acid (e.g., HCl), are hydrolyzed upon heating, e.g., **magnesium** chloride crystals ($MgCl_2 \cdot 6H_2O$) when heated yield hydrogen chloride (HCl) gas and basic magnesium chloride $\left(Mg\begin{array}{l}\diagup Cl\\ \diagdown OH\end{array}\right)$ or, at higher temperature, magnesium oxide (MgO).

d. The hydrolysis of ethyl acetate ester is discussed elsewhere in detail (see **Chemical Changes**). Many classes of organic compounds are hydrolyzable, some preferably in acidic, some in basic, and some in either media. Such compounds include **esters, acetals, acid anhydrides**, polysaccharides (see **Carbohydrates**), **glucosides, tannins, amides** (to form ammonium compounds), **cyanides** (to form **carboxylic acids**), **proteins, oximes, phenylhydrazones**, osazones, semicarbazones, non-benzenoid halogen compounds.

e. **Acetylene** reacts with water in the presence of a **catalyzer**, e.g., **mercuric** salt, to form **acetaldehyde.** This is a reaction of great importance.

2. Production of Water. This topic is concerned with all reactions in which water is a resultant.

a. In the field of inorganic chemistry, neutralization of acids and bases is a common instance of the production of water. Also, the reduction of oxides, such as **copper, lead, iron** oxides, by heating them in a current of **hydrogen** gas; the burning of hydrogen gas in air or oxygen; and the loss of water of crystallization of crystals.

b. In the field of organic chemistry, the combustion of organic hydrogen compounds (rapid, as in burning, or slow) results in the formation of water from the contained hydrogen.

c. The reaction of **alcohols** plus **acids** to form **esters** (esterification) results in the accompanying formation of water. Esterification is a special case of a general reaction, namely, loss of **hydroxyl** by a compound and loss of **hydrogen** by the same or another compound (chemical dehydration). Examples, ethyl alcohol, 1 molecule, into ethylene ($CH_2:CH_2$) plus water, thus $\begin{array}{l}H_2C\vdots H\\ H_2C\;OH\end{array}$; ethyl alcohol, 2 molecules, into ethyl ether ($(C_2H_5)_2O$), thus $\begin{array}{c}CH_3CH_2O\vdots H\\ CH_3CH_2\;OH\end{array}$; ethyl alcohol, 1 molecule, plus acetic acid, 1 molecule, into ethyl acetate ($CH_3COOC_2H_5$) thus, $\begin{array}{c}CH_3CH_2O\vdots H\\ CH_3CO\;OH\end{array}$.

d. Another group of reactions of frequent occurrence in organic chemistry belongs in this category. The reactions are illustrated by the behavior of **nitric** or **sulfuric acid** with benzenoid compounds. These processes, known as **nitration** and **sulfonation**, respectively, result in the formation of water and a **nitro-compound** or a sulfonic acid compound.

3. Water as Catalyzer. In some reactions water plays the role of **catalyzer.**

A mixture of extremely dry hydrogen and oxygen gases is ignited with difficulty, if at all, although water is a resultant when the reaction occurs, and in the presence of water ignition is easily accomplished by flame or electric spark. Dixon found that the rate of explosion of **carbon monoxide**-oxygen gas mixtures was definitely affected by the presence of water vapor, thus, when the mixture was saturated with water vapor at 28° C. (3.7% water vapor) the rate of explosion is 1713 meters per sec., when moderately dry, 1305 meters per sec., and when dried with phosphorus pentoxide, 1264 meters per sec.

Baker (1902) showed that extremely dry **hydrogen** (2 volumes) plus oxygen (1 volume) does not explode even when heated to redness. No combination of the gases occurs when heated below 960° C. (although an electric spark induces an explosion). Previously, it had

been demonstrated that extremely dry **ammonia** and **hydrogen chloride** gases do not unite to form ammonium chloride as ordinarily occurs. Burk and Hinshelwood (1927) admitted the dried gases into a glass receiver that had been heated at 200° C. in vacuum to remove all water *except* a film of **adsorbed** water on the interior surface of the glass receiver. They showed that no ammonium chloride smoke was formed in the gas upon admitting extremely dried ammonia and hydrogen chloride gases, but that solid ammonium chloride was formed on the surface of the receiver *beginning* at the place of entrance of the gases. The reaction probably takes place between ammonium ions (NH_4^+) and chloride ions (Cl^-) in water solution.

An extremely dried mixture of hydrogen and chlorine does not explode in sunlight (as does the moist mixture). Similarly, dried **nitric oxide** and oxygen mixture does not yield **nitrogen** dioxide; **carbon**, when heated to bright redness in dried oxygen, does not burn; **sulfur**, when distilled in dried oxygen, does not burn; **potassium**, when vaporized in dried oxygen, does not burn; **sodium**, burning freely in air, is extinguished when lowered into a jar of dried oxygen. Baker (1922) reported remarkable elevations of the boiling point of liquids that had been subjected to drying for several years by means of phosphorus pentoxide, e.g., bromine, dried 8 years, original boiling point 63° C., new boiling point 118° C., elevation of boiling point 55° C.; benzene, 8.5 years, 80°, 106°, 26° C., respectively; ethyl alcohol, 9 years, 78.5°, 138°, 60° C., respectively. (R.K.S.)

REACTIVE POWER. **Alternating-Current Circuits.**

REACTOR. **Choke Coil.**

REALGAR. The mineral realgar is a **monosulfide** of **arsenic** corresponding to the formula AsS. It is **monoclinic**, showing short prismatic crystals, or may be in granular or compact masses. It is a soft sectile mineral; hardness, 1.5–2; specific gravity, 3.5; luster, resinous; color, red to orange-yellow; transparent to translucent. Realgar occurs associated with other arsenic minerals and with **gold, silver,** and **lead** ores, although not in great quantities. It has been found as a hot-spring deposit and in volcanic sublimations. Realgar has been found in Macedonia, Japan, Switzerland; and in the United States in Yellowstone National Park, as a hot spring deposit, and in Utah and Nevada. The name realgar is derived from the Arabic words *rahj al ghar,* which means the powder of the mine. (E.S.C.S.)

REAMING. Two-lipped twist and straight fluted drills are satisfactory agents for originating holes, but if a cored hole is to be finished or if a drilled hole is to be enlarged, two lips do not provide sufficient support for the body of the drill and an irregular non-cylindrical hole will result. For this type of work, therefore, drills or reamers with three or more cutting edges must be employed. There are two general classes of reamers, side-cutting and end-cutting types. Fig. 1 shows a rose reamer for enlarging drilled holes or for machining

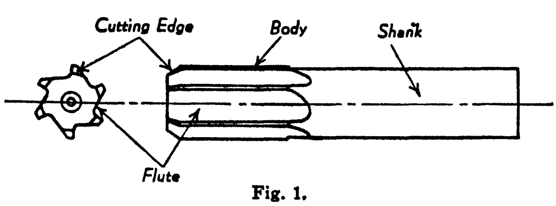

Fig. 1.

punched or cored holes. Such reamers cannot be used for originating holes. The reamer has six cutting edges and is of the end-cutting type. It has no radial clearance on the margin of the flute, but is provided with a back taper of about .002″ per foot. End-cutting tools can be resharpened frequently since all the cutting is done at the tips. Rose reamers are made somewhat under the nominal size, as they tend to cut oversize. Holes are generally finished to exact size by using either hand or machine side-cutting reamers, with either straight or spiral flutes. Hand reamers are designed to remove only a few thousandths of an inch of metal, and are very slightly tapered on the entering end to facilitate starting.

Adjustable reamers have inserted blades; the main body of the reamer including the straight shank is a solid piece of steel. The blades are made of high-speed steel, and are held by a lock nut at one end and set screws at the other end. The blades can be moved axially along a tapered key which causes them to move radially outward at the same time. The reamer has an adjustment of 1/16″, and the blades can be replaced by another set when they are worn to the limit of adjustment. The adjustable reamer permits variation in size, but its chief advantage is economy since the blades can be repeatedly adjusted and reground when they become dull.

Hand expansion reamers are used when it is necessary to increase diameters very slightly, especially in repair work. They are intended for light cuts only and are expanded by screwing in the taper expanding plug. The front pilot is generally .010″, and the rear pilot .005″, under the normal size of the reamer.

Shell reamers are hollow cylinders with fluted edges on the outer periphery, and are used with separate arbors to decrease the tool cost.

Taper reamers are used for reaming tapered holes after they have been drilled. Bridge reamers are made in both straight and spiral fluted types, and are used for aligning and reaming punched holes in structural and pressure-vessel work. They are principally used in portable electric or pneumatic tools. Reaming is far superior to drifting for this purpose particularly since it removes the metal around the punched hole, which is likely to be defective on account of the punching process. (H.C.H.)

REARRANGEMENTS. These are reactions in organic chemistry which involve the transfer of an **atom** or group from one part of the **molecule** to another. **Tautomerism** is a special case of rearrangements in which the two forms are in dynamic **equilibrium.** When such reactions take place the establishment of structural formulae is complicated, since such reactions do not serve as proof for the establishment of structural formulae. (See **Chemical Formulae.**) The following is a list of the more important cases of rearrangements.

1. Allyl Rearrangement:

$$CH_3CH{:}CHCH_2Br \rightarrow CH_2{:}CHCHBrCH_3$$

2. Pinacol Rearrangement: takes place when pinacol is heated with dilute acid, pinacolin formed.

$$(CH_3)_2\underset{\displaystyle OH}{\underset{|}{C}}-\underset{\displaystyle OH}{\underset{|}{C}}(CH_3)_2 \rightarrow (CH_3)_3C-\overset{\displaystyle OH}{\overset{|}{\underset{\displaystyle OH}{\underset{|}{C}}}}(CH_3)$$

3. Benzil Rearrangement: into benzylic acid.

$$C_6H_5\overset{\displaystyle O}{\overset{\|}{C}}-\overset{\displaystyle O}{\overset{\|}{C}}-C_6H_5 \rightarrow (C_6H_5)_2C\begin{matrix}\diagup OH \\ \diagdown COOH.\end{matrix}$$

4. Hoffman Rearrangement:

$$RCO\cdot N\begin{matrix}\diagup H \\ \diagdown H\end{matrix} \rightarrow RCONHBr \rightarrow RNCO \rightarrow RNH_2$$

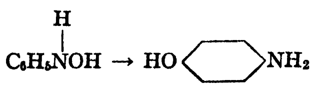
5. Beckmann Rearrangement: results when oximes of ketones are treated with certain reagents such as phosphorus pentachloride.

$$\underset{\text{NOH}}{\overset{\text{R'C—R}}{\|}} \rightarrow \underset{\text{R'N}}{\overset{\text{RC—OH}}{\|}} \rightarrow \underset{\text{R'N—H.}}{\overset{\text{R—C=O}}{|}}$$

The exchange is between R′ and OH on the opposite sides of the CN bond.

6. Benzidine Rearrangement: Treatment of hydrazobenzene with strong acids.

7. Rearrangement of hydroxylamine derivatives



8. Rearrangement in reaction of nitrous acid and alkyl amines

$$CH_3CH_2CH_2\cdot NH_2+HNO_2 \begin{cases} \nearrow CH_3CH_2\text{—}CH_2OH \\ \searrow CH_3CHOH\text{—}CH_3 \end{cases} +N_2+H_2O$$

9. Walden Inversion. A rearrangement takes place in the reaction of optically active substances. The structural formula does not change but the configuration changes due to the interchange of two groups attached to the asymmetrical carbon atom during the course of the reaction. (R.K.S.)

REAUMUR SCALE. **Temperature Scales.**

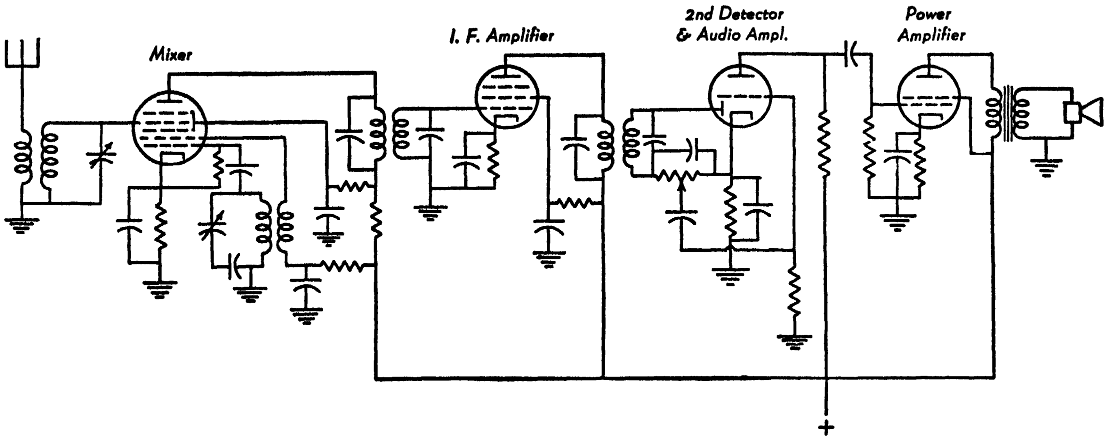
RECALESCENCE. A singular phenomenon exhibited by iron and some other ferromagnetic metals. If iron is heated white hot and allowed to cool, it will, at a certain temperature, suddenly evolve enough heat to halt the cooling and even produce a momentary heating. This is easily exhibited by stretching an iron wire against the tension of a spring and arranging a lever index to show slight changes in length. The wire is first heated by an electric current. As it cools and contracts, the index will at a certain point give a perceptible jerk, and then resume its steady motion of contraction. The effect is due to an exothermic change in the crystalline structure. The reverse phenomenon, exhibited on heating, is called "decalescence." For cast iron the recalescence point is a little below 700° C. Pure iron has two such points, at 780° C. and 880° C.

A somewhat analogous effect is exhibited by some amorphous solids upon **devitrification**, which takes place when the temperature becomes high enough for the substance to crystallize. Non-crystalline sodium silicate, for example, has such a transition point near 500° C., where it suddenly begins to glow. (L.D.W.)

RECAPITULATION. **Evolution.**

RECEIVER. The radio receiver is the device which picks up the wave from the transmitter and converts it to sound. The simplest form of practical receiver is the crystal set which was once used extensively, then with the advent of satisfactory and cheap vacuum-tube circuits was largely discarded, and which is now coming back as a receiver for ultra high and super high frequencies. Such a set consists of some means of selecting or tuning the desired signal, a rectifying type crystal (galena, silicon, etc.) as a **detector** and a head-set. In its present application for the extremely high frequencies the tuning elements are **lines** and **wave guides**. In the early days of broadcasting the regenerative receiver was almost universally used. However, it has serious limitations, chief among them being its poor audio quality and its radiating ability. As a consequence it is no longer used for regular broadcast reception and its present use is confined to the reception of continuous wave signals. (See **Radio Telegraphy**.) Tuned radio-frequency receivers were also widely used at one time but are not used much except in the cheaper broadcast receivers and in some long wave commercial stations. This receiver has an antenna-coupling circuit for tuning and coupling the **antenna** to the **grid** of the first amplifier **tube**. This tube may be coupled by a second tuned circuit to another **amplifier** or in smaller sets it may be coupled to the **detector**. Each coupling circuit up to the grid of the detector is tuned and for home receivers the present-day sets have all tuning elements controlled by a single dial. Early sets had each element controlled by a separate dial. While the detector may be any of the conventional types it is usually a triode biased almost to cut-off. This produces rectification and hence demodulation of the radio signal. The audio output of the detector is then amplified by one or more audio-amplifier stages and fed to the **speaker** where it is converted to sound. What might be called the standard receiver today is the superheterodyne which was developed by Armstrong in the early '20's. This circuit differs from others in that it converts all incoming radio-frequency signals to a common carrier frequency. This is accomplished in the first detector, mixer or converter as it is variously called. The signal from the antenna is fed by a tuned coupled circuit to the mixer tube (or in more elaborate sets a tuned radio-frequency stage may be inserted between the antenna and the mixer). In the mixer stage the incoming signal is heterodyned with a locally generated signal so a beat frequency signal, called the intermediate frequency, is produced. This new frequency signal is radio frequency, ranging from around 450 kc. to several megacycles depending upon the purpose for which the receiver is designed. The intermediate frequency has exactly the same modulation as the original signal. In many broadcast receivers the mixer tube combines the functions of mixer and oscillator by using a multiplicity of grids (the **pentagrid converter** is an example of such a tube). However, at higher frequencies it is desirable or even necessary to use a separate tube for **oscillator** and feed its output into the mixer. Regardless of how the oscillator operates, its frequency is always adjusted by the main tuning control of the receiver so the beat frequency output of the mixer is a fixed value. This intermediate frequency signal is then amplified by fixed-tuned radio-frequency amplifiers and then fed to the detector (commonly called the second detector) where it is demodulated. The audio is then further amplified and coupled to the speaker. The simplified-circuit diagram will serve to indicate the various circuits and their relative positions. In some of the cheaper superheterodynes the antenna signal is coupled to the pentagrid first detector, then the intermediate frequency output of this coupled without further amplification to a grid bias or regenerative detector and hence to the final power tube. Various refinements are often added to the higher quality sets. Among these are **automatic volume control, automatic frequency control, noise suppression, tone control,** fidelity and selectivity controls, etc. The superheterodyne gives much greater selectivity by its system of frequency changing and also permits the use of circuits having a more uniform response to the **sidebands**.

The development of television has led to extensions of the principles involved in the usual radio receiver but has not required any radically different ones. The main difference between the sound receiver and the picture receiver is in the width of the bands which must be handled, television requiring a band several megacycles wide while sound requires only a few kilocycles. This means that the radio frequency channels must be capable of selecting between stations yet also pass very wide sidebands. In addition the amplification circuits after the detector (corresponding to the audio amplifiers of the sound set) must satisfactorily amplify over a range of a few million cycles. **Frequency modulation**, on the other hand, has necessitated the use of a some-



Simplified-circuit diagram of superheterodyne receiver.

what different type of detector. The incoming frequency modulated signal is amplified, converted to the intermediate frequency and this further amplified as in the usual set. However, since the modulation is present as a frequency variation and the loud-speaker responds to an amplitude variation it is necessary to change from one to the other upon detection. This is accomplished in a **discriminator** (a frequency sensitive detector) and then the resulting audio signals, which are amplitude variations, are amplified in a standard audio **amplifier.** However, the radio and intermediate frequency channels of the FM set must be fairly wide band (about 200 kc.) and the audio must be good to about 15,000 cycles to realize the full benefits of this type modulation.

Besides these basic circuit distinctions radios are often classified according to the type **power supply** used. Thus battery receivers for rural and portable use, a-c sets for operating from the 110-volt a-c house-supply circuit, a-c–d-c sets for use with either 110 (nominal) volts a.c. or d.c., etc., are among the various types available.

For special problems involved in the reception of unmodulated signals see **radio telegraphy.**

The common telephone receiver operates by an electromagnetic action. An iron diaphragm is placed in the magnetic field of a permanent steel magnet of U-shape, having soft iron extensions on the pole pieces. When the receiver is not in use, the iron diaphragm is at rest under a constant pull from the permanent **magnet.** On the soft iron extensions are wound coils carrying the receiver current, and which, by electromagnetic action, modulate the constant magnetic **flux** provided by the permanent magnet. The resultant variable magnetic flux vibrates the diaphragm in accordance with the variation of receiver current until it produces sound waves which duplicate those used to vary the current at the **transmitter.** (L.R.Q.)

RECEPTACULUM SEMINIS. A reservoir associated with the genital ducts of the female. The seminal fluid received from the male during coitus is stored in this organ. The term spermatheca is also applied to such reservoirs.

In some of the **insects** a pouch of independent origin receives the seminal fluid. In some species it is connected with the vagina and in others its external opening is independent, but in both forms it is called the bursa copulatrix. It may be associated with a true spermatheca or may itself be the storage reservoir. (A.W.L.)

RECESSIONAL MORAINE. **Terminal Moraine.**

RECIPROCAL OF NUMBER. **Division.**

RECIPROCAL SYSTEMS OF VECTORS. From the **quadruple vector product** formula, we obtain:

$$\mathbf{r}[\mathbf{abc}] = [\mathbf{rbc}]\mathbf{a} + [\mathbf{rca}]\mathbf{b} + [\mathbf{rab}]\mathbf{c},$$

where $[\mathbf{abc}] = (\mathbf{a} \times \mathbf{b}) \cdot \mathbf{c}$, or

$$\mathbf{r} = \mathbf{r} \cdot \frac{\mathbf{b} \times \mathbf{c}}{[\mathbf{abc}]} + \mathbf{r} \cdot \frac{\mathbf{c} \times \mathbf{a}}{[\mathbf{abc}]} + \mathbf{r} \cdot \frac{\mathbf{a} \times \mathbf{b}}{[\mathbf{abc}]}.$$

The three **vectors**

$$\frac{\mathbf{b} \times \mathbf{c}}{[\mathbf{abc}]}, \quad \frac{\mathbf{c} \times \mathbf{a}}{[\mathbf{abc}]}, \quad \frac{\mathbf{a} \times \mathbf{b}}{[\mathbf{abc}]},$$

which are perpendicular, respectively, to the planes of **b** and **c**, **c** and **a**, **a** and **b**, are said to form the system reciprocal to the vectors **a**, **b**, **c**.

It is found that if we denote this system of reciprocal vectors by $\mathbf{a}'$, $\mathbf{b}'$, $\mathbf{c}'$, then

$$\mathbf{a} = \frac{\mathbf{b}' \times \mathbf{c}'}{[\mathbf{a}'\mathbf{b}'\mathbf{c}']}, \quad \mathbf{b} = \frac{\mathbf{c}' \times \mathbf{a}'}{[\mathbf{a}'\mathbf{b}'\mathbf{c}']}, \quad \mathbf{c} = \frac{\mathbf{a}' \times \mathbf{b}'}{[\mathbf{a}'\mathbf{b}'\mathbf{c}']}.$$

We also find that

$$[\mathbf{abc}] \cdot [\mathbf{a}'\mathbf{b}'\mathbf{c}'] = 1.$$

The system $\hat{\mathbf{i}}$, $\hat{\mathbf{j}}$, $\hat{\mathbf{k}}$ of unit vectors is reciprocal to itself. (L.L.S.)

RECONNAISSANCE. **Surveying.**

RECRYSTALLIZATION. Metals and alloys consist of an aggregate of individual grains or crystals. (See **Metallography.**) When subjected to mechanical deformation as in forging, rolling, or wire-drawing the grains are distorted, usually elongated, and if severely worked as by a 50% reduction in thickness by cold rolling, the grains will be fragmentated. These crystal fragments will, in general, have different **orientations** from the parent crystal but tend to seek certain preferred orientations dependent on the material and the mode of deformation. Plastic deformation of this type tends to harden and strengthen rather than weaken ductile metals. (See **Slip, Plasticity, Cold Working.**) If the final product must meet a maximum hardness or minimum ductility requirement, or if further cold processing is to follow, it may be necessary to recrystallize by means of a process anneal.

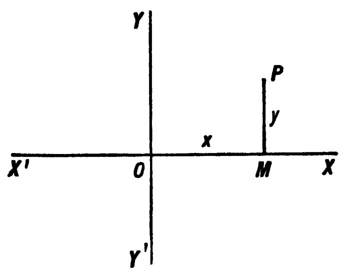
Recrystallization is the growth of certain of the grain fragments at the expense of others, resulting in larger, strain-free grains. The recrystallization process is possible because of the increased atomic activity at the elevated annealing temperature.

In the case of severely cold-worked metals recrystallization occurs over a relatively small range of tem-

peratures and at quite low temperatures; for example, about 500° F. for aluminum and copper, and 1000° F. for iron. At these temperatures marked reduction in hardness and strength and a corresponding increase in ductility occurs, however the crystal size as observed in a metallurgical microscope remains quite small. Higher annealing temperatures result in further growth in crystal size and some additional softening. The lowest temperature at which recrystallization can be observed in heavily cold-worked pure metals is even lower than the temperatures given; e.g., 300° F. for pure aluminum. Impurities or intentionally added alloying elements raise the minimum and the practical recrystallization temperatures.

Some metals, notably lead and tin, recrystallize below room temperature, therefore it is impossible to produce any permanent hardening by cold working because of spontaneous recrystallization. Hot forging operations on steel and many of the non-ferrous alloys are carried out well above the recrystallization temperature, therefore spontaneous recrystallization is effective in maintaining the softness and workability of the metal. (R.H.H.)

RECTANGULAR COORDINATES IN A PLANE. In most mathematical investigations involving geometrical figures, it is necessary to fix the positions of points by means of some system of coordinates, which consists of a set of numbers referred to a framework of reference. For a point in a plane, the simplest way to fix its position is by means of a pair of numbers called its rectangular coordinates.



Rectangular coordinates.

Let $X'X$ and $Y'Y$ be two straight lines perpendicular to each other. These lines are to be used as a framework of reference, and are called rectangular coordinate axes, and their intersection O is called the origin; $X'X$ is called the X-axis and $Y'Y$ the Y-axis. The X-axis is usually drawn horizontally.

Let P be any point in the plane; draw line PM perpendicular to the X-axis. Let the distance OM be regarded as positive when M is to the right of the origin and negative when M is to the left of the origin; let the distance MP be regarded as positive when P is above the X-axis and negative when P is below the X-axis. These distances with the associated algebraic signs are called directed distances.

The rectangular coordinates of the point P are the directed distances OM and MP. The directed distance OM is called the abscissa of P and is usually denoted by x, and the directed distance MP is called the ordinate of P and is usually denoted by y. Together the abscissa x and the ordinate y are the rectangular coordinates of point P. A point whose rectangular coordinates are x and y is commonly denoted by the symbol (x, y).

Every point in a plane has a single pair of rectangular coordinates, and conversely, every pair of rectangular coordinates determines a single point.

Rectangular coordinate paper (or squared paper) is paper ruled into small squares, and is very useful for plotting points given by rectangular coordinates in the plane.

The distance between the points whose rectangular coordinates are (x_1, y_1) and (x_2, y_2) is given by the formula

$$d = \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2}.$$

A point of division P which divides the line-segment P_1P_2 joining the points whose rectangular coordinates are $P_1(x_1, y_1)$ and $P_2(x_2, y_2)$ so that $P_1P/P_1P_2 = r$ has rectangular coordinates given by the formulae

$$x = x_1 + r(x_2 - x_1), \quad y = y_1 + r(y_2 - y_1).$$

In particular, the mid-point is given by

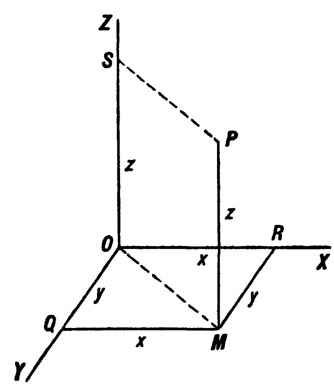
$$x = \tfrac{1}{2}(x_1 + x_2), \quad y = \tfrac{1}{2}(y_1 + y_2).$$

(L.L.S.)

RECTANGULAR COORDINATES IN SPACE. The simplest method for determining the position of a point in space is by means of a set of three numbers called the rectangular coordinates.

Let three mutually perpendicular **planes** be chosen, intersecting in lines $X'X$, $Y'Y$ and $Z'Z$; these lines are also mutually perpendicular. These planes are called rectangular coordinate planes, and are labeled the XY, YZ and ZX planes; the intersection lines $X'X$, $Y'Y$ and $Z'Z$ are called coordinate axes and are labeled the X-axis, Y-axis and Z-axis respectively. The point of intersection of the planes and of the axes is called the origin.

Let us suppose the XY-plane to be horizontal, with the X-axis in the plane of the paper, the ZX-plane to coincide with the plane of the paper and in vertical position, and the YZ-plane therefore perpendicular to the plane of the paper and in vertical position. This is sometimes called a left-handed system. Frequently the X- and Y-axes are interchanged from the preceding position, and we then have a right-handed system.



Rectangular coordinates in space.

In the above left-handed system, let P be any point and draw PM perpendicular to the XY-plane, then MR perpendicular to the X-axis and MQ perpendicular to the Y-axis. Let the directed distance MP be regarded as positive when P is above the XY-plane and negative when below; let the directed distance QM (or OR) be considered positive when P is to the right of the YZ-plane and negative when to the left; let the directed distance RM (or OQ) be considered positive when P is in front of the ZX-plane and negative when behind.

The rectangular coordinates of the point P are the directed distances QM (or OR), RM (or OQ) and MP (or OS), and are usually denoted by x, y, z respectively. These rectangular coordinates of a point are therefore the directed perpendicular distances of the point from the coordinate planes.

The distance between the points whose rectangular coordinates are (x_1, y_1, z_1) and (x_2, y_2, z_2) is given by

$$d = \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2 + (z_1 - z_2)^2}.$$

A point of division P of a segment joining the points in space whose rectangular coordinates are $P_1(x_1, y_1, z_1)$ and $P_2(x_2, y_2, z_2)$ so that $P_1P/P_1P_2 = r$ has coordinates given by

$$x = x_1 + r(x_2 - x_1), \quad y = y_1 + r(y_2 - y_1), \quad z = z_1 + r(z_2 - z_1).$$

In particular, the mid-point is given by

$$x = \tfrac{1}{2}(x_1 + x_2), \quad y = \tfrac{1}{2}(y_1 + y_2), \quad z = \tfrac{1}{2}(z_1 + z_2).$$

(L.L.S.)

RECTANGULAR HYPERBOLA. Hyperbola.

RECTIFIER. The numerous advantages of a.c. for power transmission and utilization (see **Electric Power Transmission**) have led to its almost universal adoption. There are, however, many applications where d.c. must be used or where it is preferable. Of course, this needed d.c. could be obtained by using a motor-generator set to convert the a-c power into mechanical power and then back into electrical power in the form of d.c. This method is used in many applications, but for many others it is a cumbersome and unnecessary method. The rectifier, in one form or another, is the most used method of converting the a-c supply to d.c. for utilization. Rectifiers may be obtained in several forms but they all depend upon the same effect for their operation, the ability to pass current in one direction and not the other (or much more pronounced in one direction than the other). The thermionic rectifier has a hot **cathode** which emits **electrons** which in turn are attracted to the **anode** when the anode-cathode potential is positive (i.e., the anode is positive) and are repelled by the anode when the potential reverses. Thus the current can flow only when the anode is positive so the applied a.c. is converted to d.c. For low currents and for certain radio applications where gas-filled tubes are objectionable the envelope is evacuated. However, for most industrial applications and for many communications applications the tube is filled with a gas (mercury vapor, neon, argon, xenon, etc.) at low pressure. Such tubes, called **phanotrons,** have much higher efficiencies than vacuum tubes but cannot withstand as high voltages without back-firing, i.e., conducting in the reverse direction. They are not inherently self-limiting in the current they will pass and hence may be seriously damaged or destroyed by excess currents. The **mercury-arc** rectifier is very widely used for large power demands and is rapidly replacing other types of conversion equipment for heavy industrial loads. The copper oxide and selenium disk type rectifiers find many fields of use where the currents required and the voltages applied are not too large. These units depend upon the unidirectional impedance properties of the barrier surface between two dissimilar materials. They are widely used for battery chargers, bias sources for tubes, rectifier type **instruments,** etc., since they have no stand-by losses such as the cathode heating power of the thermionic types, nor any starting requirements like the mercury-arc type. In rating rectifiers various quantities are of importance. Since the applied voltage is alternating, the rectifiers must be rated in terms of the forward peak voltage, i.e., anode positive, and negative peak voltage which they can safely withstand. Current ratings include the peak current (necessary since the current flows in pulses), average current (the d-c value) and sometimes another short-time peak current rating. The various types of rectifiers cover a range of sizes from smaller than a grain of corn to huge tanks as large as a fair-sized room. **Thyratrons** are often called grid-controlled rectifiers. (L.R.Q.)

RECTIGRADATION. Aristogenesis.

RECTILINEAR CHART. A method of representing change by means of a curve drawn on chart paper having rectilinear, or right-angled uniformly spaced coordinates. In general, the independent variable is plotted along a horizontal, and the dependent variable along a vertical axis. (H.C.H.)

RECTUM. A terminal portion of the alimentary tract (**digestive system, intestine**) in which the feces accumulate, pending their periodical discharge. It may be a part of the true gut, lined with endodermal tissue, or a part of the **proctodaeum,** lined with ectoderm. (A.W.L.)

RED BELLY. Pisces, Teleostei. A **sunfish** of olive color with red belly and lower fins. It is found from Maine to Louisiana. (A.W.L.)

RED CLAY. The most common of deep-sea sediments. A ferruginous clay formed from the alteration products of volcanic ash and other **aeolian** sediments, including **meteoric** material. **Manganese** concretions develop in these muds which are deposited exceedingly slowly and contain little or no organic or **calcareous** matter, due to the solvent power of the sea water under great pressure. (R.M.F.)

RED HARDNESS. Most metals, including tool steels, lose much of their hardness at red heat—about 1000° F. and above. Tool materials such as **high-speed tool steel, Stellite, cemented carbides,** and **diamond,** which retain a considerable part of their hardness at these temperatures are said to have high red hardness or hot hardness. (R.H.H.)

RED LEAD. Lead, Oxides.

RED MUD. A reddish-brown deep-sea mud composed of **aeolian** terrigenous dust or **loess** which is deposited off the seaward end of a large delta or off desert coast lines. (R.M.F.)

RED SHIFT. Spirals; Doppler Effects.

REDFIN. Pisces, Teleostei. The common shiner or **dace,** *Luxilus cornutus,* and another species of the same group which becomes red below during the breeding season. Both are small fishes which are abundant in small streams. (A.W.L.)

REDFISH. Pisces, Teleostei. 1. The Tahoe **trout,** *Trutta henshawi,* found in streams and lakes on the eastern slope of the Sierras. 2. The channel **bass,** *Sciaenops ocellata,* an important marine food fish taken along the Atlantic and Gulf coasts of the United States. 3. A species of **salmon,** *Oncorhynchus nerka,* second only to the king salmon in the fisheries of the Pacific Coast. Also called the blueback. Its flesh is deep red. (A.W.L.)

REDHORSE. Pisces, Teleostei. Fresh-water fishes (**Pisces**) of the genus *Moxostoma* found in rivers and lakes of the eastern half of the United States. The common redhorse is a good food fish, also called the white sucker or mullet. (A.W.L.)

REDPOLL. Aves, Passeriformes. A small bird (**Aves**) related to the finches. Named for its red crown. One species nests in the northern parts of the northern hemisphere and is known in Europe as the mealy redpoll. Europe has another species, the lesser redpoll, and Asia and North America have the related hoary redpoll, *Acanthis hornemanni,* which only occasionally enters the northern United States. (A.W.L.)

REDSHANK. Aves, Charadriiformes. A Eurasian bird (**Aves**), *Tringa totanus,* related to the snipes and sand-

pipers, named from the red color of the bare part of the legs. The name is also applied to a larger related species of Europe, *T. erythropus.* (A.W.L.)

REDSTART. Aves, Passeriformes. 1. Birds (**Aves**) of Europe, northern Africa, and palaearctic Asia. The common redstart, *Phoenicurus phoenicurus,* also called the firetail, has the tail and rump chestnut above. This and the allied species are related to the thrushes. 2. The American. *Setophagea ruticella,* and painted, *S. picta,* redstarts of North America are **warblers.** Both are variable in color according to age and sex, adult males showing black and white with red or orange markings. The painted redstart extends into Mexico. (A.W.L.)

REDTAIL. Aves, Falconiformes. The red-tailed **hawk,** *Buteo borealis.* (A.W.L.)

REDUCED VARIABLES OF STATE. **Critical State.**

REDUCING MOTION. A reducing motion is one in which a given displacement of rectilinear, rotary, or curvilinear character is converted by the apparatus to a similar motion in which the displacements are at all times proportional to the original motion, but on a smaller scale. The multiplying lever, the large and small pulley, and the inclined plane are a few examples of the many common elements of mechanisms which may be adapted to reducing motions. These are not necessarily exact reducing motions, for frequently very close approximations serve just as well as exactly similar motion. The pantograph, which is described in the article on **parallel mechanisms,** is typical of another group of reducing motions, in which the apparatus is of a more specialized character, and not merely some adaptation of a general element of mechanism. (F.T.M.)

REDUCTION. **Reactions Involving Oxidation-Reduction.**

REDUCTION OF AREA. **Tension Test.**

REDUCTION OF PRESSURE TO SEA LEVEL. In order to properly analyze the pressure distribution of the atmosphere it is necessary to refer all atmospheric pressure measurements to some level, and this level is accepted as sea level. All pressure measurements taken above sea level must be reduced to a comparative sea-level value by adding the weight of a fictitious column of air extending from the level of the observatory down to sea level. If the fictitious column of air is not great, no significant error arises in applying the correction, but if the observatory is at several thousands of feet above sea level a considerable error often enters the correction. In general, if the air is very cold, the corrected pressure is too high and if the air is very warm, it is too low. (P.E.K.)

REDUNDANCY. In a structure of the type of a **truss,** redundancy refers to the condition in which there are more members than would be needed to produce stability if the joints act as hinges. Redundant members may be used for the purpose of producing a more rigid structure than that which would be obtained with just enough members to satisfy the conditions for static equilibrium. A flag pole held in a vertical position by 4 guy wires which are spaced equidistant around the pole is not a redundant system, since the wires are incapable of carrying **compression** and only 2 wires act at one time. If the guy wires were replaced by stiff members capable of carrying either **tension** or compression the system would be redundant, as but two are necessary. A truly redundant structure is incapable of analysis by statical mechanics because the distribution of load between the redundant members and the other members depends upon the elastic properties of the members. The distribution of stress between the stiff members in the above example would depend upon their size and elastic properties. The analysis of such structures can be made by the method of **least work** or other recognized methods for the solution of **indeterminate structures.**

The degree of redundancy or indeterminacy (see **Indeterminate Structure**) of a structure is a number which represents the difference between the number of unknown conditions which must be satisfied and the number of equations of static equilibrium which are applicable. (C.W.C., F.T.M.)

REDUNDANT MEMBER. **Indeterminate Structure; Redundancy.**

REDWING. Aves, Passeriformes. 1. A European **thrush,** *Turdus musicus,* named from the red markings of the sides and under surface of the wings. 2. The American red-winged **blackbird,** *Agelaius phoeniceus.* The species is black with a conspicuous red patch on the shoulder, margined with whitish or yellowish. (A.W.L.)

REDWOODS. **Conifers.**

REEDBUCK. Mammalia, Artiodactyla. *Redunca.* A small African **antelope.** The male has relatively small horns which turn forward. Also known by the Dutch equivalent, reitbok. (A.W.L.)

REEVE. **Ruff.**

REFLECTION. When an emission, such as radiation or sound, traveling in one medium encounters a different medium, part of it in general passes on and undergoes **refraction,** while part is reflected. Even water waves exhibit reflection upon meeting an obstacle, and some of the characteristics of the process are conveniently observed by watching surface ripples. In all cases of "regular" reflection, in which the direction of propagation is sharply defined after reflection, the change takes place in accordance with a very simple law, viz., the reflected and incident wave trains travel in directions making equal angles with the normal to the reflecting surface and lie in the same plane with it. These angles are called, respectively, the angle of reflection and the angle of incidence. For normal incidence, both of these angles are zero. Rough surfaces reflect in a multitude of directions, and such reflection is said to be "diffuse." Only part of the emission or of the energy associated with it is reflected; the ratio of that part to the whole incident emission is called the "reflectivity" of the surface.

Various phenomena may accompany reflection under appropriate circumstances. Sometimes there is a change or even a reversal of phase (see **Vibrations and Waves**); the reflected wave train may be polarized (see **Polarized Light**); or the incident and reflected waves may, through their **interference,** produce stationary waves. If the incident waves are of complex character, the reflection may be selective, due to the difference in reflectivity for the different components. (See **Mirrors and Lenses,** and **Total Reflection.**) (L.D.W.)

REFLECTIVITY. **Reflection; Thermal Radiation.**

REFLEX. An involuntary secretory or motor response to an external stimulus (see **Nervous System**). Reflex action depends on the passage of impulses from a receptor organ (the skin, muscles, or organs of special sense) to the central nervous system, and then out again to an effector organ (muscle or gland). The route

traveled by the impulse is the reflex arc. The contraction of the pupil of the eye in response to light, and the jerking away of the hand when a painful stimulus is applied, are examples of motor reflexes. They are often protective and purposeful. The secretion of saliva and gastric juice when appetizing food is seen or smelled is a secretory reflex.

Conditioned reflexes were first described by Pavlov. He conducted experiments with dogs in which the animals were trained to respond with certain actions to a stimulus not basically related to the action. Thus, if a dog were repeatedly subjected to a certain noise and then fed immediately, he came to associate the noise with food. Eventually he responded to the noise with salivation and gastric secretion, even though the food was not given. This is a conditioned reflex, and illustrates the rôle of higher cortical centers in reflex action. Playing the piano and operating a typewriter are examples of conditioned reflexes. During the learning period, these are voluntary actions, but eventually, the complex motions are carried out instantly, as the eye sees the letter or note, without voluntary thought.

In the physical examination of the nervous system, abnormalities in certain simple reflex movements are valuable aids in testing the integrity of nerve pathways. Normally, tapping the **tendon** just below the flexed knee causes the leg and foot to extend rapidly and come back immediately to the starting position. This reflex movement is called a knee jerk. Overactive, underactive, or unequal knee jerks on the two sides may indicate an abnormal situation somewhere along the reflex arc. Other simple reflexes routinely tested are ankle jerks, biceps and triceps tendon reflexes in the arms. Abnormalities in these and other reflexes occur in such conditions as multiple **neuritis**, **central nervous system syphilis**, brain and cord **tumors**, **poliomyelitis**, etc. (D.M.H.)

REFLUX. **Distillation.**

REFLUX RATIO. **Distillation.**

REFRACTION. The term refraction properly applies to the change of direction which light or other wave emission experiences on passing obliquely from one medium to another in which its velocity of propagation is different The physical nature of the effect can be visualized by considering a regiment marching in column of platoons across a boundary between smooth turf and freshly plowed ground. If the line of march is perpendicular to the boundary, the platoons are simply slowed up and thus crowded more closely together; but if it is oblique, one end of each platoon is retarded sooner than the other, and the file swings around to a direction nearer the normal (Fig. 1). A train of waves is similarly affected as it passes into a new medium with change of velocity.

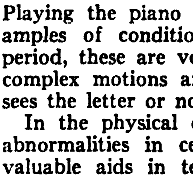


Fig 1. Change of wave length and (in general) of direction of wave train upon entering new medium.

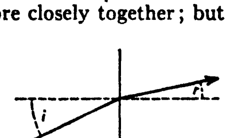

Fig. 2. Angles of incidence (i) and refraction (r).

It is easy to show that if i is the angle of incidence and r the angle of refraction at such a boundary (Fig. 2), the refraction is governed by a simple relation known as Snell's law:

$$\sin i = n \sin r;$$

in which n has the same value for various angles of incidence and refraction. This constant n, known as the **refractive index**, depends upon the character of the wave train and of the two media. Physically it represents the ratio of the velocity of the disturbance in the first medium to that in the second. For light passing from one medium to another in which its velocity is greater, so that $n < 1$, we may, for a sufficiently large angle of incidence, encounter the curious phenomenon known as **total reflection.** (L.D.W.)

REFRACTIVE INDEX. When light passes from one medium into another, it in general changes velocity. The ratio of the velocity in the first medium to that in the second is the "relative index of refraction" for the two media. It is the constant of proportionality which appears in Snell's law of **refraction.** If light enters a medium from a vacuum, the ratio is called the "absolute index" for that medium. Let the absolute indices for two media A and B be respectively n_A and n_B. Then it is easy to show that the relative index for light passing from A to B is $n_{AB} = n_B/n_A$. If, for example the absolute indices of water and of glass are respectively 4/3 and 3/2, then the relative index from water to glass is $3/2 \div 4/3 = 9/8$; while from glass to water it is 8/9.

The absolute index for all ordinary transparent substances is greater than 1; but there are some metals (e.g., silver) for which it is less than 1. Since the absolute index for air exceeds unity by less than 0.0003, the relative indices for solids and liquids in air are very nearly equal to their absolute indices. It should be noted that since the refractive index varies with the wavelength (see **Dispersion**), any exact statement of its value must specify the wavelength to which it refers; in tables it is usually given for sodium light (5893 angstroms).

Measurements of refractive index may be made by using a **prism** of the substance at minimum deviation; by the **interferometer**; or by observing the "critical angle" of **total reflection,** as with a **refractometer.** Some typical values are given below (for 5893 angstroms).

Substance	Absolute Index	Substance	Absolute Index
Air	1.00029	Glycerine......	1 47
Bromine....	1 66	Helium...... .	1 00007
Carbon dioxide..	1 00097	Ice.....	1 3
Diamond......	2.419	Rock salt......	1.54
Glass..... ..	1.5 to 1 7	Water..........	1 33

(L.D.W.)

REFRACTOMETERS. Several types of instruments, called refractometers, have been devised for measuring the **refractive index** of any substance. Special forms are used for solids, for liquids, and for gases. Solid and liquid refractometers usually depend upon the principle of **total reflection** and the fact that the sine of the critical angle is equal to the refractive index for light passing from the more to the less refractive medium. The critical angle is what is measured, or deduced from other measured angles.

Suppose that a specimen of the solid or liquid to be tested is brought into optical contact with one face of a glass prism (or "block") of known, higher refractive index and known angle, and that a slightly convergent pencil of light, entering the test substance, is directed at grazing incidence upon the interface between it and the prism. Those rays incident at less than 90° to the normal of the interface enter the prism; the others do not, and the boundary between is sharply defined. The resulting half-pencil traverses the prism and emerges from the other face where the direction of its cut-off edge can be observed (Fig. 1). The angle between the cut-off boundary of the pencil and the first prism face,

inside the prism, is the critical angle, and can be easily calculated from the observations and the known data. This is the principle of the Pulfrich refractometer.

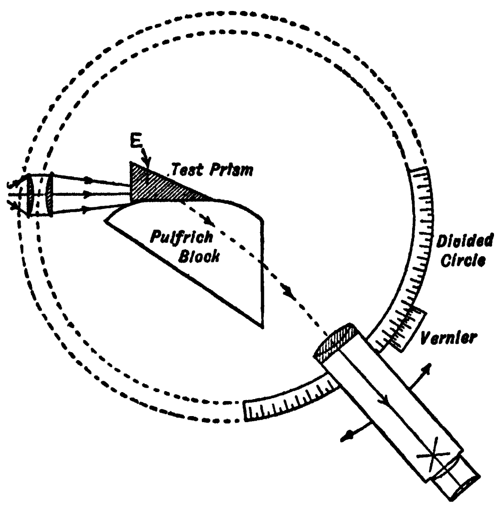

Fig. 1. Pulfrich refractometer (diagrammatic).

Another form, due to Abbe, is used for liquids. A film of the liquid is enclosed between two similar glass prisms (Fig. 2), and the total reflection at the inter-

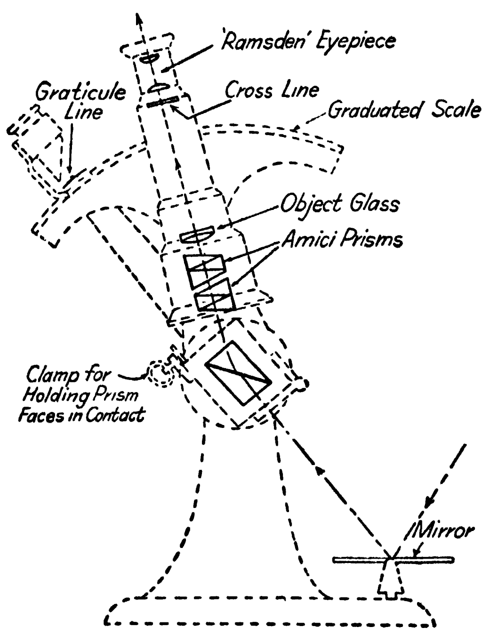

Fig. 2. Optical system of Abbe refractometer.

face observed. Any spectrometer, with a pair of good prisms (preferably right-angled) mounted on the prism table, can be used in this way.

Rayleigh utilized an **interference** method for measuring the indices of gases. Using a **collimator** to render the rays parallel, the stream of light entering one of the slits of the apparatus for **Young's experiment** is passed through a tube of the gas to be tested. The resulting retardation in phase causes a shift of the interference fringes, the amount of which gives the retardation and hence the refractive index of the gas relative to the air outside the tube. (L.D.W.)

REFRACTORIES. Materials which will resist change of shape, weight, or physical properties at high temperatures are known as refractories. The materials which are chiefly used for refractories are fire-clay, silica (see **Silicon**), kaolin, diaspore, alumina (see **Aluminum**), and certain products of the electric furnace, such as silicon carbide. Refractories are used most often in the form of bricks. Refractories are chiefly used to line regions in which **combustion** creates a very high temperature. Also, they are needed to line passages or chambers remote from the combustion region, but which contain high-temperature gases. When refractories are used to line a vessel in which a fluid such as molten steel or molten glass is to be contained, the chemical reaction of the refractory is important. Basic and acid refractory brick have their industrial uses. The greatest use of refractory is in **furnaces.** Certain materials (fire-clay, silica, ganister) are resistant to acid slag and are used to contain metallurgical products of acid reaction while others (magnesite, dolomite, alumina) are suitable for basic reaction. Chromite, silicon carbide, and carbon are neutral, but the use of carbon is confined to localities where the atmosphere is reducing. Fire-clay bricks are preferred wherever they give satisfactory service, because of their low cost. Fire-clay brick are classified for temperature duty on the basis of the pyrometric cone scale (see **Seger Cone**). High-temperature duty fire-brick is classed as that which possesses a pyrometric cone rating equivalent to a temperature about 3056° F., whereas low-duty fire-clay must have refractoriness at not less than 2876° F. Between these two limits, the American Society for Testing Materials recognizes two intermediate classifications.

In use, refractories must successfully withstand:

1. *Shrinkage.* A linear shrinkage test of not more than 1.5% when subjected to a temperature of 1400° C. (2550° F.) is recommended. Whenever the shrinkage in use amounts to, say, 3% it is necessary to shut down and repair the installation.

2. *Fusion.* The load test deformation at 1350° C. (2460° F.) should not be more than 1.5%. There is a wide range of refractory materials available through a range of temperatures resistant to fusion, but with their costs approximately in proportion to their temperature resistance. A representative list of these is displayed below. It should be remembered, however, that safe working temperatures are considerably lower than the melting temperatures shown.

3. *Spalling.* Whether due to heating, or to mechanical or structural defects, spalling is a serious matter, since the effective material is thereby lost. A preliminary test is recommended, such as using an air-water mist blast under specified conditions at 1600° C. (2910° F.) when not more than 15% should spall off.

4. *Slag Erosion.* When the face of a refractory material is wetted by a molten slag, and the two are chemically reactive with each other, the refractory is corroded and thereby lost. Acid refractories resist acid slabs best, and basic refractories resist basic slags best.

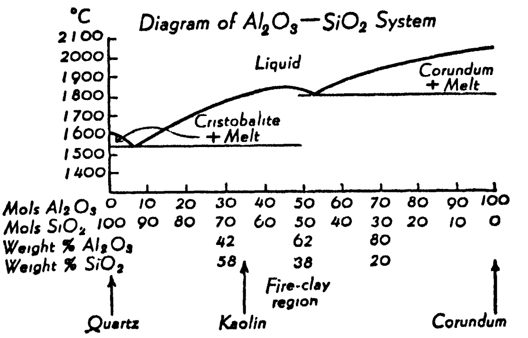
5. *Abrasion.* Resistance of refractories to the impact of and erosion by solid particles, such as the charge in a pig iron or cupola furnace or the solid ash carried in a furnace flame, is frequently an important matter of concern.

6. *Water Absorption;* 7. *Modulus of Rupture;* 8. *Heat Conductivity;* 9. *Electrical Conductivity* are other points that frequently require consideration in refractory installations.

Refractories play a vital rôle in steam-boiler settings, in pig iron smelters, in open-hearth steel furnaces, in the production of copper, lead, and zinc from their ores, in lime burning, glass, and Portland cement kilns, and in by-product coke ovens.

Refractory Material	Melting Temperature, °C.	Melting Temperature, °F.
Kaolin, $Al_2O_3 \cdot SiO_2$	1815	3300
Fire-clay (see diagram of Al_2O_3-SiO_2 system below)		
Alumina, fused bauxite	1870	3400
Alumina, Al_2O_3, pure sintered	2050	3720
Silicon carbide, 85–90%	1870	3400
Silicon carbide, SiC, pure	2250	4080
Silica, quartz, or quartzite	1425–1710	2600–3080
Magnesia, 90–95%	1970	3980
Magnesia, MgO, pure sintered	2800	5070
Chromite, $FeO \cdot Cr_2O_3$	2180	3960
Chrome, 38% Cr_2O_3	1970	3580
Chromium oxide, Cr_2O_3, pure	2140	3880
Beryllia, BeO, pure sintered	2550	4620
Zirconia, ZrO_2, pure sintered	2700	4890
Thoria, ThO_2, pure sintered	3000	5430
Graphite, C, pure (in reducing atmosphere) (softens at 2500° C. (4500° F.))	3500	6300

(F.T.M., R.K.S.)



REFRIGERANT. A refrigerant is a substance which is suitable as the working medium of a cycle of operations wherein refrigeration is accomplished. To be satisfactory for this service, the refrigerant should be capable of absorbing heat at a low temperature (i.e., the temperatures associated with ice-making, cold storage, and other forms of refrigeration) and release it at a higher temperature. This may be accomplished only by a suitable expenditure of energy, in accordance with the second law of **thermodynamics**, and through processes involving expansion, evaporation, or chemical change. (The last method is not used.) Refrigerants in actual use can be either gases or vapors.

The use of a gas is but little favored in refrigeration, due to the bulk of the equipment necessary in the cycle; however, refrigeration systems using air as a working medium are entirely successful. Most refrigeration equipment operates with a vaporizable liquid as a working medium. Those refrigerants which are or might be used are shown in table below.

The given data are compiled by W. R. Woolrich, who also states that the properties that the most suitable refrigerant should possess are:

1. It should be readily obtainable.
2. It should condense at normal cooling water temperatures at relatively low pressures.
3. Its boiling point should be sufficiently low not to require vacuum operation.
4. It should have a high latent heat of vaporization.
5. For the service desired the odor should not be objectionable.
6. It should not seriously interfere with lubrication.

(F.T.M.)

REFRIGERATION CYCLE. A refrigeration cycle is any that takes heat at a lower temperature and rejects it at a higher. To do this, the cycle must receive a power input from an external source, and the amount of heat rejected is more than that taken in by the amount of work required to effect the cycle. Theoretically, any power cycle which is reversible could be reversed to create a refrigeration cycle. Actually, practical considerations have caused modification of the reversed power cycle for refrigeration use. Nevertheless, the ordinary vapor compression refrigerating cycle resembles the **Rankine** power cycle to a close degree. In the power cycle, work is done by an **engine,** and in the refrigerating cycle work must be supplied to a reversed engine, which then becomes a pump to pump heat from a lower to a higher temperature. This heat pump is a **compressor.** Most refrigeration cycles make use of a vaporous **refrigerant,** and the following discussion will be confined to that type. In a power cycle the efficiency is the work done divided by the heat supplied. In the refrigeration cycle the efficiency expression is re-

REFRIGERANTS

Refrigerant	Chemical Formula	Boiling Point (atmospheric pressure)	Minimum Pressure Required (80° F. cooling water)	Melting Point	Latent Heat of Vaporization
Ammonia	NH_3	− 28° F.	140 lbs. gauge	−107° F.	589.4 B.T.U. per lb.
Carbon dioxide	CO_2	Not liquid at atmospheric pressure	960 lbs. gauge	−161° F.	158.6 B.T.U. per lb.
Sulfur dioxide	SO_2	+ 14° F.	45 lbs. gauge	−102° F.	172.3 B.T.U. per lb.
Ethyl chloride	C_2H_5Cl	+ 54° F.	10 lbs. gauge	−244.5° F.	168.6 B.T.U. per lb.
Methyl chloride	CH_3Cl	− 10.6° F.	73 lbs. gauge	−132.5° F.	180.6 B.T U. per lb.
Butane	C_4H_{10}	+ 32° F.	25 lbs. gauge	−211° F.	165.2 B.T.U. per lb.
Propane	C_3H_8	− 48° F.	130 lbs. gauge	−310° F.	182.6 B.T.U. per lb.
Ethane	C_2H_6	−127° F.	615 lbs. gauge	−277° F.	234 B.T.U. per lb.
Isobutane	C_4H_{10}	+13.6° F.	40 lbs. gauge	−229° F.	158 B.T.U. per lb.
Nitrous oxide	N_2O	−128° F.	880 lbs. gauge	−152° F.	163 B.T.U. per lb.
Ether	$(C_2H_5)_2O$	+ 94° F.	7 in. vac.	−177° F.	162 B.T U. per lb.
Carbon bisulfide	CS_2	+115° F.	15 in. vac.	−169° F.	153 B.T.U. per lb.
Chloroform	$CHCl_3$	+142° F.	21 in. vac.	− 82° F.	109 B.T.U. per lb.
Carbon tetrachloride	CCl_4	+170° F.	25 in. vac.	− 9° F.	83 B.T.U. per lb.
Dichlorodifluoromethane	CF_2Cl_2	+ 21° F.	85 lbs. gauge	−247° F.	72 B.T.U. per lb.

placed by "coefficient of performance," which is the reciprocal of efficiency. A coefficient of performance is the heat energy extracted at the low temperature divided by the work which must be supplied to operate the cycle. It measures the cycle performance in that it is an expression of the refrigeration obtained per unit of work supplied to the cycle.

$$\text{Coefficient of performance} = \frac{778Q}{W}$$

Q = heat in B.T.U. absorbed from the ice tank, cold storage room, etc., per pound refrigerant.
W = work in foot-pounds supplied to the compressor per pound refrigerant.

The unit of refrigeration corresponding to the absorption of heat equivalent to the production of 1 ton of ice per day of 24 hours is called a "ton." Normally, about 144 B.T.U. must be abstracted to convert a pound of water to ice. Using this value, together with the proper conversion factors, a ton of refrigeration is found to be equivalent to a heat abstraction of 200 B.T.U. per min. This rate of heat flow is 4.715 hp. As the coefficient of performance measures the ratio of heat abstraction to input, the horsepower which would theoretically be necessary per ton of refrigeration capacity is

$$\frac{4.715}{\text{coefficient of performance}}.$$

An elementary cycle of refrigeration can be operated with a minimum of four pieces of equipment. These are shown in an accompanying figure. Beginning the

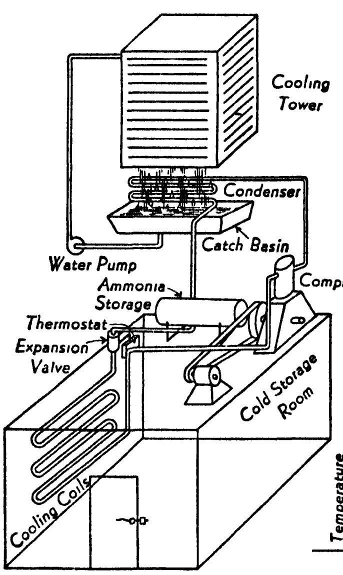


Diagram of refrigerating plant.

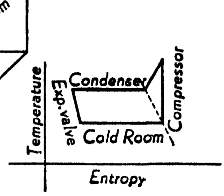


Refrigerating cycle.

description with the refrigerating coils, note the bank of pipes in a cold storage room. In these pipes is a liquid whose boiling temperature is lower than the temperature of the cold storage room, so heat is passed through the pipes into this liquid, which absorbs it as heat of vaporization, changing the liquid to a vapor. The vapor is withdrawn from the cooling coils by a motor-driven compressor which increases its pressure until, at the discharge pressure from the compressor, the refrigerant has a saturation temperature high enough so that it may be condensed by some available cooling source such as water. The compressed vapor is discharged into a condenser. This is usually a bank of tubes over which cool water trickles. The heat of vaporization is passed from the vapor to the water, condensing the former to a liquid. The warmed water is then either wasted, or cooled (by spray pond or cooling tower) and recirculated. The liquid refrigerant then is passed through an expansion valve to the lower pressure of the cooling coils. This is a throttling process. The condition of the refrigerant as it emerges from the expansion valve is liquid, a very small portion of which has been flashed into vapor. The delivery of the refrigerant from the cooling coils to the compressor takes place under the action of natural flow of a vapor in the direction of lowest pressure.

The vapor entering the compressor is dry, or nearly so, and an **adiabatic** compression raises it to a superheated state. This is shown on the cycle diagram. Known as dry compression, this entails considerably more work from the compressor than is needed merely to raise the vapor to the higher pressure. If the vapor could be brought back along the saturation line instead of the adiabatic line, a large amount of work would be saved, and the coefficient of performance increased. In practice this is sometimes done by:

1. Spraying a small amount of liquid ammonia into the compressor cylinder (wet compression system).
2. Jacketing the compressor cylinder with cold water.
3. Cooling the refrigerant in coolers located between the cylinders of a multi-stage compressor.

Control of a refrigerating system of this type is exercised thermostatically on the expansion valve, allowing it to discharge more or less liquid ammonia into the cooling coils. There are important differences between the system just described, which resembles that employed in central refrigeration or ice-making plants, and the small domestic refrigerator. Whereas ammonia is the refrigerant chiefly used in the central plant, domestic refrigerators operate on a variety of **refrigerants**, among which Freon (F12) is very popular. Air is used as the condensing medium in a domestic refrigerator, and variable load operation is secured, not by operating the compressor at constant speed and controlling the expansion valve, but by a fixed setting of expansion valve and on-off operation of the compressor. The larger the refrigerating load, the smaller the off intervals of time for the compressor motor. In one leading make, sulfur dioxide vapor is compressed in a small cylinder by a piston whose connecting rod is driven from a crankshaft attached directly to the motor shaft. The compressed vapor is delivered at around 100 lbs. per sq. in. pressure to a condenser which resembles an automobile radiator. Air is drawn by a fan through the openings in the condenser core, and Freon vapor is reduced to a liquid. The liquid flows to a float chamber where a constant level is maintained by a float valve. As more liquid flows into this chamber, the valve passes it into the freezing unit, where it absorbs heat from the refrigerator box and is vaporized. The pressure there is about 20 lbs. per sq. in. gauge. The vapor is drawn by the suction of the compressor into the compressor chamber, where it is ready to begin the cycle again. Despite the small sizes, the coefficient of performance of the domestic refrigerators is not markedly inferior to the large-scale central plant. (F.T.M.)

REGELATION. This curious phenomenon is a direct consequence of the fact that the melting point of ice is measurably lowered by intense pressure. Ice at the normal melting point will, if subjected to great pressure, become liquid, and will "regelate" or refreeze when the pressure is removed. Crushed ice or snow may thus be molded into clear blocks of any desired shape. A small, heavy object placed on a cake of ice not too far below the melting point will gradually bury itself in the ice, the water which results from the pressure escaping from under it and refreezing above it. In the same way a cake of ice resting on a metal grid will hook itself around the bars of the grid. Ice is slippery even when below the freezing point, because

the pressure of any hard object, as a skate blade, produces a film of water at the surface of contact. Water extruded under pressure from the terminal wall of ice at the foot of a **glacier** sometimes freezes into snakelike spirals of ice. Regelation is believed to explain the flowing motion of the glacier itself. Only substances which, like water, expand on freezing are capable of exhibiting regelation. (L.D.W.)

REGENERATION. Positive **feedback.**

In zoology, regeneration is the development of a **tissue** or part of the living body to replace a similar structure that has been damaged or destroyed.

A conspicuous degree of regeneration is possible in some of the simpler animals, including sponges, **coelenterates,** and **worms.** When cut into pieces, the fragments undergo a reorganization of their materials to form complete individuals of smaller size. The process is not unlimited, however, for abnormalities of regeneration take place in some groups when the mutilation is of a certain type. In experiments with flatworms (**Platyhelminthes**), for example, C. M. Child has found that halves of worms or a segment from the middle of the body develop into complete animals, but a head produces only another head and so perishes. T. H. Morgan, in experiments with a species of **earthworm,** found that the amputation of a limited part of the anterior end was followed by complete regeneration but that the removal of more segments resulted in the formation of a minimum number like the original extreme anterior end. Starfishes undergo the regeneration of amputated arms very readily and **mollusks** and **arthropods** are capable of some restoration of lost parts. Insects and crustaceans develop new appendages if the loss occurs before the completion of their growth.

Among the most remarkable cases of regeneration are those of the **bryozoans** and sea cucumbers. The animal (polypide) breaks down within the body wall (zooecium) in the former group to become a disorganized mass called the brown body. From the zooecium a new animal is formed. Sea cucumbers, under extremely irritating stimuli, sometimes discharge the entire intestine, along with the defensive Cuvierian organs. The tract is later replaced.

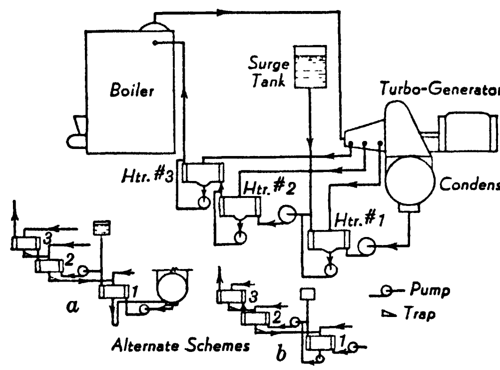
In complex animals, including man, regeneration is limited to the replacement of parts subject to wear and easy loss, such as hair and nails, and to the renewal of damaged tissues, such as skin. Even the renewal of tissues is limited, some kinds undergoing normal and complete regeneration while others are repaired by the formation of scar tissue of different origin but cannot be replaced.

Researches reported in 1944 indicate that special methods of treatment to prevent the rapid completion of normal healing processes may make it possible for animals of great complexity to regenerate amputated limbs. These studies are in too early a stage to permit an estimate of their ultimate practical importance. (See **Thermal Regeneration.**) (A.W.L.)

REGENERATION, THERMAL. Regeneration is the restoration of a property or quantity to some original state. Thermal regeneration is the restoration of thermal potential by additions of heat.

A furnace so arranged that heat from the flue gases is restored to the furnace by being imparted to incoming air is frequently termed a regenerative furnace. For an example of this, see **Open Hearth.**

Most of the large central power stations of the present time operate on a cycle known as the regenerative cycle, so called because of the method of regenerating the thermal potential of the working medium (feed water) in order to condition it for the boiler. Nearly fifty years ago Cotterill perceived that the extraction of some of the steam from an **engine** for the purpose of bringing the boiler **feed water** nearer to the saturation temperature of the **boiler,** would result in considerable **thermodynamic** gain over the simple **Rankine cycle.** This idea was first applied to reciprocating steam engine plants, but did not enjoy its present widespread use until the advent of the high capacity steam central station. The reason for the efficiency gain of the regenerative over the Rankine cycle lies in the fact that the steam, as extracted from the turbine, has performed a certain amount of work, but whereas the percentage of the available heat converted into work before extraction is considerable, the percentage decrease in the total heat of the steam is small, and hence, by extracting it before it reaches a low thermal potential, it has remaining in it a high degree of availability as a feed water heating medium. This factor becomes of more and more importance as boiler pressure increases. The elements of the regenerative vapor cycle, shown in the figure, consist



The regenerative vapor cycle.

of the boiler-turbine-condenser combination, and one or more heaters to which steam is extracted, and through which the water flows on its way back to the boiler. Plants using this cycle differ, of course, in the number of heaters employed, and in the manner of handling the heater condensate. The usual arrangement is to employ from two to four extraction heaters, which heat the water to about 80% of the saturation temperature. (F.T.M.)

REGENERATIVE MOTOR. Rockets.

REGIONAL METAMORPHISM. Metamorphism.

REGOLITH. Soil.

REGRESSION. The regression of y on x is given by a functional relation $y = f(x)$. If $f(x) = a_1x + b$, then the regression of y on x is linear. Otherwise it is curvilinear. This result may be extended to m variables $y = f(x_1, x_2, \cdots x_m)$, and if $f(x_1, x_2, \cdots x_m) = a_1x_1 + a_2x_2 + \cdots + a_mx_m$ we have multiple linear regression, otherwise the regression is said to be curvilinear. The constants $a_1, a_2, \cdots a_m$ are usually found by the method of least squares, solving for them by **Doolittle's method.** If the actual points cluster closely about the regression line, curve, plane, or surface, then the dependence of y on $x_1, x_2, \cdots x_m$ is close. The measure of the dependency of y on $x_1, x_2, \cdots x_m$ is given either by the **coefficient of correlation,** the **coefficient of multiple correlation,** the **index of correlation,** or the **index of multiple correlation,** or the index of multiple curvilinear correlation. Tests of significance may be made by the **analysis of variance.** (L.A.A.)

REGULATION, SPEED. Steam **engines,** steam **turbines, internal combustion engines** under automatic governing, also certain types of **electric motors,** vary slightly in speed between no load and full load

In the case of electric motors, this variation of speed is accounted for by the electrical characteristics. In the case of the prime movers, the variation in speed is due to the characteristics of the governors. The speed regulation is the speed variation between no load and full load expressed as a percentage of the full load. The basic actuation of governors is caused by a change of centrifugal force during change of speed. Usually the centrifugal force is opposed mechanically by springs. The modulus of the springs has a direct bearing upon the speed regulation created by the governor. (F.T.M.)

REGULATION, VOLTAGE. The voltage regulation of a circuit or device is:

$$100 \times \frac{(\text{No load voltage}) - (\text{full load voltage})}{(\text{full load voltage})}.$$

(L.R.Q.)

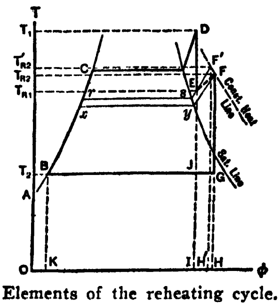
REGULATOR. Induction Regulator.

REGULATOR TUBE. One of the characteristics of the glow and arc types of **discharge** is their tendency to maintain a constant voltage across the tube. This property is used in the various voltage regulator tubes which are two **electrode** glow discharge tubes operated in the current range where this constant voltage characteristic is very pronounced. When such a tube is connected in series with a **resistance** across a source of d.c. it will maintain a constant voltage across its terminals for wide variations in the source voltage. While the current which can be supplied by such a circuit is rather limited it is sufficient for numerous electronic circuits. (L.R.Q.)

REGULUS. Regulus (α **Leonis**) has been a famous star in all ages. According to the best authority the present name was given to the star by Copernicus. Among the ancients a great variety of different names were used. Regulus has always been regarded as a royal star and among the Persians was considered one of the four rulers of the heavens. As one of the royal stars, Regulus was considered by the **astrologers** as portending the greatest good fortune. (W.K.G.)

REHEATING. A material, having once been heated, may be found to have undergone important changes; and it may be still further modified when subjected to reheating. In some cases the reheating may have been carried out until the original state was restored, in others to some different temperature. Many industrial processes in which heat plays a part, employ reheating, sometimes to the extent of several "reheats." In annealing, steel is subjected to several reheating processes, which are controlled as to temperature reached, length of time, and cooling, so that treated steels of desired characteristics are produced. When air is compressed to be used in air power tools, it usually cools off between the time it is compressed and the time it is used. Often it is found economical to reheat this air with fuel in order to increase its volume. This is especially true in cases where the air is used expansively in the appliance.

A very interesting application of reheating is to be found in the dozen or so extremely high-pressure (1200 lbs. per sq. in. and up) steam plants operating in this country. An adiabatic heat drop, such as is approximated in steam nozzles, engines, and turbines, implies that the mechanical energy which appears has been produced at the expense of the heat in the steam. The physical properties of steam are such that superheated steam will lose its superheat and become more and more wet as the expansion proceeds to lower pressures. It is found by experience that moisture in expanding steam is undesirable. The inevitable effect of higher pressures is that the saturation line is reached more quickly in an adiabatic expansion and more of the turbine stages operate in the relatively undesirable saturated steam region. In order to relegate the point of saturation to a lower thermal level where high stage efficiency will not be so vital, the steam is resuperheated before it becomes wet. In the resuperheating, or, as



Elements of the reheating cycle.

it is commonly termed, the reheating vapor cycle, the reheating is accomplished by constructing the turbine so that all of the steam may be extracted at a suitable point, resuperheated, then readmitted to the remaining stages for further expansion. This is possible on both single-cylinder and compound turbines but is much simpler on the compound type where the break between high-pressure and low-pressure sections offers a logical point for resuperheating. An additional advantage of reheating is that the reduction in exhaust steam volume per unit of power capacity developed permits some reduction in condenser size.

There are objections to reheating, the principal ones being the added complication of the plant layout and the increased investment cost. Reheat lines are of such size and are so located that concealment is virtually impossible and, furthermore, the whole of the reheat piping is difficult to construct and install. Another objection arises from the energy storage in the steam contained in the reheater and the reheat piping. Close governing will require governor devices on the low- as well as the high-pressure units to overcome the lag in response to normal governor movement. (F.T.M.)

REINDEER. Mammalia, Artiodactyla. A deer of arctic Eurasia. It has antlers in both sexes, set well back on the head and palmately branched at the tips. They are important domestic animals in Lapland and in other parts of the Old World, and have been introduced successfully into Alaska. The two North American species of caribou and several other species of deer are closely related to the true reindeer. (A.W.L.)

REINDEER MOSS. Lichens.

REINFORCED CONCRETE. Briefly described, reinforced concrete is plain concrete in which steel rods or bars are incorporated in such a manner as to reinforce or strengthen the more or less naturally brittle plain concrete. The use of reinforced concrete is of quite recent date, usually being considered as covering about the last 75 years. Its discovery is commonly ascribed to a Parisian gardener named Monier in about the year 1860. Unquestionably the major development of reinforced concrete has taken place since the year 1900 and the United States leads the world in the use of this structural material.

Plain concrete will carry relatively heavy compressive stresses, but any attempt to impose tensile stresses of appreciable magnitude will result in rupture and consequent failure. For this reason plain concrete cannot be used for structural members subjected to a bending action or to a direct tensile action. However, if steel bars are incorporated in such a manner as to carry such tensile action as may develop in the member, then a safe and satisfactory "reinforced concrete" member may be used where otherwise a plain concrete

member of the same size, or even larger size, would be wholly inadequate and unsafe.

There are two physical phenomena which are primarily responsible for the successful use of steel and concrete jointly to form structural units or members: 1. The **coefficients of expansion** and contraction for concrete and steel are very nearly the same, thus preventing undesirable, or even disastrous, internal stresses due to differential expansion or contraction. 2. When the concrete hardens it grips the steel bars very tightly and securely and thus permits stress action between the two materials, the result of this joint action being exhibited as the strength of the structural member to resist the imposed load. Usually the steel bars are roughened to give the so-called "corrugated bar" which further assists in strengthening the adhesion between the concrete and steel by affording a sort of mechanical or interlocking bond.

In some structural members, where minimum cross-sectional size is desirable or necessary, steel may be used to carry some of the compressive stress as well as the tensile stress. This condition may occur often in the case of columns and occasionally in the case of beams. In the great majority of cases, however, the steel is used to resist tensile action. Where, as in the case of a continuous girder, the tensile stress alternates between top and bottom of the member, it is customary to bend the steel accordingly, into a zig-zag shape.

The amount of steel required for adequate reinforcement is commonly quite small, varying from 1% more or less for beams and slabs to as much as 6% in some cases for columns. The percentage is usually based on the area in a right cross-section of the member. The bars vary by eighths of an inch from ¼–2", and may be either round or square. The steel may be either mild, medium, or hard, the medium grade being more commonly used with, however, an increasing preference in recent years for the use of the harder grades.

A few of the more important characteristics of reinforced concrete which have made it increasingly popular with architects and engineers as a structural material are as follows: durability in resisting the disintegrating action of the elements, the ease and economy with which it may be cast to any desired form or shape, the fireproof character of the construction, its massiveness and consequent freedom from vibration, and the monolithic character of construction permitted (E.W.S.)

REITBOK. Reedbuck.

REJUVENATION. The restoration of youth, a process which is in the strict sense impossible. Some animals, however, gain increased vigor through special processes. This change is most evident in the one-celled animals as a result of **conjugation,** but the renewal of vigor characterizes the line to which they give rise after conjugation rather than the individuals themselves, and is comparable to the maintenance of diversity by sexual **reproduction** in higher forms.

Rejuvenation in complex animals, particularly man, is a partial restoration of waning functions through various means of stimulating the organs concerned. Since the **endocrine glands** are important in the maintenance of normal functions, the grafting of gland tissue from other animals into the human body has been undertaken to a limited extent. The gonads especially are concerned in such measures. The endocrine functions of these organs have also been found to respond to other operative procedures.

The term rejuvenation is used by geologists (geomorphologists) to describe the increased or renewed erosive power of a river, or river system, by the uplift or tilting of the land. (See **Entrenched Meander.**) (A.W.L., R.M.F.)

RELAPSING FEVER. A group of acute infectious diseases caused by **spirochetes** which are transmitted to man by several species of ticks and lice. Relapsing fever has been known all over the world but the chief centers of spread are Russia, Poland, and the Balkan states. An African form is also known and is called African tick fever. Epidemics of relapsing fever and typhus are often associated, and occur in periods of depression following war when overcrowding, famine, and poor hygienic conditions are prevalent.

The incubation period is usually 7–10 days. The disease is characterized by paroxysms of acute fever lasting several days with intervals between the attacks when the temperature is normal and the patient is apparently well. The diagnosis is easily established by finding the organism in specimens of the patient's blood during a paroxysm of fever.

The disease has been treated with arsenicals such as neoarsphenamine and mapharsen, given during a febrile episode. More recently **penicillin** has been given with strikingly good results. (R.S.M., D.M.H.)

RELATION BETWEEN ROOTS AND COEFFICIENTS OF A POLYNOMIAL EQUATION. Polynomial Equations.

RELATIVE FREQUENCY. If the frequency in a class is f_i, and the total frequency in the distribution is Σf_i, then the relative frequency in the ith class is defined as $\frac{f_i}{\Sigma f_i}$. Similarly the relative frequency of an event is defined as $\frac{x}{s}$ where x is the number of successes and s is the number of trials. (L.A.A.)

RELATIVE GROWTH. Growth of a part in relation to the whole, or in relation to the growth of another part. As living organisms grow, certain parts grow at the same rate as that of the whole organism, some faster, some slower. Growth at the same rate is isogony, at different rates heterogony. The giant chela of the fiddler crab, for instance, is produced by heterogony; the chela grows faster than the crab. In plant seedlings the roots, at first, grow faster than the stem; then the situation is reversed and the stems grow faster than the roots. Some fruits, such as the cucumber, grow faster in length than in width. The final form of organisms and of organs depends upon relative growth.

For the evaluation of data on relative growth a special method has been devised. Growth curves may be obtained by plotting cumulative size against time. This results in a sigmoid curve; growth starts slowly, speeds up, then slows down and ceases. Relative growth is studied by plotting pairs of measurements taken simultaneously against each other on a double logarithmic grid, or the logarithm of one measurement against the logarithm of another on ordinary plotting paper. Time is thus eliminated from the study and the curves turn out to be straight lines for each phase of growth. If the relative growth is isogonic the line forms an angle of 45° with the x-axis, the tangent of which is unity. The equation for the curve is $y = bx^k$, where y is the size of a part at any given moment, x the size of the whole organism (or of another part) at the same moment, b the intercept of the curve on the y-axis on a double logarithmic grid, and k is a constant for the relative growth rate. The constant k is the tangent of the angle which the curve makes with the x-axis, so it is obvious that if $k = 1$ the relative growth rates are isogonic, if greater or less than 1, heterogonic, and that k is a measure of the relative growth rate.

The linear nature of the equation $y = bx^k$ is best revealed by writing it $\log x = \log b + k \log x$. It is used in this form when the logarithms of the data are plotted. The validity of the hypothesis has been well tested. Growth is here considered as a multiplicative process, the growth at any instant being proportional to the size of the organism at that instant. The curve

represents a geometric series and, with large amounts of data, grouping is by geometric classes. Time is eliminated because no new data can be plotted until growth has actually occurred. Actual rates of growth are not studied—only relative rate, which permits time to cancel. The chief difficulty with the method lies in the determination of the value of k. It may be roughly approximated by drawing a line on the plotting paper to represent the grouping of the dots and then determining the slope of the line by the usual methods, but if large amounts of data are available and the constant is to be determined with some accuracy it is necessary to resort to rather elaborate equations based on the method of least squares. (P.A.W.)

RELATIVE HUMIDITY. **Humidity; Atmosphere; Hygrometers.**

RELATIVE VARIABILITY. Relative variability is the ratio of some measure of **dispersion** to some measure of **central tendency.** The only one in use is the **coefficient of variation.** (L.A.A.)

RELATIVE WIND. Velocity of air with reference to a body in it. It is usually determined by measurements made at such a distance from the body that the disturbing effect of the body upon the air is negligible. (F.T.M.)

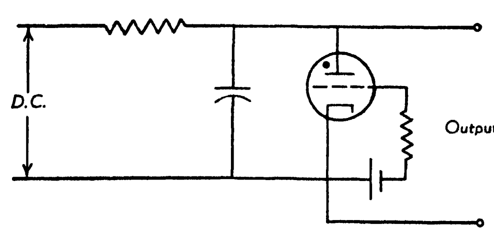
RELATIVITY. It is impossible, in a brief article, to indicate more than the general trend of the far-reaching domain of scientific thought known as the theory of relativity. This revolutionary philosophy, due largely to the work of Albert Einstein, had its origin in the ambiguities connected with attempts to detect absolute motion, or rather, motion with respect to a supposedly universal and omnipresent medium, the **ether.** The **Michelson-Morley experiment** on the one hand and the **aberration of light** on the other, together with the results of numerous less familiar experiments to similar purpose, had given conflicting evidence. The outstanding conclusion which emerged from them was that, while the motion of bodies relative to one another can be readily observed and has significant results in the physical world, the absolute motion of bodies, or motion with reference to a stationary ether, is not capable of detection and therefore may as well be omitted from physical reasoning.

Proceeding on this basis, Einstein set for himself the problem of formulating the mathematical laws of physics in such a way that they should not depend either upon the positions of the points and lines chosen as a reference system (such as origin and coordinate axes), or upon whether that reference system is supposed to be moving or not. To do this it was necessary, as the reasoning became more general, to give up the cherished Newtonian concepts of absolute length, absolute mass, and absolute time. For the Michelson-Morley experiment, explainable only on some such basis as the **Lorentz-Fitzgerald contraction** hypothesis, had shown that length varies, in a manner not directly observable, with motion in space; so that the absolute or "static" length of a body cannot be determined. Lorentz had concluded, incidentally, that the masses of electric particles, and hence presumably of whole bodies of matter, vary with motion. In the case of high-speed electrons in a vacuum tube, this variation can be detected by their failure to follow the paths prescribed by the Newtonian laws; but the actual, absolute or "rest" mass of a body must be forever unknown because we do not know its absolute motion. Time, also, loses its independence. If we watch things happening on two stars (such as variations in brightness), events which appeal to us to be simultaneous may have actually occurred centuries apart, because of the difference in distance; and the same monochromatic light from the two stars may reach us with measurably different frequency because of the **Doppler effect.** Since all the magnitudes of physics, such as density, speed, momentum, etc., are analyzable in terms of length, mass, and time, it is clear that all magnitudes are dependent in more or less complex ways upon the forever unknowable absolute motion of the bodies concerned. The outcome of all this was that, in order to avoid incorporating this unknown absolute motion in physical equations as a result of its inseparable connection with the physical magnitudes involved, the equations themselves had to be recast in such a way as to leave out that factor and permit us to forget about absolute motion altogether.

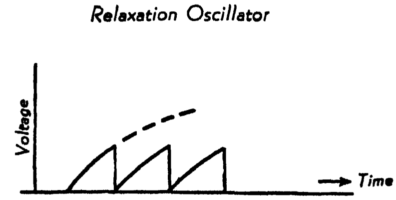
Among the important by-products of this general relativity analysis were the endowment of **energy** with the characteristics of **mass,** the interrelation between **gravitation** and **inertia** (see **Einstein Equivalence Principle**), and the recognition of various fields of force (electric, magnetic, gravitational) as being different aspects of a common phenomenon—the "unified field theory."

In order to facilitate the difficult thinking required for these generalizations, Minkowski devised the plan of describing physical processes in terms of a symbolic space having four coordinates, three being the usual linear coordinates (x, y, z) and the fourth being time. A graph in this 4-dimensional "space-time" or "Minkowski world," called a "world line," represents the continuous history of the particle to which it pertains, any point on the graph corresponding to its position at some particular time. By equations of transformation analogous to those arising upon change of axes in ordinary geometry, Lorentz showed how the description of the performance of a particle can be adapted to the viewpoints of different observers having a uniform motion relative to each other. (L.D.W.)

RELAXATION OSCILLATOR. The relaxation oscillator is an electron tube **oscillator** whose frequency is determined by a condenser-resistance or inductance-resistance circuit rather than the more conventional capacitance-inductance resonant circuits. These oscillators have very distorted wave shapes, giving various outputs such as square waves, trapezoidal waves, triangular waves and pulses of very short duration. These distorted waves have made them ideal for many control and triggering purposes in more elaborate electronic circuits. The relaxation oscillator may be easily synchronized with another oscillator or other source of voltage by injecting some of the other voltage into the



Relaxation Oscillator



Output

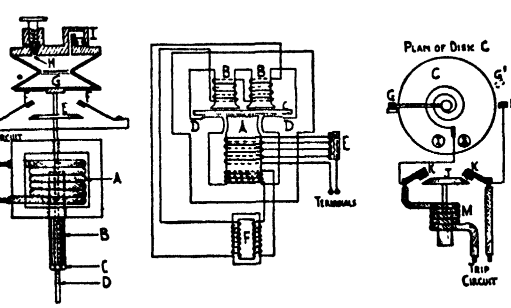
relaxation circuit at the proper point. A simple, but widely used, relaxation oscillator is shown in the figure. Here the condenser is charged through the resistance

until the voltage across the thryratron reaches the breakdown value when it breaks down and discharges the condenser very rapidly. The process is then repeated and the resultant voltage output is as shown. This oscillator is used for the sweep oscillator of many cathode-ray oscilloscopes (see **Cathode Ray Tube**). The multivibrator is another relaxation oscillator and is widely used for frequency measurements since its output is rich in **harmonics** (see **Frequency Meter**). This oscillator is merely a two-stage resistance coupled **amplifier** which has its output connected back to its input. (L.R.Q.)

RELAY. The electrical relay is a device which utilizes the variation of **current** in an **electric circuit** as a controlling factor in another. For example, a certain change of current in one circuit may cause current to begin to flow in another, by the operation of a relay connected between them. There are numerous types of electrical relays, as they have been widely used in industry, particularly in apparatus of an automatic or semi-automatic nature, or for the protection of electric power equipment, or for communication systems. Protective relays are highly specialized and developed to where they will detect any electrical abnormality, and open the circuit containing that abnormality in any required time interval. Suitable relays will detect over-current, under-current, over-voltage, under-voltage, overload, reverse current, reverse power, abnomal frequency, high temperature, grounds, and phase unbalance.

Usually the relay involves two circuits, the energizing circuit and the relay circuit (the latter variously called the trip circuit, the sounder circuit, etc.). Protective relays may close the trip circuit immediately, or after a definite time interval, or after an inverse time interval. If the trip circuit contacts are normally open, the relay is called circuit closing; if they are normally closed, the relay is called circuit opening.

The automatic protection of electric power circuits is necessary for safety and economy. **Fuses** and automatic circuit **breakers** are the devices most used for opening the circuit. A relay must be used to operate the tripping circuit of the circuit breaker. Fig. 1



Plunger type. Induction type.

Fig. 1. Relay.

illustrates the principle of two types of protective relays. They are, respectively, the solenoid and induction relays. Simple inverse-time limit overload relays of the circuit-closing type are shown in each case. Explaining the plunger type, *A* is the operating coil which may be connected in series with the line or through the medium of tripping transformers. *B* is the iron plunger which will be pulled upward against gravity by the "sucking" action of the coil when a predetermined current is reached. The setting for current at which the contacts are closed may be adjusted by moving the plunger up and down on its stem *D* by the adjusting nut *C*. When the plunger starts upwards the pulling force on it increases due to the increased portion within the coil *A*. Thus no floating in an intermediate position is possible. However, the air compressed by bellows *G* delays the closing until enough can leak out through port *H* to permit the disk *E* to move up to where it will close contacts *FF* of the trip circuit. By adjustment of the leak port needle, the amount of time delay may be changed. *I* is a quick reset valve.

The induction relay receives its current through the connection block *E* by means of which the number of effective turns in the primary winding may be varied. The secondary winding on *A* is connected to the upper pole pieces *BB* through a torque compensator *F*. The magnetic circuit of *F* becomes saturated at high overloads, the strength of the poles *BB* does not increase further and the relay then has a definite-time limit feature. At less severe overloads the relay is inverse-time limit. The interaction of magnetic fields produces a turning torque in the disk *C* which is resisted by a spiral spring. A plan view of the disk is shown in connection with the secondary contacts. The holes *I* are beneath the poles. As they move out under the influence of an overload the torque increases and the contact *G* is swung around to *H*. The holes prevent floating of *G* at some position *G'*, an effect which would destroy the inverse-time feature. The contacts are delicate and often the heavy trip current is passed through secondary contacts, the primary contacts carrying only enough current to energize coil *M*, draw up plunger *J*, and close secondary contacts *KK*.

The telegraph relay has probably served man longer than any other type, and there are few persons indeed who have not listened to the busy clicking in the local telegraph office. The audible signal is made by a sounder which is actuated by a polarized telegraph relay. (See Fig. 2.) This relay consists of soft iron cores on which windings connected to the main line are placed. These cores become magnets under the action of the windings. The relay is polarized by a magnet of the horseshoe type, mounted as shown in the diagram. An armature operates in an air gap between the cores. With no current flowing in the windings, the armature is attracted equally by the electromagnet and the armature tends to remain in a mid position. When the current flows through the windings in a certain direction it will strengthen one electromagnet and weaken the other, so that the armature will be attracted in one direction, carrying with it the contact point, which will close the sounder circuit. Relays have an important place in all wire communication systems.

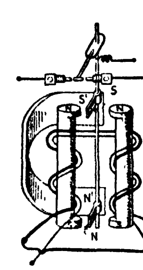


Fig. 2.

The telephone relay is probably the most widely used relay since in its various forms it occurs hundreds of times in the usual telephone system. While there are various specialized types of relays used in telephone circuits, the one commonly referred to as a "telephone" relay has an energizing coil surrounding a soft iron core. This core extends slightly beyond the end of the coil and when the coil is energized attracts a soft iron

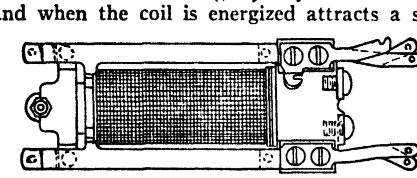

Fig. 3. Telephone relay.

armature, which in turn pushes the contacts open or closed. In many of these relays there are several contacts, some of which may open and others close when the relay is energized. Fig. 3 shows one form of this relay. (F.T.M., L.R.Q.)

RELIABLE SAMPLE. A sample is said to be reliable if the **statistics** calculated from it are reliable,

that is, such statistics have **confidence limits** which are sufficiently narrow for the purpose at hand. (L.A.A.)

RELIABILITY. The reliability of a **statistic** is determined by tests of significance. If these tests of significance show certain hypotheses are denied, then the statistic is said to be reliable. At the present time more stress is placed on **confidence limits** rather than on computing reliability by use of a standard error of a statistic.

In general the notion of reliability refers to the idea that repeated samples or repeated tests will give essentially the same results. (L.A.A.)

RELIEF. Used by geographers and **physiographers** to define the difference in altitude within a specified or limited region. (R.M.F.)

RELIEF PROCESSES. Methods of color photography classified as relief processes are those in which, instead of an image composed of black silver in gelatin, there is a layer of gelatin of variable thickness. Such a film thus has a variable thickness (gelatin) instead of a variable density (silver). Relief images may be formed from silver images by means of tanning development, by the hardening action of light on silver in a dichromated colloid, or by chemical etching. The relief images may be dyed with appropriate colorants which may then be bound together to form a transparency or they may be transferred to suitable gelatin surfaces by **imbibition.** Films or tissues of gelatin are also obtainable containing pigments of the proper colors. These sheets are then superimposed after the reliefs are prepared to form transparencies or prints on a paper support. (H.C.C.)

RELUCTANCE. Magnetic Circuit.

REMAINDER THEOREM OF ALGEBRA. If a **polynomial** $P(x)$ is divided by a binomial divisor of the form $x - r$, the remainder is $P(r)$; that is, the remainder may be found by substituting $x = r$ in the polynomial $P(x)$. (L.L.S.)

REMORA. Pisces, Teleostei. Marine fishes (**Pisces**) whose anterior dorsal fin is modified to form an oval sucker on the top of the head. This sucker is used to attach the animal to boats, turtles, or other large objects by which the fish may be carried about without effort. From their frequent attachment to sharks they are also called shark suckers, and the name sucking fish is sometimes used. (A.W.L.)

RENAL CORPUSCLE. A structural unit of the vertebrate **kidney.** A renal corpuscle consists of a knot of blood vessels enveloped by a thin-walled expansion of the excretory tubule known as Bowman's capsule. The knot of blood vessels, called a glomerulus, does not lie in the cavity of the tubule but merely bulges into the cavity of the capsule, covered by its thin wall. The portion of the tubule which leads out of the capsule is the secretory tubule. It is also involved in the removal of wastes from the blood. (A.W.L.)

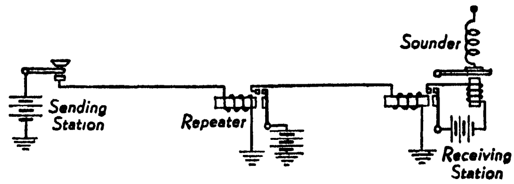
RENAL PAPILLA. 1. A projection extending from the body of **cephalopod** mollusks into the **mantle** cavity. It bears the opening of the excretory duct. 2. The summit of a renal pyramid in the mammalian **kidney.** (A.W.L.)

RENOPERICARDIAL CANAL. A passage connecting the **pericardial** cavity of **mollusks** with the **kidney.** (A.W.L.)

REPEATED LOAD. Load.

REPEATED INTEGRALS. Double Integrals and Triple Integrals.

REPEATER. In communicating over long lines the electrical pulses gradually become attenuated and often distorted so they must be built back to sufficient amplitude and correct shape to satisfactorily operate the receiving equipment. The restoration of these attenuated signals is the function of repeaters. In telegraph circuits various mechanical repeaters are often used. One of the simplest is shown in the diagram. In this simple form



Simple Telegraph Station

communication is possible in one direction only, for the receiving station cannot break the circuit, as it would have to do in order to insert a key. A repeater station, more complicated than that diagrammed, can be installed to provide two-way telegraphy. Two repeaters having holding **coils,** and extra **batteries** are required in this system. These, however, do not restore the original spacing and shape of the pulses and the resulting signals may still give false operation of the receiving devices. In order to overcome this fault regenerative repeaters are used on many telegraph circuits, particularly on **teletype** or printing circuits. These are much more complicated than the simple form shown. They are designed to transmit a restored signal of correct amplitude and shape under the control of only the center portion of each pulse received at the repeater. In this way the outgoing pulse is correct if the center of the incoming one is correct, regardless of what has happened to the incoming pulse outside of this narrow center region. Vacuum-tube repeaters are also used on telegraph circuits and are always used on telephone circuits where the complexity of the signals prevents the use of mechanical repeaters. Telephone repeaters are basically amplifier circuits employing special input and output circuits to connect them to the **lines.** (See **Telephony.**) (L.R.Q.)

REPRESENTATIVE FRACTION. Map.

REPRESENTATIVE SAMPLE. A representative sample is one which in some way reflects the main characteristics of the population. If a deliberate attempt is made to choose a sample which reflects known characteristics and to use this sample for inferences of unknown characteristics, then such a representative sample has been found to be decidedly incorrect. The type of representative sample which is recommended is the **stratified sample.** (L.A.A.)

REPRODUCTION. The production of units of living matter by other usually similar units already in existence. In the ordinary use of the word these units are individual organisms but the power of reproduction is a fundamental property of living matter through which units subordinate to the individual also arise.

Reproduction is at its simplest in unicellular animals (**Protozoa**) such as Amoeba. These animals are single **cells,** composed of a naked mass of **protoplasm** without constant form. In the process of binary fission they divide into two parts, each an independent cell like the parent. Protozoans with constant body form also reproduce by binary fission but in them each half must undergo a reorganization for the development of the complete normal form of its kind. Some protozoans

subdivide into more than two parts by multiple fission.

Fission in multicellular animals is limited to simpler forms, such as a few **coelenterates** and flatworms (**Platyhelminthes**). Here it involves a change in the relations of the cells of the body, accompanied by subdivision either longitudinally or transversely and by reorganization within the resulting halves.

In true fission the individuality of the parent merges with that of the resulting offspring.

Multicellular animals also reproduce by budding. In this process the individuality of the parent is retained and its offspring develop gradually from a limited portion of its body. The growth of a coral polyp from the extended margin of the parent is a good example. The process also takes place in sponges, other coelenterates, and some of the worms.

All of these processes are asexual, in contrast with the widespread process of sexual reproduction. In sexual reproduction two reproductive cells (**gametes**, germ cells) normally unite to form a single cell, the zygote, which develops into a new individual. In isogamous reproduction the two cells are similar. More frequently they are distinctly different, a condition known as heterogamy. In the latter case the differences of the cells are the foundation of **sex** in the individuals producing them. One form, the ovum or egg cell, contains a large amount of cytoplasm and often some stored food or yolk. It is produced by the female. The germ cells of the male, known as sperms or spermatozoa, are microscopic in size and are motile, usually through the action of a slender tail resembling a flagellum.

The role of the parents in reproduction may be no more than the production and discharge of the germ cells, involving some special behavior in **mating** and sometimes a close association in **conjugation** or **copulation**. In other cases, notably in the mammals, the young develop in the body of the mother. If the species produces eggs it is said to be oviparous. If the eggs hatch within the body of the parent, it is ovoviviparous. And if the young undergo a long development, nourished by close connection with the body of the mother, it is viviparous.

Specialization of the body of the mother for the nourishment of the young in viviparous species is essential to reproduction, and in the mammals the secretion of milk for their nourishment after birth is equally necessary for their development to an independent stage.

Incubation of the eggs by birds and extensive postnatal care by birds, social insects, and a few other forms are also essential corollaries of reproduction, although not strictly a part of the reproductive process.

Sexual reproduction has the advantage of combining hereditary qualities of different individuals. Through this means it maintains maximum diversity within the species, an end of great value in meeting varied environmental conditions.

A fundamental modification of the sexual process is **parthenogenesis**. (A.W.L.)

REPRODUCTIVE SYSTEM. The assemblage of organs which give rise to the reproductive cells and carry out all accessory functions directly involved in the production of young.

The essential organs of reproduction are the **gonads**, in which the reproductive cells arise, together with the ducts, if any are present, through which these cells are discharged from the body. In the female the gonads are known as ovaries and their ducts as oviducts. The gonads of the male are testes and their ducts are sperm ducts or vasa deferentia.

Regions of the ducts are specialized for various functions in relation to the **germ cells**. In the female they give rise to yolk glands which produce the food to be stored in the egg, and glands which secrete enclosing membranes or shells, as well as glands which secrete fluids to cover the outside of the egg for various purposes. Other regions become reservoirs (**receptacula seminis**) for the storage of the seminal fluid of the male after **copulation**, and the terminal part of the female genital passages becomes a **vagina** for the reception of the male intromittent organ during that act. The ducts of the male produce glands whose secretions constitute a liquid medium in which the spermatozoa swim.

In many invertebrates the reproductive system is independent of other organic systems, aside from the usual nervous and circulatory connections. In others it is connected with the digestive tract. Vertebrates, on the contrary, have the organs of reproduction usually associated with the **excretory system**, and the common ducts primitively discharge into the **cloaca**, which is also part of the digestive tract. The gonads in this class arise from mesoderm in close association with the mesonephroi, although the germ cells themselves may have another origin. Some of the mesonephric tubules become the slender vasa efferentia of the testes, leading to the principal ducts, the vasa deferentia, which are derived from the mesonephric ducts. Thus in some fishes (**Pisces**) and in **amphibians** the male reproductive and excretory systems have common ducts, and above these classes the loss of the mesonephroi leaves their ducts to the reproductive system alone. In the female a separate pair of oviducts arise, beginning near the ovaries in the funnel-shaped ostia abdominales, which open to the coelom, and extending to the cloaca.

In mammals the union of the posterior parts of the oviducts forms a single terminal passage, the vagina. Anterior to the vagina portions of the ducts are specialized as the uterus, which may remain a forked or paired structure or may, as in man, become a single chamber. In the last type the more slender parts of the ducts leading toward the ovaries persist as the Fallopian tubes. The vagina opens independently to the exterior, but is close to the urethra in an external furrow called the vestibule.

In the male the ventral part of the cloaca separates as a urogenital sinus which forms, in part, a urethra common to the excretory and reproductive systems. Flanking the external opening of this structure in the embryo folds of tissue arise which join to extend the duct and to form a projecting erectile organ, the penis. In more primitive vertebrates such an **intromittent organ** may arise from the wall of the cloaca. As a result of this close association of the two systems, the term urogenital system is often used in vertebrate anatomy.

Various accessory organs of reproduction, not an integral part of the reproductive system, appear in the animal kingdom. Among them the **mammary glands** of mammals are noteworthy. They are developed in two rows along the ventral surface of the trunk or at certain points along these rows. These glands secrete milk for the nourishment of the young and are subject to the intricate regulation of **hormones**. (A.W.L.)

REPTILIA. The reptiles, including the **lizards** and **snakes**, **crocodiles**, **alligators** and related forms, and **turtles** and **tortoises**. A class of the phylum **Chordata**.

The class is characterized as follows: 1. The **skull** articulates with the spinal column by a single process. 2. The **mandibles** are made up of several bones, joined with the skull by the quadrate bone. 3. The skin is covered with scales. 4. The **heart** is 4-chambered but the separation of the ventricles is incomplete. 5. They are **poikilothermal**. 6. They have extraembryonic membranes during development, a fundamental requirement of terrestrial life in the vertebrates.

Although the group is the lowest class of vertebrates

to attain the capacity for entirely terrestrial life, many reptiles are now amphibious or aquatic. Even the aquatic species, however, come to the land to deposit their eggs.

Reptiles are economically important to a rather limited extent. The flesh of some turtles, lizards, and even snakes is used as food, and the skin of the alligator makes an excellent, if conspicuous, leather. In some regions crocodiles have been known to kill human beings. Usually it seems that the danger from them is very limited. Poisonous snakes also may destroy human life, but here again the danger is usually encountered only under special conditions and snake bites may be regarded as accidental.

The classification of the reptiles is briefly as follows:

Order Prosauria. A single living species, the tuatara of New Zealand, makes up this order. It is a lizardlike animal with a few primitive structural characteristics, including a well-developed **pineal eye**. The order also bears the name Rhynchocephalia.

Order Chelonia (Testudinata). The **turtles, tortoises,** and related species. Characterized by the shell, consisting of an upper **carapace** and a lower plastron, formed of bony plates with a horny sheath.

Order Crocodilia. Large reptiles resembling lizards in form. The jaws are elongated. The thick skin is provided with bony plates. The **crocodiles, alligators, garial,** and related species.

Order Sauria. The lizards and snakes. In some classifications these forms are included in separate orders, and in some the lizards constitute the suborder Sauria and the snakes the suborder Serpentes of the order Squamata. The order including the lizards is also named Lacertilia. All of these animals have elongate bodies. The skin bears horny scales and in some cases bony plates. (A.W.L.)

RESIDUAL. A residual is defined as $x_1 - x_1'$ where x_1 is the actual value of the **variate** and x_1' is the value found from a **regression** equation. The standard error of the residuals is the **standard error of estimate.** In the method of **least squares** the regression equation $x_1' = f(x_2, x_3, x_4)$ is found by making the sum of the squared residuals a minimum. (L.A.A.)

RESIDUAL RADIATION. When light or other radiation falls on the surface of a transparent body, part of it is reflected, part is transmitted, and part is absorbed. The **spectrum** of the transmitted portion, when compared with that of the original radiation, may reveal that certain sharply defined wavelength ranges have failed to get through, but does not indicate whether they have been absorbed or reflected.

Transparent media sometimes reflect very copiously those wavelengths whose absence from the transmitted radiation causes conspicuous absorption bands. Quartz, for example, reflects (or absorbs and re-radiates) **infrared radiation** of 8.5 microns and also that of 20 microns wavelength almost as well as a polished metal. Rock salt does the same at 50 microns. Rubens and Nichols devised an ingenious method of isolating beams of these infrared rays by reflection at polished surfaces of quartz or rock salt, the residue, after several reflections, called by them *Reststrahlen* (residual rays), being almost monochromatic. Analogous properties are exhibited in the visible spectrum by many aniline dyes, the selectively reflected light appearing as a "surface color" complementary to the transmitted portion. (L.D.W.)

RESILIENCE. The resilience of a body measures the extent to which energy may be stored in it by elastic deformation. The implication of the word "stored" in the above definition is that this energy may be released in the form of mechanical work when the force causing the elastic deformation is removed, and that resilience is a property of a material within its proportional limit. The "modulus of resilience" is the maximum energy storage in a unit volume of the material. In practical units it is the inch pounds of energy stored in a cu. in. of the material stressed to the proportional limit (**elastic limit**). The modulus of resilience is directly proportional to the square of the stress, and inversely proportional to the modulus of elasticity. (F.T.M.)

RESINS. Natural resins (for synthetic resins, see **Plastics**) are complex compounds composed of **carbon, hydrogen** and relatively small amounts of **oxygen,** which are secreted in various tissues of many plants. In the **pine family,** where resins are very common, they are secreted as oleoresins in resin canal cells, which break down finally, producing resin canals. These canals appear as longitudinal ducts in the sapwood and inner bark, connected laterally by resin canals in the compound wood rays, thus forming an extensive network. A common name given to the oleoresin in this group is pitch, the sticky juice which exudes from the plant wherever it is wounded. On exposure to the air the **volatile oil** in this pitch (oil of turpentine) gradually evaporates, leaving a clear hard glassy substance, the resin, which forms a protective coating over the wound.

Most resins have the same physical properties, being clear, translucent, and of a yellow or brownish color. **Amber,** a fossil resin, is a more or less familiar example. Resins are insoluble in water, but soluble in common organic solvents such as ether and alcohol. All resins burn with a sooty flame. Resins seem to be mainly of value to the plant in that they form protective coverings against the entrance of disease-producing organisms and also prevent excessive loss of water from the thin-walled tissues exposed in the wound.

Resins are separated into several classes. Many of the resins contain almost no volatile oil and are hard, without taste or odor. These are the varnish or hard resins. Other resins, when removed from the plant in which they are formed, and dissolved in volatile oils, form a thick semi-solid mass: these are the oleoresins. In still other cases the resin occurs in combination with a **gum,** forming a gum resin.

Hard Resins. Several of the hard resins, used mainly for making varnishes, are called copals. Most of them come from Africa and are either found in fossil form or obtained from living plants. Other copals come from Australia, New Zealand and East Indian islands. The plants which form them are members of the legume and pine families. The African copals are products of several species of *Trachylobium,* fairly large trees growing in east Africa and Madagascar. The best resin from these trees occurs in a fossil form, often deeply buried in the ground—sometimes in regions where the trees no longer grow. These resins dissolve slowly and are used in making varnishes which are very durable. A South American tree of large size, *Hymenaea Courbaril,* also of the Leguminoseae, yields a very similar resin, which is also found in lumps in the ground around the trees, and used in varnishes.

Another copal is obtained from *Agathis australis,* a very large coniferous tree native in Australia and New Zealand, where it is known as the Kauri pine. Like the other copals, that from the Kauri pine is found in lumps buried in the ground. Most of these lumps are 1 or 2 in. in diameter, but some are much larger, weighing up to 100 lbs. Nearly all of this resin comes from the northern part of North Island of New Zealand. It is frequently called Kauri gum, though it is not a gum, but a true copal resin. Another group of hard resins, known as dammar resins, is obtained from many different trees growing in southern Asia and the East Indian Islands. These resins dissolve readily in alcohol, forming spirit-varnishes.

One of the commonest and most important of the hard resins is rosin, obtained by distilling the pitch, or turpentine, which is a product of several of the

native pines of the southeastern United States. This rosin, also known as colophony, is a very important product of that region. Originally the turpentine was obtained by chopping a deep hollow in the base of the trunk of the tree and allowing it to fill up with the turpentine, which was then scooped out. This method was very destructive and wasteful, since much of the oleoresin, turpentine, was lost during the process. The weakened trees were easily blown down.

Now turpentine is obtained by cutting V-shaped gouges in the bark and inserting metal gutters beneath the gouges. These gutters carry the turpentine to a cup placed underneath. As soon as the cut is made, turpentine begins to flow and continues to do so for two or three days, gradually slowing as the drying turpentine allows resin to accumulate and plug the wounds. A new flow is obtained by cutting off a narrow strip of bark from the upper edge of the cut. The process is continued as long as the pitch will flow, which is usually all summer and well along into late fall. Each tree may be turpentined for 6 or 7 successive years or even longer before it ceases to be profitable.

The crude turpentine collected in the cups and the product which has dried on the wound of the tree are removed and carried to the still. Here the turpentine, to which a little water is added, is carefully heated to drive off the oil of turpentine present, together with the water added. The distillate is condensed by passing it through a coil around which cold water is flowing, and collected in a barrel or any suitable container. The two substances, water and oil of turpentine, which make up the distillate, are immiscible and soon separate, the lighter oil of turpentine rising to the top and floating on the water, which is drawn off from the bottom. Oil of turpentine is often called spirits of turpentine, or, in the paint trade, turpentine. In medicine the word turpentine is reserved for the oleoresin which upon distillation yields oil of turpentine and rosin.

The residue remaining in the tank at the end of the distillation is skimmed to remove any impurities such as twigs, bits of bark and dirt, and run into vats to cool. Then it is put into barrels and allowed to harden, forming rosin.

Oil of turpentine is used principally as a solvent for paints and varnishes, because it mixes readily with the various substances used and also because it evaporates quickly, causing the paint or varnish to dry. It is also used in making such things as sealing wax and shoe polish. Very pure grades of turpentine (the oleoresin) are used medicinally.

Large quantities of rosin are used in sizing paper, which makes it take ink without spreading or blotting, gives it a smoother surface and makes it heavier. Rosin is also used in cheaper varnishes, in paints, and in soap making. It is furthermore used as an adulterant of the more expensive resins. Linoleum manufacturers use large amounts of rosin.

In early times large quantities of crude turpentine were used to waterproof the rigging of the sailing vessels and to calk the seams of the hull.

Mastic is a hard resin exuding from the branches of one of the Pistachio trees, *Pistacia Lentiscus,* native of Mediterranean Europe and Southern Asia. Formerly it was extensively used medicinally, for stomach troubles and dysentery, as well as other ailments. Now it is used in making varnishes and in lithographic work. Natives of the region in which it is found chew mastic, which has a pleasant taste.

Since turpentine is a mixture of a volatile substance, spirits of turpentine and a hard resin, it is one of the oleoresins.

Oleoresins. Canada balsam is one of the oleoresins. It is obtained from the bark of *Abies balsamea,* the common balsam fir of northern North America. Canada balsam, because its refractive index is so near that of glass, is much used in optical work and in preparing materials for examination with a microscope.

Little used today is Dragon's blood, an oleoresin obtained from the fruits of *Calamus Draco,* a native palm of southeastern Asia and the Molucca Islands. The resin exudes from the surface of the ripening fruits. It is removed from them by boiling in water. The resin is then moulded into balls or long sticks. It is sometimes used in making varnishes and lacquers.

True lacquer, obtained from the juice of *Rhus vernicifera,* a sumac tree of southeastern Asia, is another oleoresin. To obtain the juice lateral cuts are made in the bark. The exuded sap is collected not only from these cuts but from small branches which are cut off and soaked in water. The juice is cleaned of any foreign substances by straining it through hemp cloth. By slow heating, either artificial or by the sun, the juice is evaporated and stored until used. Lacquer is a poisonous substance, causing intense irritation of the skin in many people. Others seem to be immune. Lacquer is usually applied over some soft wood, commonly soft pine, the pores of which have first been filled by rubbing in a paste of rice and resin, followed by a paste of soft clay and resin. The surface is then covered with cloth and layer after layer of lacquer put over that. Each layer is allowed to dry and rubbed down very smooth before the next layer is added. Any color which is to be added is mixed with the lacquer, with each colored layer covered by a clear layer before another is put on. The final product is a thick covering composed of many thin layers of lacquers. If this is carved the edges of the carving, on careful examination, will show the fine lines separating the different layers. Lacquering is a very old industry, having been carried on in China since the 6th century. Lacquer work is made in many other oriental countries, and the juice of many other trees used as a source for the lacquer used.

Certain resins occur in combination with fragrant volatile oils. One of these is benzoin, obtained from *Styrax Benzoin* by cutting notches in the bark and allowing the resin to collect in them. It is used in making perfumes, in incense, and as a source of benzoic acid, used medicinally.

Another fragrant oleoresin is storax, obtained from *Liquidambar orientalis,* a medium-sized tree growing in southwestern Asia. The resin is obtained by boiling the bark and wood of young branches. It is used medicinally and also in incense.

Gum Resins. Gum resins include myrrh, which exudes from the trunk and branches of *Commiphora Myrrha,* a tree growing in the region around the Red Sea. The lumps of resin are used medicinally, and also in making incense. Another gum resin is frankincense, obtained by cutting notches in the stem of *Boswellia Carterii,* which grows in northeastern Africa and in Arabia. This resin is used in incense. **Asafoetida** is also a gum resin. (R.M.W.)

RESISTANCE. This word describes the opposition offered by a material body to forces which would tend to produce motion, or to the migration of electrons or ions in **electric conduction.** The mechanical resistance of a body may arise from friction, from stresses set up in rigid anchors or from inertia. Resistance is offered by fluids, such as air or water, to the passage of bodies through them. Aerodynamic resistance is treated elsewhere in this volume. (See **Drag, Aeronautics, Airfoil.** Fluid friction is also treated under **Fluid Friction, Viscosity.** See also **Friction, Mechanics.**)

Electrical resistance is the reciprocal of electrical conductance. Electric conductors are believed to contain free electrons, the movement of which through the substance constitutes electric conduction. In this migration the moving particles evidently meet with some restraint, since their progress is very much slower than in a

vacuum tube under the same potential difference. It is natural to visualize this resistance as due to collisions with the atoms, occurring so frequently that the electricity must filter along slowly. If driven by considerable **electromotive force,** they produce sensible heat; but by what mechanism this comes about is not so evident, and the whole question is complicated by uncertainties as to the nature of the electron and of the atom.

The measure of the resistance of a given conductor is the electromotive force required per unit current, and is usually expressed in **ohms.** (See **Ohm's Law.**) The resistance of a wire or other linear conductor of uniform cross-section is proportional to the length l and inversely proportional to the cross-section a: $R = \mathfrak{r}l/a$. The constant $\mathfrak{r}$ is the "resistivity" of the substance, usually expressed in ohm-centimeters; and its reciprocal is the "electric conductivity." The dependence of resistivity of metals upon temperature is one of the major problems of electron physics. (See **Resistance Thermometers** and **Superconductivity.**)

Pieces of wire may be cut off at such lengths as to have definite resistances, and mounted with convenient connections to form a "resistance box," used in many electrical measurements. A "rheostat" is usually a rugged conductor, often with adjustable resistance, used to introduce a resistance load into a circuit. Resistances are commonly measured by means of some form of **bridge,** of which the **Wheatstone bridge** is most familiar.

Some typical resistivities are given in the table below:

RESISTIVITIES OF SOME COMMON MATERIALS
(In ohm-centimeters at 20° C.)

Aluminum...	2.83×10^{-6}	Mercury... ..	95.78×10^{-6}
Brass.......	7.	Nickel	7.8
Copper.	1.72	Platinum.....	10.
German silver	33.	Silver..	1.63
Iron (pure)..	10.	Tin	11.5
Lead..... ..	22.0	Tungsten	5.51

For some purposes it is convenient to express the resistivity as the resistance of one foot of wire of the given metal having a cross-section of one circular mil (a circular mil is the area of a circle 0.001" in diameter). This value may be obtained by multiplying the resistivity in ohm-centimeters by the factors 6.015×10^6.

The dependence of resistance of many metallic conductors upon temperature is expressed with fair approximation by the linear equation

$$R = R_0(1 + At),$$

in which R_0 is the resistance at 0° C. and t is the centigrade temperature. The temperature coefficient A is a constant characteristic of the metal.

There remains yet another type of resistance for consideration—heat resistance. This might be said to be the property of offering opposition to the flow of heat. This property is desirable in a heat insulator such as pipe covering, but undesirable in heat transfer equipment. The term resistivity is rarely used in connection with heat flow, as its reciprocal, thermal **conductivity,** is quite satisfactory, and enjoys the advantage of common usage. (See **Heat Transfer, Heat Insulation.**) (L.D.W.)

RESISTANCE THERMOMETER. The fact that the electrical **resistance** of a metal wire increases with rising temperature is the basis of a very useful class of thermometers. One has only to calibrate a given length of wire, as to its resistance in relation to its temperature, enclose it in a suitable protecting tube, and keep it connected with the resistance-measuring **bridge,** to have a resistance thermometer adapted to a variety of uses over a very wide temperature range. The metal nearly always employed is platinum. The variation of resistivity with temperature of platinum is very nearly linear, being closely approximated by the formula $\mathfrak{r} = 0.0000000037t + 0.000011$, in ohm-centimeters and centigrade degrees. Callendar found that for any given platinum resistance thermometer there is a slight systematic departure from this formula, characteristic of the particular sample of wire. It is best, therefore, to calibrate each instrument throughout the range for which it is intended. (See **Thermometry.**)

Care must be taken, in mounting the platinum wire, that it does not come in contact with materials which will contaminate it at high temperatures. Compensation is also necessary for the change of resistance in the wires leading to the platinum spiral. This is commonly effected by balancing against these wires a pair of "dummy" wires similar to and laid alongside them. The instrument is usually provided with a suitably designed resistance bridge, such as the Callendar and Griffiths or the Mueller bridge; which for practical purposes should be portable and self-contained, with battery, galvanometer, balancing rheostat, etc., all in one case, and with a cable leading to the thermometer proper. The **bolometer** is a highly sensitive special type of resistance thermometer. (L.D.W.)

RESISTIVITY. Resistance.

RESOLVING POWER OF PHOTOGRAPHIC MATERIALS. The resolving power of a photographic material is usually expressed as the number of lines per mm. which are clearly defined as separate lines in the image. Resolving power is usually determined by photographing, with a well-corrected lens, a test object consisting of lines separated by a distance equal to the width of the line.

The resolving power depends principally on the emulsion varying with the range in the sizes of the silver halide grains, the thickness of the coating, its turbidity and color sensitizing. Other factors affecting the resolving power are:

1. The exposure. Resolving power tends to decrease with the exposure because of the increased spread of the image due to the scatter of light in the emulsion.
2. The contrast of the image. The resolving power tends to increase with the contrast of the subject.
3. The color of the exposing light. The resolving power varies with the color of the exposing light but not in the same way for all materials. At present no general statement can be made.
4. The developer. The composition of the developer, in general, does not appear to have a marked effect on the resolving power, but it varies with the developing time increasing to a maximum, then drops slightly and remains approximately constant.
5. Temperature of the developer. The resolving power appears to become less as the temperature of the developing solution increased.

The following values are for a subject with a contrast of 1:30, using a light source of 5400° K and development in a borax-type of developer except as noted.

	Lines per Mm.
High-speed pan film..........................	45
Fine-grain film.......	55
Positive motion-picture film...	70
Contrast-process film (contrast developer).......	130
Photomechanical film (contrast developer)......	200

Special emulsions of much higher resolving power have been made for special purposes. These are very slow, requiring from 10 to 20 times the exposure of bromide paper, but the resolving power is from 600 to 1000 lines per mm. (C.B.N.)

RESONANCE. Every physical system, in general, has one or more natural **vibration** frequencies characteristic of the system itself and determined by constants

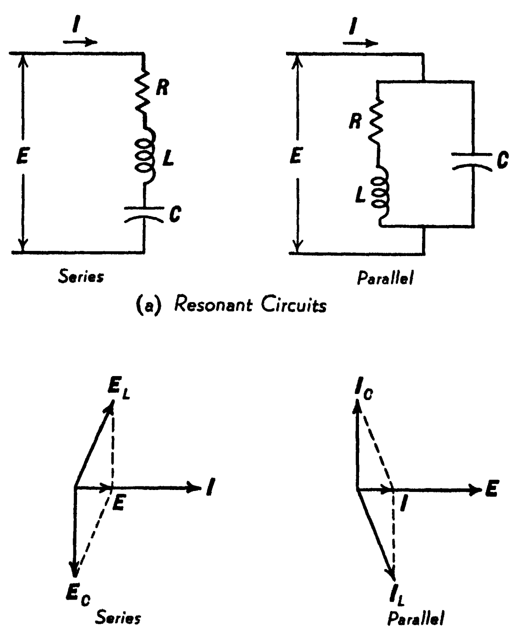
pertaining to the system. Thus a flexible string of length l and mass δ per unit length, and subjected to a tension f, will, if struck or plucked and left to itself vibrate with frequencies equal to $\frac{1}{2l}\sqrt{\frac{f}{\delta}}$ and to various integral multiples thereof (overtones). If such a system is given impulses with some arbitrary frequency, it will necessarily vibrate with that frequency even though it is not one of those natural to it. These "forced vibrations" may be very feeble; but if the impressed frequency is varied, the response becomes rapidly more vigorous whenever any one of the natural frequencies is approached, its amplitude often increasing many fold as exact synchronism is reached. This effect is known as resonance. Thus, if one sings a clear note in front of a piano (holding down the "loud" pedal), the string nearest in tune with that note gives an audible resonant response. Applications of the principle are very numerous; among them are the tuning of a radio receiving set to the carrier wave frequency of the broadcasting station, the amplification of musical sounds by resonators, as in a reed organ pipe, and the disproportionate response of **microphone** diaphragms to certain voice frequencies. The resonance is said to be highly selective if impressed impulses in exact synchronism bring much more energetic reponse than those slightly "off key"; sharp tuning of a radio receiver depends upon this condition. (L.D.W.)

RESONANCE DUCT. Jet Engine.

RESONANCE, ELECTRICAL. In an a-c circuit containing **inductance** and **capacitance** in series the **impedance** is given by:

$$Z = \sqrt{R^2 + \left[(\omega L) - \left(\frac{1}{\omega C}\right)\right]^2}$$

where R is the resistance, ω is 2π times the frequency, L is the inductance and C the capacitance. It can readily be seen that at some frequency the terms in the brackets will cancel each other and the impedance equals the resistance alone. This condition, which gives a minimum impedance (and thus a maximum current for a fixed impressed voltage) and unity **power factor,** is known



(a) Resonant Circuits

(b) Vector Relations

Fig. 1.

as series resonance. Where the resistance is small the current may become quite large. As the voltage drop across the **condenser** or coil is the product of the current and the impedance of that particular unit it may also become very large. The condition of resonance may even give rise to a voltage across one of these units which is many times the voltage across the whole circuit, being, in fact, Q times the applied voltage for the condenser and nearly the same for the coil. This is possible since the drops across the coil and condenser are nearly 180° out of phase and thus almost cancel one another leaving a relatively small voltage across the circuit as shown in Fig. 1*b*. For a circuit composed of an inductance unit in parallel with a capacitance the opposite effects of these two types of reactance will counteract one another at some frequency and produce unity power factor for the circuit. This is parallel resonance or antiresonance as it is sometimes called. In such a circuit the currents in the individual branches may be many times that in the line since they are out of phase and combine vectorially to give the line current. The impedance of a parallel resonant circuit is very high, its behavior being almost identical with that of the current in a series circuit if the Q of the parallel circuit is above 10. Fig. 2 shows a typical frequency-response curve for resonant

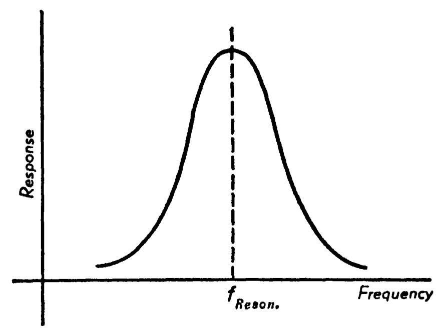


Fig. 2. Typical frequency-response curve for resonant circuit.

circuits, the ordinates being current for a series and impedance for a parallel resonant circuit. In series resonance the resonant condition is given exactly by the following expression which also holds for parallel resonance if the Q is high:

$$\omega L = 1/\omega C.$$

Both types of resonance are widely used in communication circuits to select certain frequencies in preference to others. An example is the tuning circuit of the radio **receiver.** (L.R.Q.)

RESONANCE RADIATION. It has long been known that when a gas or a vapor is traversed by light having the same wavelength as that corresponding to some line of the emission **spectrum** of the gaseous substance, a portion of that light is absorbed. It is this fact that gives rise to absorption spectra. (See **Atomic Spectra.**) R. W. Wood observed that if the gas is viewed from one side against a dark ground when traversed by such a beam, the path of the beam becomes visible as a luminous streak. In short, the gas is "excited" and emits this characteristic wavelength; but if the frequency of the incident light is slightly changed, the luminous streak disappears, which would not be so if the phenomenon were ordinary **scattering.** Until recently it was supposed that this re-emission of energy was an example of **resonance,** namely, that the atom was set into resonant oscillation by light waves having one of its own natural frequencies, and that thereupon it became an emitter of the same frequency. Hence the term "resonance radiation."

This view can no longer be supported. For example, Wood used the yellow D radiation of sodium,

the wave number (reciprocal wavelength) of which is 16973/cm., and got resonance radiation of the same kind. But Strutt excited the sodium vapor with the second line of the sodium series, wave number 30273 (in the ultra-violet), and found that the resulting secondary radiation consisted of both frequencies. Since the ratio of two wave numbers, 16973 to 30273, is not a simple fraction, the excitation of the former by the latter cannot be explained as resonance. The **quantum theory** avoids the difficulty. From that standpoint a 30273 photon excites the atom to its 30273 or 2Π energy level. In returning to its ground state the atom emits its 30273 spectrum line; but some atoms may first return to the 1Π state, to which the 16973 D radiation would have raised them, and then drop to the ground state from there, emitting the D radiation observed. For some reason the drop from the 30273 to the 16973 level does not result in observable radiation, which would be of wave number 13300, in the extreme red. Instead, that part of the energy seems to be converted directly into heat. Resonance radiation appears to be a species of fluorescence, except that it may take place with no change of frequency. (See **Luminescence.**) (L.D.W.)

RESONANT LINES. **Lines.**

RESORCINOL. **Phenols.**

RESPIRATION. The process of securing **oxygen** from the surrounding air or water and combining it with materials in the body for the release of energy.

Some animals secure oxygen by diffusion through the walls of the body while others are provided with special organs for its absorption, constituting a respiratory system. In either case the oxygen is dissolved in the fluids of the body in reaching the **tissues.** Transportation of oxygen to the various parts of the body may also be accomplished by diffusion in small and simple forms. In the insects and some other **arthropods** it is brought about to a considerable degree by the branching air tubes (tracheae) through which air is taken into the body. **Annelid** worms, **phoronids, mollusks,** vertebrates, and possibly a few other invertebrate forms have respiratory pigments in the blood which combine with oxygen for transportation. The more common pigments are a copper compound, haemocyanin, and an iron compound, haemoglobin. They unite with oxygen readily and give up oxygen as readily to the tissues.

In animals with special respiratory systems some muscular movement is necessary to bring fresh supplies of air or water to the surfaces which absorb oxygen. In the terrestrial forms these are the movements of breathing. Insects extend and retract the walls of the abdomen to take in and discharge air, respectively. Mammals elevate the ribs and contract the diaphragm during inspiration, and when the muscles are relaxed expiration takes place. Fishes swallow water and divert it through the **pharyngeal clefts,** where it bathes the **gills** in passing. Other animals carry on respiratory movements appropriate to their own structure.

The intake and transportation of oxygen constitute external respiration. Once the gas reaches the tissues it is available for the **oxidation** of energy-bearing compounds in the process of internal respiration. This union is accomplished through the action of **enzymes.**

The products of oxidation are partly eliminated from the body by the respiratory system, although this phase of respiration is an excretory function. (A.W.L.)

RESPIRATION IN PLANTS. Except in actively photosynthesizing tissues (see **Photosynthesis**) plant organs are continuously using oxygen from and releasing carbon dioxide to the atmosphere. These gaseous exchanges are the usual external manifestations of the process of respiration which, with respect to plants, is usually defined as the oxidation of foods in plant cells. Hexose sugars are the foods most commonly oxidized in plant cells, the chemical equation for the process being:

$$C_6H_{12}O_6 + 6O_2 \rightarrow 6CO_2 + 6H_2O + 673 \text{ kg. cal.}$$

This process is the exact opposite of photosynthesis. Green parts of plants also carry on respiration, but when they are exposed to conditions favorable to photosynthesis this process goes on much more rapidly than respiration so that the net gaseous exchanges of the plant are the opposite of those which occur in respiration. In the dark, however, green plant tissues lose carbon dioxide and use oxygen just as non-green tissues do in either light or dark.

Less commonly other kinds of foods, such as fats and proteins, may be oxidized in plant cells. When sugars are oxidized the respiratory ratio (ratio of volume of carbon dioxide released to volume of oxygen absorbed) of the tissue is 1, when fats are oxidized it is about 0.8, and when proteins are oxidized about 0.9. When certains kinds of organic acids are oxidized the respiratory ratio is greater than one. This is also true when part or all of the respiration is of the anaerobic type (see below).

The essential biological significance of respiration is that a part of the energy released is used in the maintenance of metabolic processes and in growth. A considerable part of the energy is usually released as heat, however, and passes out of the plant body without any significant effect upon its metabolism. Release of heat energy in the respiration of plants can easily be demonstrated by placing a mass of germinating seeds in a thermos bottle and determining the temperature rise of the mass with a thermometer. All of the energy released in respiration represents radiant energy of sunlight which was trapped as chemical energy in sugar molecules during the process of photosynthesis.

The rate of respiration varies greatly from one kind of plant tissue to another. In general it is greatest in young, growing tissues such as germinating seeds, root tips, opening buds, or expanding flowers, and least in dormant or senescent tissues such as dry seeds or spores, or ripe fruits. The principal environmental factor affecting the rate of plant respiration is temperature. Within the approximate range of 0°–45° C. the rate of respiration approximately doubles for each 10° C. rise in temperature.

The foregoing discussion refers primarily to aerobic respiration which is the term used to designate respiration occurring at the expense of atmospheric oxygen. Another type of respiration occurring in plants is *anaerobic respiration.* A familiar example of such a process is alcoholic fermentation. This process ensues when a dilute sugar solution becomes inoculated with yeast cells:

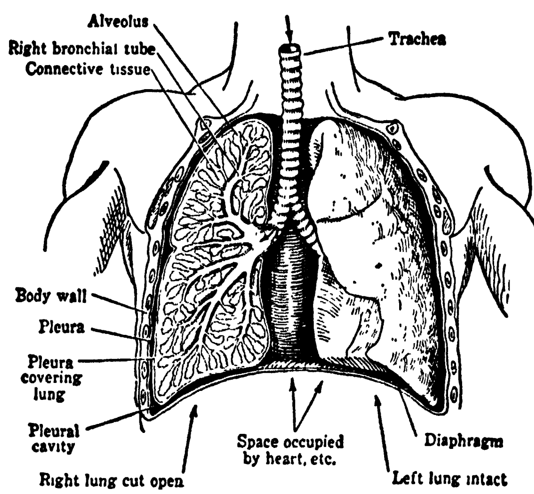
$$C_6H_{12}O_6 \rightarrow 2C_2H_5OH + 2CO_2 + 25 \text{ kg. cal.}$$

Alcoholic fermentation can proceed in the complete absence of oxygen; it is the process by which yeast plants obtain most of the energy used in metabolic processes. In the higher plants anaerobic respiration is a much less important process than aerobic respiration. The tissues of higher plants vary greatly in their capacity to tolerate anaerobiosis. Many such tissues are injured if deprived of oxygen for more than a few hours. Others, such as apple or pear fruits, can be kept in an atmosphere of pure nitrogen or hydrogen for months without injury and continue to release carbon dioxide all the while. Some seeds and grains such as those of the pea, oat, and sunflower have coats which are impermeable to oxygen, hence they carry on anaerobic respiration during the early stages of germination. Likewise the skin of the grape and some other fruits is impermeable to oxygen and considerable anaerobic respiration occurs in such organs. (B.S.M.)

RESPIRATORY SYSTEM. The assemblage of organs by which air or water is brought into contact with **tissues** which can absorb part of its contents of **oxygen.**

Many animals absorb oxygen through the surface of the body. This is particularly true of small and simple forms, but the skin of the **earthworms** and that of some **amphibians** absorb all of the oxygen required by the animals, and any moist skin may absorb small quantities. The simplest modification to be introduced as a respiratory system is some extension of the surface to provide for the needs of a more bulky body. Tufted or thin plate-like structures called **gills** project into the water from the surface of many aquatic animals. Such structures are not adapted for air-breathing because their epithelium must be moist for the ready passage of oxygen and their extensive surface favors drying when exposed to air.

In aquatic insects gills contain gas-filled tubes (**tracheae**) and are known as tracheal gills, but in most animals the blood or body fluids circulate through them. Gills of this kind are found in many **annelid** worms and in the **crustaceans.** In the latter group they are sometimes protected by a fold of the body wall. This fold encloses them in a chamber through which water is propelled by special appendages.



Respiratory system. (*Hegner's College Zoology, Macmillan.*)

In many terrestrial **arthropods** the respiratory system consists of air tubes or tracheae, metamerically arranged. In the primitive state each segment contains a pair of tracheae opening to the surface of the body separately through small pores called spiracles or stigmata. The openings are usually guarded by some closing device or by a grating formed from the **cuticula.** The tracheae have coiled **chitinous** filaments (taenidia) in their walls which keep them distended, and at their inner ends they communicate with finer tracheoles which lack these filaments. These fine tubules lead to the various tissues of the body, although oxygen probably passes from them into the body fluids, rather than directly to the cells. The gas-filled tubes form a closed system in aquatic insects. In these forms the oxygen content is renewed by diffusion from the surrounding water in tracheal gills, as mentioned above.

Spiders have a pair of lung books formed of many thin leaves in depressions in the abdomen. Blood circulates in these leaves and air between them.

The respiratory system of **vertebrates** is associated with the **pharynx.** In primitive **chordates, cyclostomes,** fishes (**Pisces**), and larval **amphibians** the gill slits persist along this passage, so that water taken into the mouth may be expelled from the pharynx without being swallowed. Finely divided blood vessels in the walls of the pharynx or in special outgrowths known as gills along the walls of the pharyngeal clefts receive oxygen from the water as it flows over these surfaces.

In some fishes and in terrestrial vertebrates generally, a saccular outgrowth of the ventral wall of the pharynx forms lungs for the reception of air. In the simplest forms the outgrowth branches to form two sac-like lungs. In more complex lungs the surface is increased by ridges projecting into the cavities from their walls, and in the most highly developed organs of this type there are many minute chambers (alveoli) in a spongy mass of tissue containing muscle and elastic fibers. The original connection with the pharynx persists, leading into a single tube, the trachea, supported by cartilage rings. The principal branches of the trachea are the **bronchi** or bronchial tubes. They lead into finer bronchioles whose branches communicate with the alveoli. (A.W.L.)

RESPIRATORY TREE. A branching diverticulum of the **cloaca** of sea cucumbers (**Holothuroidea**). The structure extends into the body cavity. Contractions of the cloaca pump water through the pair of respiratory trees to the thin-walled ampullae with which they end, thus supplying **oxygen** to the fluid in the body cavity. (A.W.L.)

REST MASS. **Relativity.**

RESTRAINED BEAM. **Fixed Beam.**

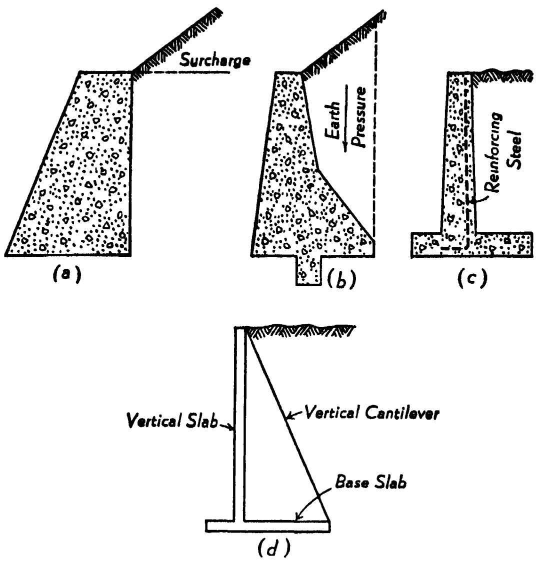
RESTSTRAHLEN. **Residual Radiation.**

RESULTANT. In **stress** analysis the resultant is a single vector quantity which will have the same effect on the equilibrium of a body as two or more vector quantities which it replaces. If these latter vectors are parallel the resultant is the scalar sum of these vectors, but if they are not parallel the addition must be made vectorially. (See **Vector and Mechanics.**) (C.W.C.)

RESURGENT. A term proposed by R. A. Daly, in 1908, for **juvenile** gases and vapors which are derived from the assimilated fragments of the intruded rock. These gases may play an important role in the formation of deep-seated **igneous rocks,** or may escape as **magmatic** emanations. (R.M.F.)

RETAINING WALL. A retaining wall is a structure for supporting loose material at an angle greater than its natural **angle of repose.** Usually a retaining wall is of concrete construction, and used to retain a bank of earth. The three principal types of retaining walls are illustrated. They are the simple trapezoidal section with vertical loaded face, the section with earth pressure aiding masonry weight, and the cantilever retaining wall. The successful retaining wall must be built so that it will neither slide on its base under horizontal pressure, nor tip over. The pressure of the earth is, of course, variable, depending on its composition and moisture content. If the earth back of the wall is well drained, so that its moisture content is a minimum, it will possess more cohesion, and exert less overturning pressure against the wall. The retaining wall may, in some cases, have to be designed to withstand pressures of a surcharged embankment having a slope of at least the natural angle of repose. The stability of a solid masonry section, such as that in (a) may be determined in much the same way as that for gravity masonry **dams,** except that earth pressure is not so directly and definitely computable as water pressure. The section shown in (b) will need less masonry because its shape causes it to make use of some of the vertical weight of earth as a stabilizing earth pressure. Also, it is keyed into the ground so that the resistance to sliding is greatly increased. A cantilever retaining wall, shown in

(c), is the one with a minimum of masonry, but, because its resistance to overturning is obtained by bending action, internal moments are developed which require that this type of wall be reinforced with steel.



Retaining walls.

A counterfort retaining wall (d) is made up of a continuous vertical slab which is connected to a continuous horizontal base slab or footing and supported at intervals by vertical cantilevers (counterforts), which rest on the base slab. The earth pressure is carried by the vertical slab, which transfers this load by beam action to the vertical cantilevers. Since concrete is weak in **tension**, the sections of this type of wall must be properly reinforced with steel rods. (F.T.M.)

RETARD COIL. This is the term commonly used in **telephony** to denote a **choke coil.** (L.R.Q.)

RETICLE. A reticle is a set of two or more fine wires placed at the principal focus of a **telescope** lens. The reticle wires are usually sections of spider web or some equally fine fiber. In accordance with the fundamental principle of telescope construction this reticle must be in the principal focus of the **eyepiece,** and when the telescope is directed on an object both the image and the reticle will be in clear view in the eyepiece.

The simplest form of reticle is two perpendicular wires so placed that their point of intersection is on the collimation axis of the telescope. In this case, when an object appears to be on the intersection of the wires the telescope is pointing directly at the object. This is the type of reticle found in telescopic gun sights. Other types of reticles are described under such instruments as the **meridian circle** and the **zenith telescope.**

For convenience in measuring small angles with a telescope the reticle wires are frequently so spaced that two points in a distant object apparently separated by the distance between the reticle wires will subtend some particular angle (e.g., 10 seconds of arc, or 1 minute of arc). Reticle wires so spaced are commonly known as "stadia lines" and are frequently found in the telescopes of sextants, field glasses, or surveyor's instruments. (W.K.G.)

RETICULO-ENDOTHELIAL SYSTEM. A group of mononuclear cells which are primarily **phagocytes.** They are distributed throughout the body in the spleen, liver, lymph nodes and bone marrow. In addition to phagocytosis, the reticulo-endothelial cells are concerned with blood cell formation, bile formation, and iron and pigment metabolism. (D.M.H.)

RETINA. The sensory layer of the camera **eyes** of mollusks and vertebrates. The retina of the human eye includes a layer of nerve fibers on the inner surface which converge to the optic nerve, and various cellular and fibrous layers. Numbering from the inner layer of nerve fibers these are an inner reticular layer, an inner nuclear layer, an outer reticular layer, Henle's fiber layer, the outer nuclear layer, a limiting membrane, the layer of rods and cones, and the pigmented layer. The rods and cones are characteristically shaped sensory cells which are sensitive to light. (See **Vision.**)

The retina is involved in disease by inflammatory processes, especially in **diabetes, kidney** disease, and **syphilis,** and by circulatory changes and hemorrhages in **anemia, arteriosclerosis,** hypertensive cardiovascular renal disease, and **thrombosis.** Detachment of the retina from the underlying layer is very serious, and complete blindness is a usual termination. Tumors may also occur, notably the pigmented tumor, malignant melanoma (see **Tumors**). (A.W.L., D.M.H.)

RETINULA. A visual element of the **eyes of arthropods.** The retinula consists of a group of cells containing pigment and a central rod, the rhabdom, formed by the cells. It is sensitive to light. In the compound eye each ommatidium contains a single retinula, but in simple eyes a group of retinulae lie beneath the single lens. (A.W.L.)

RETOUCHING. Negative retouching includes in the broadest sense all corrective work on the negative, such as spotting, removal of backgrounds by outlining with an opaque paint or bleaching out, and the application of dyes for local alteration in density, although the term retouching is often in practice restricted to corrective work on portrait negatives with a pencil.

The removing of a background on a negative by painting over it with an opaque paint is known as *blocking-out.* The first essential is a good desk. A large, flat, glass surface is required. The glass plate may be flat or inclined at an angle and should be illuminated with diffuse light from above as well as below, as it is important to be able to see the surface of the negative as well as to see through it.

A few good sable brushes of various sizes, a jar or tube of opaque, a drawing pen, a straight-edge, preferably of metal, and a celluloid draftsman's curve complete the necessary accessories.

Where the subject contains a number of straight lines it is well to rule these with a draftsman's ruling pen, starting with the horizontal lines and ruling all of these first, then the vertical lines. Many of the curves may be ruled in by using the draftsman's curve; those which cannot, must be filled in freehand with a small brush. In using the brush, it is essential, if clean work is to be expected, that the hand should not be cramped. A free, rather flowing motion of the hand from left to right and away from the body, using the fingers underneath the brush as a sliding pivot, leads to smooth, clean work.

To obtain a black background, the subject is covered with a transparent but waterproof varnish which can be obtained from photographic dealers. When the varnish is dry, the negative is immersed in a reducing solution, usually ferricyanide-hypo, or permanganate, and the background removed.

A convenient method of increasing density locally is by the application of a dye solution. A yellow-orange dye, known as neo-coccine, is usually recommended for the purpose as it is readily absorbed by gelatin and may be removed by washing in water if a mistake is made. Naphthalene black has the advantage of cor-

responding more nearly with the color of the silver deposit, so that it is less difficult to determine when the proper density has been reached. In any case the dye should be applied in a dilute form with a water-color brush and the density built up by successive applications.

Retouching of portrait negatives has as its purpose the removal of freckles and other skin blemishes, subduing over-prominent lines and softening harsh contrasts to improve the modelling. The area of the negative to be retouched is first covered with a resin varnish to retain the lead, after which a moderately hard lead pencil (2H or 3H) sharpened to a fine point is used to fill in the spots. When the spots due to freckles or other skin blemishes have been filled in, any sharp lines are filled in and harsh lines around shadow areas are blended so as to be less abrupt and harsh. (C.B.N.)

RETRACTOR. A muscle which pulls an eversible or extensible part back to its normal resting position in the body. In the starfishes (**Asteroidea**) a pair of muscles in each ray, attached to the pouches of the stomach, serve as retractors for that organ, and in the mussels retractors draw the foot back into the mantle cavity when the animal closes its shell. (A.W.L.)

RETROGRADE MOTION. Planetary Motions.

RETRO-VERSION. Uterus.

REVERBERATION. Acoustics.

REVERBERATORY FURNACE. A metallurgical furnace in which the charge, lying in a shallow hearth, is heated by flame passing over its surface and by radiation from a low roof. (R.H.H.)

REVERSAL OF STRESS. Cycle of Stress.

REVERSE BEARING. Bearing.

REVERSE FAULT. Fault.

REVERSIBLE PROCESSES. Some physical processes are of such a nature that if they are made to take place backward, that is, to go through the same stages in reverse order, the corresponding transfers of energy at each stage are reversed in direction but not in amount. Such processes are briefly characterized as "reversible." Thus a gas may have its density ρ and pressure p increased without any change in temperature (an isothermal compression). This is shown by the curve AB in Fig. 1. It necessitates the removal of heat exactly as

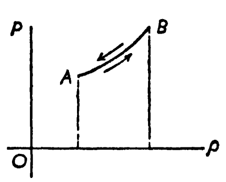


Fig. 1. Reversible pressure-density change in a gas.

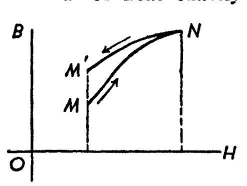

Fig. 2. Irreversible induction-intensity change in iron.

fast as it is generated by the work of compression. The process may, in theory at least, be duplicated in reverse, so that BA coincides with AB, by allowing the gas to expand and restoring the withdrawn heat energy just as fast as needed to keep the temperature constant. Each change of a **Carnot cycle** is likewise reversible.

On the other hand, consider the magnetization of iron, represented by the B-H (induction-intensity) curve MN in Fig. 2. If, after increasing the magnetization of iron until its condition reaches the stage N, the intensity of the magnetizing field is reduced, no amount of care will avail to make the curve retrace itself. The iron persists in retaining some of the energy that was imparted to it, and returns along NM' to a condition, represented by M', of higher magnetic induction than at first. Magnetizing iron is therefore an irreversible process. (L.D.W.)

REVERSIBLE REACTIONS. Equilibrium.

REVERSING LAYER. The lower part of the sun's atmosphere is frequently referred to as the reversing layer. It is a gaseous layer which is cooler than the **photosphere,** only a few hundred miles in thickness, and gradually merges into the **chromosphere.** The reversing layer receives its name because it is in this region of the sun that the thousands of dark lines in the solar **spectrum,** commonly known as the **Fraunhofer lines,** are produced. As a result of a tremendous amount of research on the identification of the Fraunhofer lines, it is confidently believed that they are all due to elements which are to be found on the earth. These elements are reduced to the gaseous state in the reversing layer because of the tremendous heat from the photosphere. (W.K.G.)

REVERSION. The appearance in an organism of hereditary characters which were not present in its parents but were found in previous generations. The term has been interpreted as the skipping of one generation, a condition more accurately known as atavism, but these two terms are essentially synonymous. The reappearance of characters after one or several generations is made entirely clear by the facts of **heredity.** (A.W.L.)

REYNOLDS CRITERION. Important information as to the behavior of fluid flow was secured experimentally by Reynolds, and the results of his work are important to many fields including heat transfer, hydraulics and aerodynamics. The critical velocity range above which a liquid flow will be turbulent, below which it will be viscous, and in which it may be either viscous or turbulent, depends upon the velocity of flow, the size or shape of the conduit, and the viscosity of the liquid. This latter property varies, of course, with the liquid and with its temperature. Reynolds established the fact that the ratio of

$$\frac{\text{fluid velocity} \times \text{hydraulic radius}}{\text{kinematic viscosity}}$$

was the same for all liquids at the critical velocity. The ratio just given is known as the Reynolds criterion. In the field of aerodynamics, a similar ratio is known as the Reynolds number. In the case of an airfoil, it is

$$\frac{\text{air velocity} \times \text{chord of the airfoil}}{\text{kinematic viscosity of the air}}.$$

These two ratios are valuable in their respective fields because tests of models are directly comparable to full scale results of geometrically similar shapes if the Reynolds ratio for the model equals that of the actual or full scale project. This has its practical applications in the field of **hydrodynamics** in the study of water resistance of hulls or floats, and in the study of water velocities, levee problems, etc., of large rivers. It is used also to establish the best proportions of hydraulic turbines through the use of models. Much of the science of **aeronautics** rests upon experimental data obtained in **wind tunnels.** Dangerous inaccuracies might exist in drawing conclusions for actual construction from model tests, unless either the model were tested at a Reynolds number equal to that of the completed project, or due corrections and allowances were made for the Reynolds number. (F.T.M.)

REYNOLDS GROUP. Heat Transfer.

REYNOLDS NUMBER. The **Reynolds Criterion** of hydrodynamics is called Reynolds number in the aerodynamic field.

$$R.N. = \frac{Vl}{\nu}$$

V = Air velocity.
ν = Kinematic viscosity of the air.
l = Some significant dimension of the object, in the direction of air flow such as the chord of an airfoil, diameter of a sphere, length of a plate, etc.

(See **Aerodynamics, Airfoil, Boundary Layer, Burble, Wind Tunnel.**) (F.T.M.)

RF. **Radio Frequency.**

RH FACTOR. **Blood Grouping.**

RHABDITE. A crystalline rod-shaped body found in the cells covering the body of **turbellarian** flatworms. They are formed in cells lying between or just below the ectodermal cells, from which they migrate to the outer cells. They have been interpreted as defensive structures but the exact nature of their functions has not yet been established. (A.W.L.)

RHABDOCOELIDA. **Turbellaria.**

RHABDOM. **Eye. Retinula.**

RHABDOMERE. A segment of a **rhabdom** when it is made up of clearly distinguishable parts. (A.W.L.)

RHAGON. **Porifera.**

RHEA. Aves, Rheiformes. *Rhea.* Large flightless birds (**Aves**) of South America. They are called the American ostriches but differ from the true ostriches in the fully feathered head and neck, the longer wings, and the lack of a tail. There are three toes on each foot. (A.W.L.)

RHEBOK. Mammalia, Artiodactyla. *Pelea.* A small **antelope** found in hilly sections of eastern and southern Africa. It has been compared with the chamois in habits. (A.W.L.)

RHEIFORMES. The rheas. An order of birds containing only the few South American species of this name. They resemble the ostriches but differ in details of structure mentioned under **rhea.** (A.W.L.)

RHENIUM. Symbol: Re. Atomic number: 75. Atomic weight: 186.31. Density of metal powder: 10 (approx.). Melting point: 3000° C. Isotopes: 185 (38.2%), 187 (61.8%).

Rhenium is a platinum-white, very hard metal; stable in air below 1000° C.; practically insoluble in **hydrochloric acid** or **hydrofluoric acid,** but soluble in **nitric acid** with the formation of perrhenic acid; forms sodium rhenate when fused with **sodium** hydroxide and nitrate. Discovered by Noddack and Tacke in 1925 in **tantalite, wolframite,** and **columbite** by the Moseley **x-ray** spectrographic method of analysis, and later found present in **molybdenite,** from which rhenium is obtained. Predicted by Mendeléeff in 1871 as an element to be discovered with properties resembling **manganese,** and named by him dvi-manganese.

Rhenium is obtained from molybdenite by dissolving in nitric acid, precipitating molybdenum as phosphomolybdate, and from the filtrate recovering rhenium as sulfide by **hydrogen sulfide** (1% Re in the product). This product is oxidized and the sublimate of rhenium heptoxide is later reduced to rhenium metal by heating in hydrogen.

Chloride: Rhenium tetrachloride ($ReCl_4$), black liquid, boiling point 500° C.

Oxides: Rhenium dioxide (ReO_2), black solid; trirhenium octaoxide (Re_3O_8), blue solid; rhenium trioxide (ReO_3), red solid; rhenium heptoxide (Re_2O_7), yellow solid; rhenium tetroxide (ReO_4), white solid; all by burning rhenium in a current of **oxygen** gas.

Perrhenate: Potassium perrhenate ($KReO_4$), stable in acid solution, reduced in acid medium by iodide but not by sulfide.

Rhenate: Sodium rhenate (Na_2ReO_4), yellow solid, soluble, stable in alkaline solution.

Sulfides: Rhenium disulfide (ReS_2); rhenium heptasulfide (Re_2S_7), black solid, by reaction of perrhenate solution and hydrogen sulfide.

Rhenium compounds color the bunsen flame pale green. (R.K.S.)

RHEOSTAT. A rheostat is a variable **resistance** used for operation or control of electrical equipment. Rheostats might be classified as metallic, carbon, and electrolytic types. The most common form is the metallic type, in which the resistance is in the form of a metal wire or ribbon, or cast grid, these being made of a metal having poor conductivity, and little deterioration from heating. The variable resistance of metallic rheostats is obtained by bringing out taps from different points of the resistance wire to the points of a multi-pointed switch which can be used to short-circuit different sections of the resistance. Laboratory rheostats are frequently coils of resistance wire wound closely on an insulating cylinder and provided with a sliding contact finger which will bear on the wires themselves, and which can be employed to short-circuit any desired number of turns of the resistance wire.

A carbon rheostat is made of granules or carbon plates held in a frame. The resistance of carbon to flow of **electric current** varies with the pressure on it, and so by providing the rheostat with a screw clamp or other means of changing the pressure, the resistance is made variable. This type of resistor is seldom used with other than small currents. On the other hand, **electrolytic** rheostats are well adapted for large currents. They consist of a tank or barrel containing a solution of salt or acid into which are dipped **electrode** plates. The electrode plates should not be of a metal which is attacked by the solution. The energy is dissipated in heat in the solution, which boils it, so that the heat is ultimately liberated by vaporization of the solution. Since water is capable of absorbing nearly 1000 B.T.U. per lb. if vaporized, it is readily seen why this type of rheostat can be used for large currents. These are sometimes called water rheostats. There are many and varied uses for rheostats, and in many cases where resistances are used some degree of variability of the resistance is desirable. A few of the applications of rheostats are: for starting or controlling the speed of motors, for adjusting the field strength of generators, for varying the circuit characteristics of radio receivers, for testing electrical equipment by interposing variable artificial loads for dimming lights, and for adjusting current flow of any description. (F.T.M.)

RHEUMATIC FEVER (Acute Rheumatic Fever. Acute Articular Rheumatism. Acute Rheumatism). A disease of unknown origin, closely associated with invasion of the body by hemolytic **streptococci.** Rheumatic fever is most prevalent in the north temperate zone. It has been estimated that 170,000 new cases per year occur in the United States, and 840,000 individuals in the United States have **rheumatic heart disease.** The disease attacks children and young adults primarily. It is rare in infancy, appears in children about 5 years of age, and has a peak incidence at 9–11 years, falling off gradually in adult life.

Although the exact cause of rheumatic fever is unknown, certain predisposing factors are well established. The disease tends to be familial and some believe that the predisposition is inherited as a Mendelian recessive (see **Heredity**). Multiple cases in a family are common. The poor are more susceptible than the well-to-do, probably because of such factors as crowding, cold, dampness, and malnutrition which are conducive to the spread of respiratory infections and therefore hemolytic streptococci.

The acute attack of rheumatic fever often begins with sore throat and tonsilitis. Fever, joint pains with redness, swelling and tenderness of the affected joints follow. The arthritis is characteristically migratory, one joint after another being involved acutely but briefly, and healing without residual symptoms or signs. The heart may or may not be involved in the original attack. Rapid pulse rate is common and the appearance of **murmurs** is indicative of heart damage. Acute **pericarditis** may also occur. Other manifestations of rheumatic fever are **pleurisy, pneumonia** and **subcutaneous** nodules. **Chorea** is generally believed to be a specific rheumatic involvement of the brain.

The pathological pattern of rheumatic fever consists of multiple microscopic nodules showing a characteristic type of **inflammation**. In the heart, these are called Aschoff bodies. They occur throughout the heart muscle and on the heart valves, particularly the mitral and aortic valves. In other organs and tissues, similar tiny granulomas appear.

The course of acute rheumatic fever is dramatically modified by the use of salicylates (aspirin). On such medication, the fever drops, and joint signs disappear rapidly. The patient may then go on to complete recovery, or he may be left with residual **rheumatic heart disease**. In either case he is subject to recurrent attacks of acute rheumatic fever. These can be decreased in number or even eliminated completely if hemolytic streptococcal infections can be prevented. (D.M.H.)

RHEUMATIC HEART DISEASE. It is estimated that approximately 25% of children with **rheumatic fever** develop permanent heart damage. The average life expectancy in this group is roughly 13 to 15 years; if the disease occurred early in childhood, the duration may be much shorter. Rheumatic heart disease is thus an important cause of death in children and young adults.

Rheumatic heart disease which persists after the acute inflammation has subsided is due to fibrosis and scarring of the heart valves. The mitral valve is affected in almost every case; both mitral and aortic valves are involved in about one third of all cases. The patient may have no symptoms of heart disease until years after his acute rheumatic fever. During these years, his heart is under a mechanical disadvantage because of insufficiency of the valves, or constriction (stenosis) of the valve openings, or both. When the strain can no longer be withstood, **heart failure** of the congestive type supervenes. Until the signs and symptoms of failure appear, the patient is said to have inactive rheumatic heart disease. (D.M.H.)

RHEUMATISM. **Rheumatic Fever.**

RHEUMATOID ARTHRITIS. **Arthritis.**

RHINENCEPHALON. The portion of the vertebrate **brain** with which the **olfactory** nerves are connected. It is the lower part of the telencephalon. (A.W.L.)

RHINITIS. Inflammation or infection of the mucous membrane of the nose. The common head cold is primarily a rhinitis, as is **hay fever**. (See **Coryza**.) (D.M.H.)

RHINOCEROS. Mammalia, Perissodactyla. *Rhinoceros.* A large animal of the Oriental region or Africa, with rather short legs and a long muzzle bearing one or two conical horns behind the nostrils. There are four species in the Oriental region and two in Africa. The common African species stands almost 6′ high at the shoulder and has an anterior horn over 3′ long. Because of its thick skin it can be killed only by carefully placed shots. All of the rhinoceroses are described as dull and timid animals but when brought to bay they are aggressive, and because of their great size they are dangerous opponents under some conditions. (A.W.L.)

RHINOPHORE. A posterior tentacle of **olfactory** function in some of the marine mollusks (**Gasteropoda**, Opisthobranchiata). These forms have two pairs of tentacles. Those of the posterior pair have a simple eye at the base and bear organs of the sense of smell. (A.W.L.)

RHIZOIDS. Rhizoids are filamentous outgrowths from the surface, or from epidermal cells, formed of one or many cells, which serve to hold the plants of **mosses** and hepatics or the prothallia of **ferns** to the substratum. Similar structures occur in the **thallophytes**. (R.M.W.)

RHIZOME. A rhizome or rootstock is a horizontal stem growing beneath the surface of the ground or at times, at the surface. It has all the characteristics of a **stem**, such as nodes and internodes, leaves and branches. Often the rhizome is very much enlarged and contains much reserve food material. (R.M.W.)

RHIZOSTOMAE. **Scyphozoa.**

RHODESIAN MAN. **Paleontology of Man.**

RHODIUM. Symbol: Rh. Atomic number: 45. Atomic weight: 102.91. Density: 12.44. Melting point: 1985° C. (**Isotopes**: page 290.)

Compact rhodium is a white metal, almost insoluble in acids, including **aqua regia**, and is attacked by **chlorine**, by hot concentrated sulfuric acid, and by fused **potassium** bisulfate. Discovered by Wollaston in 1804. Rhodium metal is used chiefly as an alloy with **platinum**, resulting in a hard, durable alloy. Such an alloy (10% Rh) is used as catalyst in the oxidation of ammonia by oxygen (air), and in conjunction with pure platinum in a **thermocouple** for the measurement of high temperatures. Rhodium itself is used as a plating finish for silverware, and as a mirror surface in searchlights.

Rhodium occurs native in platinum ores, sometimes to the extent of 2%. When **osmium** and **ruthenium** are present, they are removed as volatile oxides; when platinum and **iridium**, by precipitation of the ammonium chloro-compound; insoluble in alcohol, upon addition of ammonium chloride; and when **palladium**, by the precipitation of the ammonium chloro-compound with **ammonium** chloride and **chlorine**. Rhodium remains in the solution in each case, and is precipitated by the addition of a reducing agent, such as **titanium** trichloride, as rhodium metal.

Hydroxide: Rhodium hydroxide ($Rh(OH)_3$), yellow precipitate, by solutions of hydroxides, *e.g.*, **sodium** hydroxide), soluble in excess of the reagent.

Alum: (See Sulfate, below.)

Chloride: Sodium rhodium chloride ($Na_3RhCl_6 \cdot 12H_2O$), dark red crystals, by ignition of oxide with **sodium** chloride and **chlorine** and crystallizing from water.

Oxides: Rhodium sesquioxide (Rh_2O_3), black; rhodium dioxide (RhO_2), brown.

Sulfates: Potassium rhodium alum ($K_2SO_4 \cdot Rh_2(SO_4)_3 \cdot 24H_2O$); potassium rhodium sulfate

($K_2Rh(SO_4)_3$), rose-colored crystals, by ignition of oxide with potassium bisulfate and crystallizing from water. (R.K.S.)

RHODOCHROSITE. Rhodochrosite, **manganese** carbonate, $MnCO_3$, is a rose-pink to red **hexagonal** mineral, occurring as small crystals, in cleavable masses, granular or compact. It is a brittle mineral; hardness, 3.5–4.5; specific gravity, 3.3–3.6; luster, vitreous to pearly; color, various shades of pink, red and reddish-brown; transparent to opaque; streak, white. Rhodochrosite has a perfect **rhombohedral** cleavage. Rhodochrosite is formed by replacement and is found as well in sedimentary deposits precipitated like **siderite** by organic matter acting, in the absence of oxygen, upon bicarbonates. It may occur also as a **gangue** mineral. Localities for this mineral are in Rumania, Saxony, Westphalia, and Cornwall, England. In the United States rhodochrosite is found at Franklin, New Jersey; Butte, Montana; and in various localities in Colorado and Nevada. The name rhodochrosite is derived from the Greek meaning rose, and color. (E.S.C.S.)

RHODODENDRON. **Heath Family.**

RHODONITE. The mineral rhodonite, **manganese metasilicate**, $MnSiO_3$, is a triclinic pyroxene forming large, irregular, tabular crystals but usually occurring massive. Prismatic and basal **cleavages** excellent; fracture, conchoidal to uneven; hardness, 5.5–6.5; specific gravity, 3.4–3.7; luster, vitreous to pearly on cleavage faces; color, red to pink and occasionally greenish or yellowish shades; streak, white; transparent to translucent. A variety containing much **calcium** is called bustamite. **Zinc** may replace the manganese in rhodonite; it is then known as fowlerite. Rhodonite is found in the Harz Mountains, Germany; in the Urals of Russia; in Hungary, Italy and Sweden. Bustamite from Mexico, Franklin and Sterling Hill, New Jersey, occurs with **fowlerite.**

Rhodonite has been occasionally used for an ornamental stone. Its name is derived from the Greek meaning a rose, because of the color. (E.S.C.S.)

RHOPALIUM. **A tentaculocyst.**

RHUBARB, PIE PLANT. *Rheum Rhaponticum.* Polygonaceae. The rhubarb plant is perennial from thick short **rhizomes.** The large somewhat triangular leaf blades are elevated on long fleshy **petioles.** The flowers are small, greenish-white and borne in large compound leafy **inflorescences.** The plant is principally grown for its fleshy petioles. These are stewed to yield a tart sauce used as filling for pies and tarts. The plant is indigenous to Asia.

From the rhizomes and roots of another species, *Rheum officinale,* or Medicinal Rhubarb, also native to Asia, is prepared the drug Rheum, used as a strong cathartic, and for its tonic effect on the mucous lining of the nasal cavity. (R.M.W.)

RHUMB LINE. Unless a ship is tacking or executing some other maneuver its **course** is generally constant for several hours at least. In such a case the ship is said to be following a rhumb line. The rhumb line, or loxodromic curve, may be defined as any curve on the surface of the earth such that the tangent of the curve at any point cuts the **meridian** through that point at a constant angle. In case this angle has any value other than 0° or 90° it may be proved that the rhumb line is a spiral approaching one of the poles of the earth as a limit.

Obviously the rhumb line course between any two points is the simplest course to follow, for once having set the course it will not have to be changed until the destination is reached. However, except in the particular cases where the two points are either on the same meridian or are both on the equator, the rhumb line will not be the shortest distance between the two points. The **mercator** chart was designed for the purpose of facilitating the laying down of rhumb line courses. On a mercator chart, and only on this chart, the rhumb line appears as a straight line. (W.K.G.)

RHYNCHOBDELLIDA. **Hirudinea.**

RHYNCHOCEPHALIA. **Reptilia.**

RHYNCHODAEUM. The part of the **proboscis** of **nemertine** worms which lies in front of the brain. The proboscis is an eversible structure. When retracted it lies almost entirely behind the brain, but when extended the brain is near its base, thus the greater part of the proboscis constitutes the rhynchodaeum. (A.W.L.)

RHYOLITE. The general term for a group of **acidic igneous rocks,** the **effusive** equivalent of the **granites.** It occurs as lava flows, **breccias,** and in volcanic necks and dikes. In the porphyritic varieties the **phenocrysts** are frequently quartz or **orthoclase feldspar** imbedded in a highly **felsitic** or glassy ground mass. Rhyolites, including **obsidian,** frequently show **flow, spherulitic, nodular,** and **lithophysal structures.** (R.M.F.)

RIBBON-FISH. Pisces, Teleostei. Peculiar marine fishes (**Pisces**) with very long compressed bodies. They may reach a length of many feet with a dorsoventral thickness of less than 1′ and a width of only 1″. (A.W.L.)

RIBS. In man, the ribs number twenty-four, twelve on either side. They are attached to the vertebral column behind, and the first seven pairs are connected with the **sternum** in front and are called true ribs. The remaining five are called false ribs. The eighth, ninth and tenth are attached in front to the cartilaginous portion of the next rib above. The lower two, that is the eleventh and twelfth, are not attached in front at all and are called floating ribs. The spaces between the ribs are called intercostal spaces; they contain the intercostal muscles, nerves and arteries. The ribs form the greater part of the bony cage of the **thorax;** they preserve its outline and allow for easy motion in breathing, due to their elasticity. (R.S.M.)

RICE. *Oryza sativa.* Gramineae. Rice is an annual grass which grows wild in tropical Asia and Africa. Cultivated rice is probably derived from an Asiatic species, and is especially adapted to grow in swampy or very wet lowlands. It is a shallow rooted plant, the stems of which tiller abundantly and grow from 2–6′ or more in height. The leaves are long and smooth. The **inflorescence** is a **panicle** the branches of which may occur singly or in pairs. The laterally compressed **spikelets** are 1-flowered, and have a pair of small bristle-like **glumes;** the **lemma** is tough, parchment-like and sometimes **awned;** the **palea** resembles the lemma, but is somewhat smaller. A distinctive character of the flower is the presence of six functional **stamens.** Commonly rice is self-pollinated. The grain or karyopsis is enwrapped in the palea, and frequently also in the lemma. In this condition rice grain is known as paddy, or rough rice. The grain itself is smooth and shining, has a pair of longitudinal grooves on its surface, and a glassy endosperm. In structure it is very similar to wheat grain.

The milling of rice involves several processes. First the outer coverings are removed by revolving stones and fans. After this the outer seed-coats and **embryo** are largely removed by rubbing; the remaining grain is scoured and polished by rubbing on leather surfaces. Finally the polished grain is given a coat of glucose and talc, and is ready for market.

The principal use of rice is as a food stuff for human consumption, with China, India and Malaysia consuming the greatest quantity. In the United States rice is used to a slight extent as a breakfast food and in the preparation of other foods. Some rice is used in the manufacture of **starch**. The hulls and residues from polishing are sometimes fed to stock. Rice straw is used as stock food, for making strawboard and in the Orient for making hats, and many other articles. From the grain the fermented drink, sake, is prepared.

In North America two native grasses are frequently called wild rice. These are *Zizania aquatica* and *Z. miliacea,* tall swamp grasses closely related to *Oryza*. The grain is an important food for wild fowl, and finds a very limited use as a food for man, largely as a novelty. (R.M.W.)

RICE BIRD. Aves, Passeriformes. 1. The American **bobolink.** 2. The Java **sparrow,** also known as the paddy bird. (A.W.L.)

RICHARDSON'S EQUATION. **Thermionic Phenomena.**

RICKETS. A deficiency disease of infancy and early childhood, due to inadequate supplies of vitamin D (see **Vitamins**). The clinical picture is one of skeletal abnormalities due to the failure of lime salts to be deposited in growing cartilage and in newly formed bone. The growing ends of the bones are soft and bend under the stress of weight-bearing. In young infants, the skull is softened along the suture lines (cranio-tabes), and the eminences of the frontal and parietal bones become prominent, resulting in the typical "square head" of the disease. Bowing of the limbs, deformities of the skull, and deformities of the chest persist into adult life. The eruption of the teeth is delayed, and lasting defects in the calcification of the unerupted permanent teeth occur.

The prevention of rickets is accomplished by exposure to sunshine, and by giving vitamin D in the form of cod-liver oil, halibut-liver oil, viosterol, or other antirachitic preparations. The disease is treated by the same means. (D.M.H.)

RICKETTSIAL DISEASES. A group of diseases, world wide in distribution, which are transmitted by **arthropods.** The causative agents are various species of Rickettsia, microorganisms which stand between viruses and bacteria as to size, cannot be grown outside living cells, and are widely distributed in ticks, mites, spiders, lice and fleas.

The main groups of Rickettsial diseases are the typhus group, the Rocky Mountain spotted fever group, and the Tsutsugamushi disease group. All of these are similar in their **pathology**: they produce damage of the smaller blood vessels and thrombosis of these vessels; and all produce a clinical picture characterized by fever, lethargy, and a typical rash. Each gives a serological reaction (the Weil-Felix test) which is characteristic. The diseases nevertheless vary considerably in their severity and mortality.

Typhus occurs in **epidemic** (louse-borne) and **endemic** (flea-borne) forms. Epidemic typhus is a great scourge in wartime, with a mortality rate of 50 to 70%; its control in World War II by the elimination of the body louse with **DDT** was a major victory. The endemic or murine form occurs chiefly in southern United States. It is a much milder disease than the epidemic variety.

Rocky Mountain spotted fever is transmitted by tick bites. As its name indicates, it is prevalent primarily in the Rocky Mountain region. Its mortality varies greatly with different outbreaks, but is generally high, 35 to 80%—the higher rates occurring in adults.

Tsutsugamushi disease is mite-borne. A variety, if not the identical disease, known as *scrub typhus,* was a major problem in the South Pacific theatre of World War II. The attack rate was very high; the mortality rate was 10 to 25%.

There is no specific treatment for any of the Rickettsial diseases. They are self-limited and run a course of several days to several weeks. (D.M.H.)

RIEBECKITE. The mineral riebeckite, essentially **sodium iron silicate,** $NaFe(SiO_3)_2$, is a monoclinic member of the **amphibole** group, usually in prismatic crystals. It has a prismatic **cleavage**; hardness, 4; specific gravity, 3.4; vitreous luster; color dark bluish to black. It occurs in **granites** and **syenites** chiefly. It is found in Greenland, Portugal, Madagascar and in the United States at Quincy, Massachusetts; near Pikes Peak, Colorado, and the San Francisco Mts., Arizona. (E.S.C.S.)

RIECKE'S PRINCIPLE. The term for **thermodynamic** processes by which recrystallization may take place in **metamorphic rocks.** An explanation of one form of **foliation** and **schistosity,** whereby tabular minerals such as **hornblende** and **biotite** recrystallize with their longest dimension parallel to the developing planes of foliation. The result of differential pressures and the consequent solution where pressure is greatest, and redeposition and recrystallization where pressure is least. (R.M.F.)

RIFFLEFISH. Pisces, Teleostei. A small fish (**Pisces**) of the genus *Cottus,* related to the miller's thumb of the eastern half of the country. A **sculpin.** It is found from Alaska to the Sacramento River. (A.W.L.)

RIFLE BIRD. Aves, Passeriformes. A **bird of paradise** found in Australia and New Guinea. The several species make up the genus *Ptilorhis.* (A.W.L.)

RIGHI-LEDUC EFFECT. If heat is flowing through a strip of metal and the strip is placed in a magnetic field perpendicular to its plane, a temperature difference develops across the strip. This effect, discovered in 1887 independently by Righi and by Leduc, bears the same relation to the **Nernst effect** that the **Ettingshausen effect** bears to the **Hall effect.** It may indeed be regarded as analogous to the Hall effect, but with a longitudinal flow of heat replacing the electric current and a transverse temperature difference replacing the potential difference. If, to one looking along the strip in the direction of the heat flow, and with the magnetic field downward, the decrease of temperature is toward the right, the effect is said to be positive. It is positive in iron and negative in bismuth. (L.D.W.)

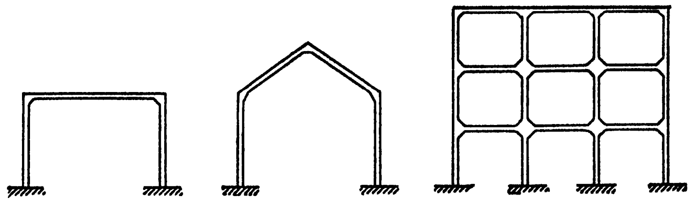
RIGHT ASCENSION. **Equatorial Coordinates.**

RIGHT TRIANGLES. **Triangles.**

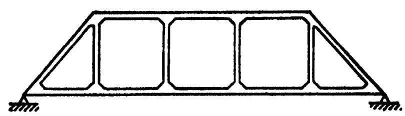
RIGID FRAME. A rigid frame, also known as a continuous frame, is an **indeterminate structure** in which continuity of action between the intersecting or adjacent members is obtained by means of moment-resisting **joints** (joints capable of resisting **bending moment**).

Rigid frames are made of structural steel or **reinforced concrete.** In the former the joints are either riveted or welded while in the latter continuity is produced by continuing the main reinforcing rods beyond the joint; additional rods may be necessary to develop the required resisting moment.

Rigid frames are used as **bridges,** and as **bents** in mill and multiple-story buildings. The Vierendeel girder bridge is a rigid frame which is similar in outline to the usual bridge **truss.** However, the diagonals are omitted since the **chords** are designed for **flexure.**



Bents



Vierendeel Girder

Rigid frames.

This truss is very useful for special cases of building framing. Rigid frame action is also utilized in the design of reinforced concrete **culverts** and sewers. (C.W.C.)

RIGIDITY. Elasticity.

RIME ICE. Icing on Aircraft.

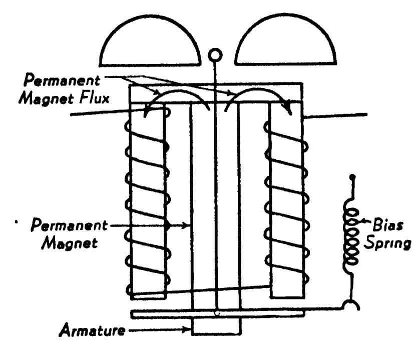
RIMMING STEEL. A steel which when cast into ingot molds solidifies with the evolution of considerable quantities of gases. In casting such an ingot, evolution of gas (mainly carbon monoxide) keeps the molten metal turbulent as the thickness of the frozen metal in contact with the ingot mold increases. The solidified ingot has scattered **blowholes** throughout but much less central pipe than **killed steels** and a relatively thick skin free from blowholes. The blowholes weld shut during hot rolling and the thick skin tends to give good surface to the finished product. Rimming steel is characterized by a lack of homogeneity in its chemical composition, especially for the elements carbon, phosphorus, and sulfur. The chemical segregation of the ingot persists in the final product. (R.H.H.)

RING CANAL. 1. In the phylum **Bryozoa**, a part of the body cavity which is incompletely separated from the principal chamber and prolonged into the tentacles. 2. A canal of the water vascular system of starfishes (**Asteroidea**) which forms a complete circle in the disk. It is connected by the stone canal with the madreporite and gives off a radial canal into each arm. The ring canal also bears the Polian vesicles and Tiedemann's bodies. (A.W.L.)

RING GAUGE. Measurement.

RING-DIKE. A more or less circular **dike** controlled by a ring-shaped **fault.** (R.M.F.)

RINGER. This is the bell mechanism of the ordinary telephone. Reference to the figure will show that it differs in principle from the ordinary electric door-bell as no make and break contacts are used. Essentially it consists of two soft iron cores surrounded by coils through which the ringing current (a low-frequency a.c.) is passed, the permanent **magnet** and the soft iron armature which attaches to the bell clapper. The permanent magnet sets up flux equally in the two cores and hence causes no unbalance of attraction for the armature and the bell is in equilibrium. Passage of the alternating ringing current causes the flux due to the coils alternately to add to and subtract from the fixed flux in the cores and thus first one core and then the other has a maximum flux. This unbalances the attraction of the armature which is pulled to the side having the most flux. Since this alternates, the armature vibrates back and forth, causing the bell to ring. For



party-line ringing this operation is modified by adding a spring to pull the armature to one side, giving what is known as a biased ringer. Then, if the ringing current is made pulsating d.c. of the right polarity it will cause an increase of flux in the other core and give a pulsating attraction to the armature in that direction. Thus the bell will ring on only one polarity of pulse. The bell at the other party-line phone has the spring attached to the other side so it will ring on the opposite polarity, thereby giving selective ringing on a 2-party line. By proper connection of the biased ringers between line wire and **ground** 4-party selective ringing may be obtained, two ringing over one line and ground and the other two over the other line and ground. (See also **Harmonic Ringing.**) (L.R.Q.)

RING-OILED BEARING. Bearing.

RING-TAILED CAT. Cacomistle.

RINGWORM (TINEA). A contagious disease of the scalp, skin, or nails caused by various **fungi.** Circular reddened patches with crusting and pustules with loss of hair occur. **Epidermophytosis** is a form of ringworm. Treatment varies somewhat with the fungus involved and the site of infection. In general it consists of mechanical removal and chemical destruction of the living fungi, and soothing applications to the irritated skin. Ammoniated mercury, salicylic acid, benozic acid, and many other ointments are used. (D.M.H.)

RIPPLE MARK. Corrugations developed in sands and muds by currents in the water which covers them. Ripple marks may be classified as due either to oscillation or translation. The former are the result of oscillation currents set up in the water by the wind; the result of ordinary water waves. The latter are the result of progressive, directional water currents, and the resulting ripple mark is essentially a sub-aqueous **dune**. Ripple mark is helpful in determining the conditions under which aqueous, clastic sediments are deposited. Ripple mark has also been used to help determine the depth of water in which the rippled sediments have been deposited. Ripple mark is also helpful in determining the original position of formations which have been subsequently deformed or overturned. (R.M.F.)

RIPPLE VOLTAGE. When an a.c. is rectified the resultant current or voltage consists of pulsating d.c. In the case of simple half-wave **rectifiers** this output is a series of half-sine waves spaced by equal intervals of no output while for full wave, single-phase rectifiers it consists of half-sine waves with no appreciable space between them. Polyphase rectifiers give outputs which, while they do not vary as markedly as this, consist of a series of adjacent portions of sine waves. In every case the output may be considered as made up of a smooth d-c component and an a-c or ripple component. The first is the value read by a d-c instrument in the circuit and the latter is the component which will produce objectionable hum in communication equipment supplied by the voltage. To reduce this ripple component various **filter** systems are used, the amount of filtering depending upon the equipment being supplied by the rectifier-filter combination. In many industrial applications the output of the rectifier alone is satisfactory, in communications the output must contain an extremely small amount of a.c. This is measured in terms of per cent ripple which is the a-c component of voltage divided by the d-c component of voltage and multiplied by 100. (L.R.Q.)

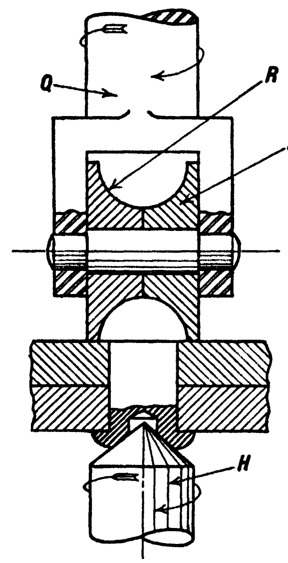
RITZ PRINCIPLE. **Atomic Spectra; Combination Principle.**

RIVET. A cylindrical member, with one preformed head, inserted in coincident holes in two or more plates, holding them together by the pressure exerted between the preformed head and a fabricated head at the other end. The fabricated head may be formed, either hot or cold, by ordinary hammering, pneumatic hammering, by a hydraulic pressure die, or by cold-working. Rivets of soft steel or wrought iron are hot-formed for all pressure vessel and structural applications. Rivet holes for pressure vessels are usually drilled to a diameter 1/16" greater than the size of the rivet. Punched holes are forbidden by the standard pressure vessel construction codes unless the brittle portion of the plate surrounding the punched hole is removed by reaming after the punching operation. Rivet holes for structural applications are usually punched, 1/8" greater than the nominal or shank diameter of the rivet.

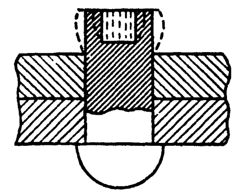
Rivet nomenclature is based upon the shape of the heads. Button-head rivets have semi-spherical heads, as shown in the figure; cone head rivets have heads shaped like the frustum of a cone; steeple head rivets have conical heads; countersunk head rivets are formed in countersunk holes, and are flush with the plate in which they are driven. The shank of a rivet is the cylindrical body; rivet grip is the length of the rivet, between the heads, after driving. (For methods of hot riveting, see **Forging.**)

Mass-production rivets are generally headed cold by hammer blows, by the application of pressure, or by spinning over the head of the rivet. Rivets are made of the softer non-ferrous metals such as brass and aluminum alloys, as well as iron and steel. Hammered rivet heads are formed on helve-type machines; the hammer often has a rotary motion in combination with its vibratory motion. Aluminum alloy rivets may be successfully headed by pressure in a hydraulic press; often a number of rivets are headed in one operation by the use of a suitable fixture or die.

The figure illustrates two methods of rivet head spinning. Spun rivets may be headed by using a coni-



Rivet Spinning



Explosive Rivet

cal-pointed rotating header H in a rivet-spinning machine which resembles a drill press in principle. This process requires a blind hole B in the end of the rivet, but is extensively used on small parts such as typewriter and sewing machine linkages. Spun rivets with button or round heads may be headed by employing a rotating spindle Q with twin rolls R and S, which are free to rotate on an axle A in the spindle fork.

Another type of rivet, shown at the right, is used by aircraft manufacturers for operations where the riveting must be done from one side of the part, thereby dispensing with the customary need of backing up the preformed head during the operation. The projecting shank of the rivet has a small hole filled with an explosive; when the rivet is inserted, the head is touched with a hot iron, which sets off the explosive and effects the deformation shown by the dotted lines. Another type of blind rivet is hollow, and is formed without backing-up by drawing a center pin through the rivet after it has been inserted.

In pressure vessel design and in structural fabrication, rivets are usually placed so that failure will occur by shear of the rivet or by crushing of the rivet body or the plate. (H.C.H.)

RIVETED JOINTS. Seams or joints for pressure vessels may either be riveted or welded, and are referred to as longitudinal or axial joints, and as circumferential or ring joints. (See **Pressure Vessels.**) Riveted joints may be either lap joints or butt joints. In lap joints, the two plate edges to be joined are lapped over each other, and rivets are driven through both plates. Lap joints are subjected to noncollinear forces which form a couple and tend to bend the plate and the rivets, resulting in a tendency to split and tear out the plate. For this reason, lap joints are rarely employed for longitudinal seams if the plate thickness exceeds 1/2". They are extensively used, however, for girth and head seams, where the cylindrical form of the telescoping sections

provides sufficient rigidity to eliminate this bending action.

In butt joints, the two plates forming the vessel shell are "butted" or placed together, and the connection is effected by butt straps placed on the inside and the outside of the plates. A connection of this character is

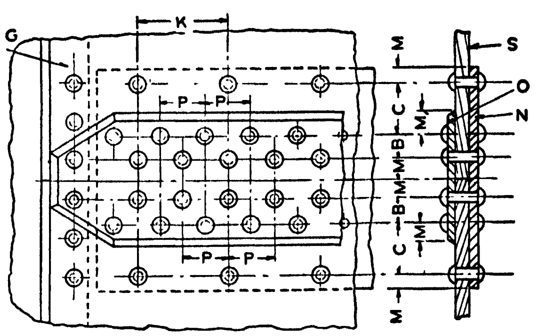


Fig. 1. Riveted joints.

shown in Fig. 1, which shows a triple-riveted longitudinal butt joint and a single-riveted circumferential lap joint *G*.

The pitch of a riveted joint is the distance between the centerlines of adjacent rivets in rows parallel to the seam, and is represented by distances *P* and *K* in Fig. 1; *P* is referred to as the short pitch, or simply as the "pitch." The distances *B* and *C* between adjacent rows of rivets are known as back pitch; the distance *M* between a rivet row and the plate or strap edge is known as the marginal pitch. Rows of rivets may be "chain" spaced, where the rivets are in alignment, or they may be "staggered," as shown in Fig. 1. (H.C.H.)

RIVETING. Forging.

ROAD-RUNNER. Aves, Cuculiformes. A long-tailed desert bird (**Aves**) of the southwestern United States. The species, *Geococcyx californianus*, is closely related to the cuckoos. It is useful as a destroyer of harmful insects and reptiles. The name comes from its ability to run rapidly, a power which very nearly supplants flight. Also called the snake bird, chaparral cock, and ground cuckoo. (A.W.L.)

ROARING FORTIES. Circulation of the Atmosphere.

ROASTING. Calcination.

ROBBER FLY. Insecta, Diptera. A predacious fly of the family Asilidae. Many of these flies are large and all capture living insects as prey, including bees of all kinds. Most of the included species have smooth slender bodies but some are quite hairy and one group is characterized by stout form and dense vestiture. These last mimic bumblebees closely and furnish an apparent case of aggressive mimicry, since the bumblebees are said to be among their victims. (A.W.L.)

ROBIN. Aves, Passeriformes. 1. The European redbreast, *Erithacus rubecula*, a **warbler**, and a related species of the Canary Islands 2. The American robin, *Turdus migratorius*, a **thrush**. 3. In Australia a species related to the **wheatear** and in New Zealand other birds of the same group. (A.W.L.)

ROBOT PILOT. Automatic Pilot.

ROC, RUC. A semifabulous bird (**Aves**) of enormous size, said to be capable of carrying an elephant in its talons. The tales have been traced to a gigantic bird of Madagascar, somewhat like the ostrich in form, which is now extinct. From the scattered remains and egg shells of these birds, the genus *Aepyornis* has been established, containing several species. (A.W.L.)

ROCHELLE SALT. Tartaric Acid.

ROCHES MOUTONNÉES. The term given by de Saussure, in 1796, to glaciated rock hills resembling the wigs which were fashionable during the late 18th century. Typical roches moutonnées have rounded surfaces sloping gently in the direction of the ice movement with steeper slopes on the lee side, due to the plucking action of the ice. (R.M.F.)

ROCK DRUMLINS. Drumlins.

ROCK SALT. Halite.

ROCKET ASSIST. This term refers to the use of a powder rocket to assist the take-off of an airplane. The thrust of the rocket is taken by the airplane structure and supplements the propeller thrust. Thus heavily loaded fighters and bombers can be assisted to rise off the flight decks of carriers, landplanes may be operated from air ports with more limited runways than would otherwise be needed, and flying boats with their moderate power loadings can be cleared from the water, this being especially helpful when water surface conditions are adverse for take-off.

A rocket containing 25 lbs. of cordite is capable of producing a thrust of over 1000 lbs. for a few seconds. It is claimed that the take-off of a fighter plane equipped with 4 such rockets can be accomplished in about 4 seconds. Rockets are mounted externally and fired electrically. When employed on high-speed military airplanes the supports and rocket tubes are jettisoned after take-off, but this would not necessarily be done where cost was important and speeds moderate. The following precautions must be observed when mounting rockets for assisted take-off.

1. Rocket efflux must miss the empennage and not be reflected from ground or deck back onto any part of the airplane.

2. The position of attachment should be such that the thrust lies in a plane, nearly horizontal (in take-off attitude), which passes through or close to the center of gravity. Thus stability and take-off control are not radically altered.

3. Possibility of shock waves impinging on empennage with adverse results should be investigated.

4. Rockets should be as close as possible to the plane of symmetry of the airplane in order to maintain control if one of the distributed rockets fails to ignite. (F.T.M.)

ROCKET FLIGHT. The flight of a rocket can be conveniently divided into the following phases:

1. Powered ascent during which the fuel is burned and an acceleration given to the rocket.

2. Upward drift as a free projectile, subject to the laws of exterior ballistics. In case the rocket is shot horizontally, as in antitank fire, this phase obviously does not exist.

3. Descent as a freely falling body, modified by air resistance.

4. Final period of deceleration for safety in landing. This also is intentionally non-existent in most rocket flights of the present time.

These phases are all shown in Fig. 1. During the first phase fuel is burned at approximately a constant rate. Where M_1 is the initial mass, M_2 the final mass, the fuel and oxygen combined become $M_1 - M_2$. If the amount of fuel carried is sufficient for T seconds of combustion the average thrust produced is

$$F = \frac{M_1 - M_2}{T} v.$$

In the above equation v is the jet velocity, relative to the rocket, based on complete expansion to atmospheric pressure.

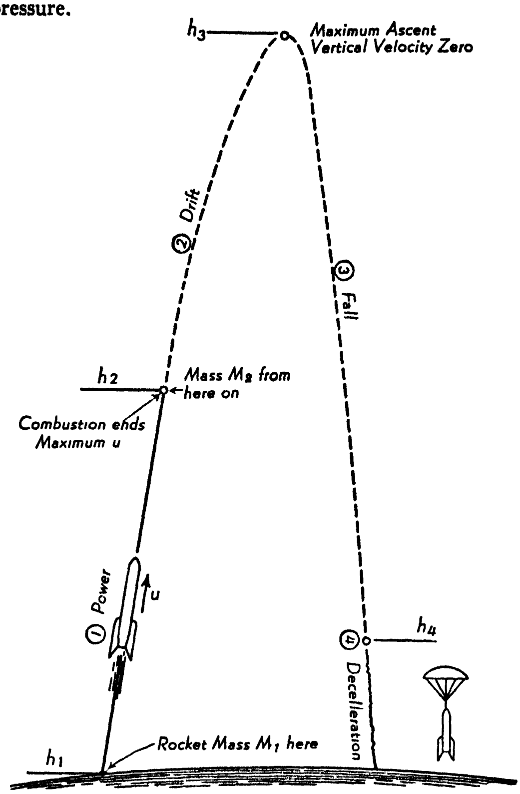

Fig. 1. Four phases of a rocket flight.

Except for the effect of air drag and gravitation, the maximum rocket velocity attained (relative to earth) is $u_2 = v \log_e \frac{M_1}{M_2}$. The actual velocity may sometimes approach half of this. Calculations for speed and altitude reached at the end of phase one are complicated and will not be shown here. In phase two the rocket drifts upward against the deceleration of gravity until brought to rest—or until its vertical velocity component is absorbed. If the end of the first phase has brought the rocket into comparatively thin air, and the trajectory is nearly vertical, then the additional height gained during this phase of the flight is $u_2^2/2g$, in which u_2 is the velocity at the beginning of "free" ascent. Future rocket development may see phase one extending to several hundred miles' altitude; then the diminishing acceleration of gravity would have to be taken into account in estimating the free ascent. An equation based on negligible air resistance and a vertical component of rocket velocity of u_2 at the outset of free ascent is:

$$h_3 = \frac{K_1 h_2 + K_2 u_2^2 (K_2 + h_2)}{K_1 - u_2^2 (K_2 + h_2)}$$

h_3 = Maximum altitude gained by the rocket, ft.
h_2 = Altitude at beginning of "free" ascent, ft.
u_2 = Velocity at beginning of "free" ascent, ft. per sec.
$K_1 = 29 \times 10^{16}$.
$K_2 = 2.12 \times 10^7$.

This same equation would serve to give the velocity at the end of the free fall from height h_3 by replacing h_2 with h_4, the altitude at which phase three of the trajectory goes into the fourth phase. However, since h_4 might be very near sea level (or might be zero for a rocket having no deceleration period), air resistance should not be neglected. To date small experimental and meteorological rockets have either been allowed to crash or were landed by a parachute. Parachutes are usually opened as soon as descent begins. However, in possible future crew-carrying rockets for extreme altitudes, the deceleration phase will be a topic of major interest—certainly to the crew.

When rockets depart, if ever, from the earth's atmosphere, the navigation problem goes over into astronomical terms. Considerable thought has been given to the problem of decelerating the returning rocket. It might approach earth from a journey into interplanetary space at such terrific velocities that to make a direct approach through the earth's atmosphere, even supposing a successful final deceleration could be accomplished, would be to invite the same disaster suffered by meteors: burning up from friction. It has been theorized that the returning rocket would have to be navigated in a manner to approach the earth's atmosphere tangentially as shown in Fig. 2. By grazing through the upper atmosphere on several deceleration loops (based on **Keplerian Laws**) around the earth, each successive one being allowed to pass through air of greater density as the rocket is slowed down, sufficient deceleration might be obtained to let the rocket be safely grounded by parachute, aided by a final burst of reverse rocket power. Some of the problems of interplanetary navigation by rockets have been investigated in great mathematical detail by astrophysicists.

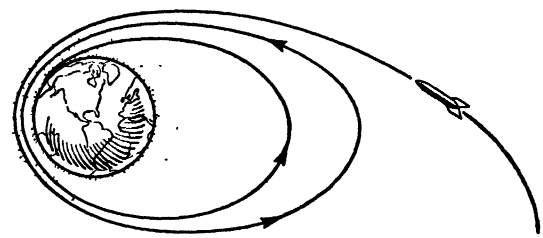

Fig. 2. Return of space-rocket to earth.

The equation (for h_3) given above will show that, in order to escape the earth's gravitational attraction, i.e., $h_3 = \infty$, the necessary vertical velocity of a projectile is 7 mi. per sec. This, of course, is in the absence of air drag. However, if a rocket were involved instead of a projectile, the rate of combustion might be adjusted to give moderate accelerations until the bulk of the atmosphere was left behind, say at 500 mi. up. The necessary velocity at the beginning of a free ascent to leave earth would still be about 7 mi. per sec. This is called the velocity of escape, or *velocity of liberation*.

The instantaneous ideal efficiency of propulsion of a rocket is zero at the start of a flight, rises to 100% when $u = v$, then begins to decrease. It has been shown by Sanger and others that the average efficiency prevailing from start, when $u = 0$ until speed has reached u, is maximum when $u_1 = 1.6v$. Since the mass ratio of the rocket equals $\log_e \frac{u}{v}$, the most efficient use of fuel is therefore when $M_0/M_1 = \log_e^{-1} 1.6 = 5$, approximately. This means that only 0.2 lb. of rocket body is permissible per pound of propellant carried.

Using gasoline and liquid oxygen as the propellants, an ideal combustion jet velocity of 14,500 ft. per sec. is indicated, but an actual velocity of $v = 9000$ ft. per sec. would be an achievement. The mass ratio of 5 which yields $u_1 = 1.6v$, neglecting gravitation and air drag, thus is seen to fall short of the 37,000 ft. per sec. necessary to escape from the earth. But if by trimming weight here and there the rocket body should be reduced to, say, .12 lb. per pound of propellants, then, for each pound of propellants, .08 lb. of another "pick-a-back" rocket could be carried along to be fired when the first rocket had reached an optimum altitude. Thus some faint

prospect of a space rocket is held out by the step-rocket principle. Alternately, energy sources yielding far higher jet velocities might be sought. When and if earth-science succeeds in dispatching a rocket into outer space it will likely be a one-way unmanned shot to the moon, relying on the crash landing creating some surface disfiguration there to advise us visually that the project was successfully terminated. (F.T.M.)

ROCKETS. Rockets are reaction-propelled bodies which carry all the oxygen needed for combustion along with them on their flight. In contrast, **jet engines** carry only fuel and rely on the surrounding atmosphere for oxygen to support combustion. Jet engines must remain in the atmosphere. Rockets travel best in the absence of an atmosphere; they are the only propulsion means yet developed which may ultimately solve the problem of the "space ship."

Rockets are to be classified according to the fuel type, and by their usage.

A. Type of fuel.
  1. Powder. Black, smokeless, cordite.
  2. Liquid. Alcohol, gasoline, etc.

B. Usage.
  1. Display and signaling. Skyrockets.
  2. Life saving. Breeches buoy line carrier.
  3. War rockets.
  4. Thrust augmenter (**rocket assist**).
  5. Rocket aircraft.
  6. Meteorological exploration.
  7. Possible future "space" rockets.

There have been several ill-considered attempts to employ rockets for purposes foreign to the nature of the rocket. Thus rocket-propelled automobiles are a dismal failure because the operating conditions do not permit an efficiency approaching that of the internal combustion engine. Rockets are high-speed affairs. For them, 50, 100, or 200 m.p.h. is a snail pace. Until speeds are attained exceeding those of our fastest airplanes, rockets will remain comparatively inefficient.

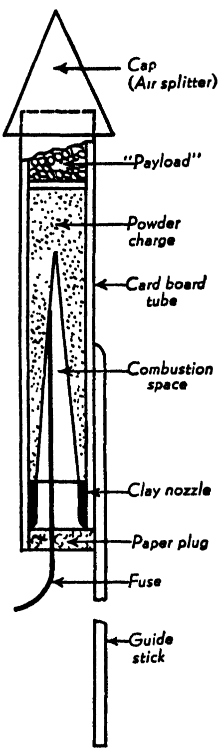

Fig. 1. Skyrocket.

Rockets are suitable for the creation of high velocities without recoil on the launching apparatus. This property gives them peculiar military significance. In rocket form heavy projectiles may readily be fired from small boats, aircraft, and by infantrymen, whereas the same projectile shot, as from artillery, would be accompanied by such a recoil that neither man, boat, nor aircraft could stand up to it. So in World War II small landing craft used in amphibious attacks were packed with fire power equivalent, it was said, to the guns of a cruiser by mounting on them multiple war rocket launchers. Two-man teams delivered the wallop of a heavy piece of anti-tank ordnance with the "bazooka," a short-range high-velocity rocket of 3½ lb. weight with high explosive war head. Comparatively small warplanes carried several rockets mounted on launching rails usually attached below the wing. This gave them an offensive power nearly equivalent to the mounting of cannon in airplanes —a wartime project that was never completely successful. But portability and simplicity of launching the missile are the war rocket's chief advantages. In long-range aiming accuracy, and efficiency of use of the propellant, artillery is greatly superior.

The subsonic velocities of modern aircraft are too low for efficient rocket propulsion, although rocket planes had some wartime development. The limited duration of flight became a handicap, but the short bursts of exceptionally high speed had a tactical use in interceptor aircraft. While the rocket has been principally the child of warfare, scientists, explorers, astronomers, and other venturesome souls look with interest on what may next come from it, for the rocket is good principally as a vehicle to navigate empty space. Here it will find the biggest field of all.

Powder rockets are probably the oldest form of jet propulsion. Records seem to place the first use of rockets by the Chinese in the 13th century. They reappear after periods of dormancy, for the rocket idea, once discovered, has never been completely abandoned. It first appeared as a weapon, then as a pyrotechnic display. In the 19th century Congreve brought the powder rocket to a high state of development, and Congreve's rockets and ideas dominated the field until comparatively recently. These rockets were used as an alternative to artillery, but the latter arm developed so rapidly that rockets were completely outclassed in World War I, when they were but seldom used. Development of the rocket to secure its peculiar and special advantages rather than in competition with highly developed artillery, was an outstanding feature of World War II, where rocket usage, as well as the rockets themselves, soared to new heights.

No rocket is simpler in construction than the skyrocket (Fig. 1). Powder is closely packed in a cardboard tube, leaving a clear cone-like space in the center to serve as a combustion chamber. A common gunpowder formula is charcoal (C) 15%, sulfur (S) 10%, and saltpeter (KNO_3) 75%. It is desirable to slow down the rate of combustion a little in rockets by using less of the oxidizing substance in the mixture. A typical rocket powder is $KNO_3$56, C32, S12. A clay nozzle is formed inside the rocket tube in order to form and guide the jet. When the powder is ignited, by means of a fuse, combustion gases form quickly at a pressure in the central chamber and are violently expelled, carrying along bits of burning carbon. As the powder burns the combustion chamber volume increases and the rate of combustion also. The powder is quickly consumed, but the acceleration produced is quite high. A rocket weighing initially 2 lbs., charged with 0.7 lb. powder, would produce an average thrust of 11 lbs. if it burned uniformly and had a jet velocity of 1500 ft. per sec. This can give the 2-lb. rocket an acceleration of 5.5 g.

Fig. 2. Aerial rocket bombs launched by airplane.

The velocity theoretically attained, neglecting air drag and gravitation, is obtained from the differential equation for momentum.

$$mdu + vdm = 0,$$

whence, by appropriate integration,

$$u_2 = v \log_e \frac{M_1}{M_2}.$$

m = Mass of rocket when its velocity is u.
v = Jet velocity relative to the rocket nozzle.
u_2 = Final velocity of the rocket.
M_1 = Initial rocket mass.
M_2 = Final rocket mass.
$M_1 - M_2$ = Weight of powder.
M_1/M_2 = "Mass ratio."

With rocket quantities as mentioned above, the mass ratio is 2/1.3, with a natural logarithm of 0.432. So

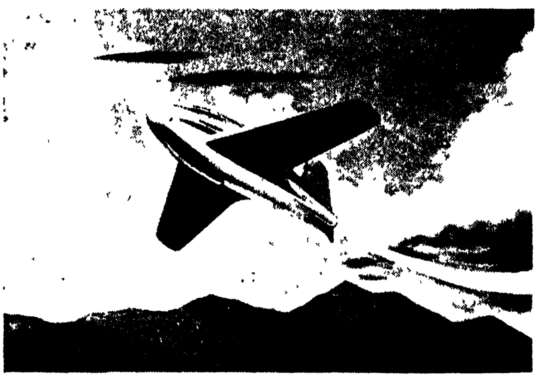

Fig. 3. Rocket plane—1945. Limited range—high speed (550 m.p h.).

the ideal maximum velocity is 43.2% of jet velocity or 650′ per sec. Were the rocket aimed for vertical ascent, part of the thrust would overcome gravitation, part would overcome air drag and the remainder would accelerate, with a final speed probably not over 400′ per sec. Still, this is 270 m.p.h.

The ideal maximum **combustion jet velocities** of gunpowder are low compared with other fuels. Also the ratio of realized to theoretical jet velocity is lower than with liquid fuels because considerable amounts of fuel are thrown out of the rocket in the form of fiery sparks (carbon). This, along with the better control over rate or combustion afforded by liquid fuels, gives the latter a decided advantage and indicates superiority of the liquid fuel rocket for long-distance rocket shots.

Liquid fuel rockets have been built to use gasoline or alcohol as fuels and liquid oxygen as the oxidizing agent. Analine, nitric acid, hydrogen peroxide also have had some use. These liquids are held in separate supply tanks from whence they flow in proper proportions into a combustion chamber. If mixing is adequate, the fuel is almost immediately oxidized, giving up its heat of combustion to the products which thereupon attain a high pressure and temperature. Fig. 4 illustrates the principle of the liquid fuel "motor." Rocket history of the past 2 decades is in large part a record of the trials and tribulations of experimenters seeking to perfect a successful liquid fuel rocket motor. Always fighting weight, these pioneers had to overcome problems of the melting and erosion of combustion chambers, proportioning of fuels, fuel feeds, handling methods suitable for liquid oxygen, the stabilization of flight paths, and a host of others. Liquid fuel rockets are still in the experimental stage. In the United States Dr. Robert Goddard led the way in this research with a succession of liquid fuel rockets of progressively better designs, his work extending over nearly 2 decades, 1920 to 1940.

A diagram of the liquid fuel rocket patterned after some of the early experimental rockets is shown in Fig. 4. A combustion chamber forms the head of the rocket

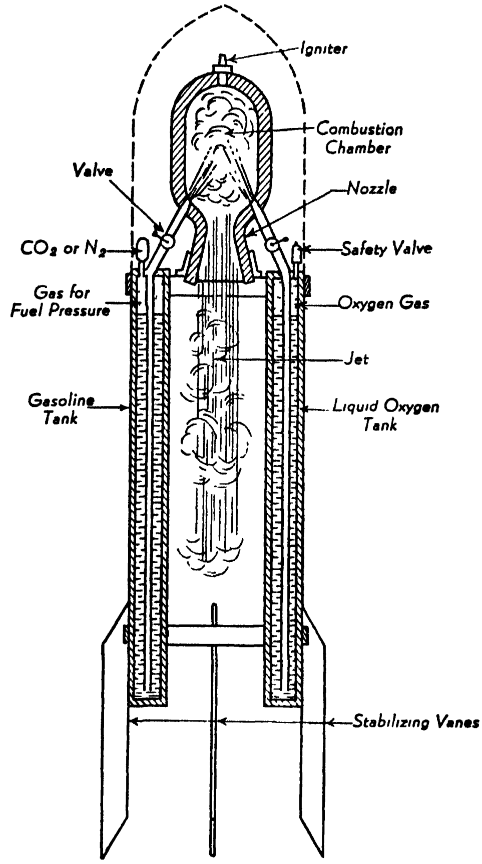

Fig. 4. Early type liquid fuel rocket.

Into this chamber are injected liquid oxygen and gasoline at as steady a rate as possible. Initially ignition is secured from an electrical igniter, after which combustion maintains itself until the fuel or oxygen supply is exhausted. The rate of fuel feed and the tank capacities determine the magnitude of thrust and duration of the powered ascent. Combustion produces high temperature products. The opening through which these may seek release from the combustion chamber will be made sufficiently small so that the products of combustion must build up a considerable fluid pressure before they flow out through the nozzle as rapidly as they are formed. This expansion to atmospheric pressure produces a jet of high velocity which will, however, fail by a large margin of attaining ideal maximum jet velocity. The reasons for this failure are:

1. The oxygen and fuel are not injected in the ideally correct proportions, or else they are not sufficiently mixed before or during combustion.

2. Combustion is not completed before the gas enters the nozzle because of the

a. Time factor, i.e., small chamber and high rate of combustion.

b. Dissociation factor, i.e., incomplete combustion within the chamber because of the thermal equilibrium of a percentage of fuel and oxygen possible at elevated temperatures.

3. Expansion ratio is not great enough to lower the internal energy of the exit gases to the initial state.

With regard to item 2b, long ago it was observed by Dugold Clerk that there was a discrepancy between the

actual observed temperature of combustion and the temperature which might be expected to exist by reason of the potential heat, mass, and specific heats involved in the process. When temperatures are several thousand degrees, the products cannot exist in a state of complete oxidation. For example, part of the CO_2 formed by combustion of C with O_2 will revert, or *dissociate,* to free constitutents. That is, there is an equilibrium, expressed by this equation,

$$CO_2 \rightleftarrows C + O_2,$$

likewise by this one,

$$H_2O \rightleftarrows H_2 + \tfrac{1}{2}O_2,$$

which lowers the maximum temperature of combustion. (If atomic energy could be made available to raise the temperature and therefore pressure of disintegration products in a rocket chamber, an ultra-high temperature would exist, as the energy is not derived from chemical combination.) However, the dissociation action takes some time for completion—which is not ordinarily allowed to it in the rocket combustion chamber and nozzle. Therefore, high chamber temperatures and nearly adiabatic expansion may be caused to prevail in rocket combustion.

During expansion the temperature falls and the dissociated products may eventually all recombine, liberating the full potential heating value. But since some of the combustion is thus accomplished during the expansion, perfect adiabatic expansion is destroyed, and the nozzle fails to convert the ideal available heat into kinetic energy. For this reason calculations based on equations premised on adiabatic expansion will be in some error for rockets but not as much so as for spark-ignition engines. The expansion through gas turbine and jet engine nozzles is not subject to the same consideration because the use of air rather than oxygen, and in considerable excess, too, usually insures that the temperatures are low enough (1000° F. to 1500° F.) to avoid any substantial amount of dissociation.

The rocket in Fig. 4 is poorly shaped for high-velocity flight. It represents a type in use when the possibility of successful liquid fuel rocket flight of any sort was in doubt. The trailing tanks and fins gave it a skyrocket-type of stability. For several reasons, rear end position of the motor is preferable, particularly in high-speed flight. The necessary rocket contents, fuel, controls, etc., can be located in a long, sleek, cylindrical case, sharply pointed at the nose to help penetrate the air at sonic speeds. Stability in flight has been secured by the use of stabilizing fins and gyro-operated control vanes. Examination of the German liquid fuel rocket (V-2) will convey some idea of the progress that already has been made in this field.

As the accompanying illustration shows, the rocket body is cylindrical and elongated. The sharply pointed nose consists of a 1-ton explosive warhead in back of which are located the radio control equipment and the gyroscopic stability devices used for remote control of the flight. But the interior is mainly filled by tanks containing the liquid propellants. (The data here used are those currently quoted during wartime use of V-2. Although these data are probably a good approximation of the precise figures, it is necessary to point out that these are not the builder's design figures.) The after part of the rocket body is occupied by the combustion equipment. A turbine is used to drive rotary pumps which withdraw the alcohol and liquid oxygen from their tanks and force them into the combustion chamber. The efflux of products of combustion from this chamber takes place through a nozzle about 18 in. in diameter. What the combustion chamber pressure might be has not been publicly stated. It has been estimated that the jet velocity was about 6000 ft. per sec., and this, coupled with the fact that some 8.5 tons of propellants were injected into a hemispherical chamber about 4 ft. in diameter in a little over a minute, implies that the combustion chamber pressure was of a high order. From its pump the fuel is led through jackets surrounding the nozzle and combustion chamber to cool them enough

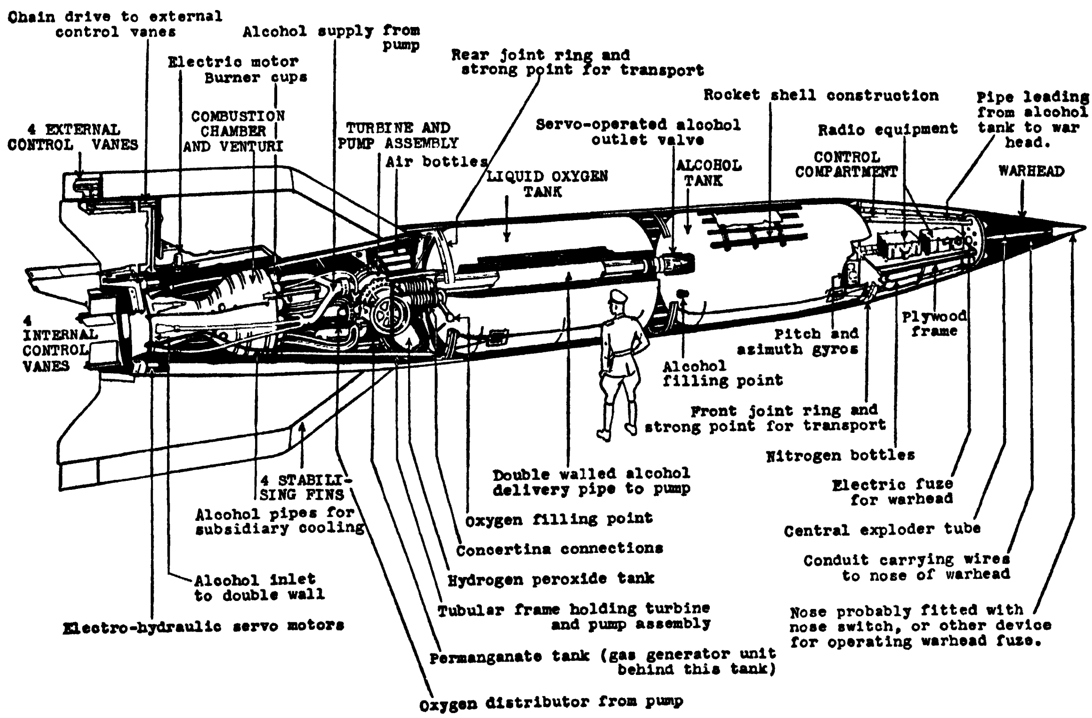

Fig. 5. Liquid fuel rocket—1945. Sectional drawing shows the German V2 rocket bomb. (*British Information Service.*)

to prevent their destruction. As the heat thus absorbed is retained by the fuel on its way to the burners, this system is called regeneration, and the rocket motor designated a *regenerative motor*. The warm alcohol is mixed with liquid oxygen in some 18 burner cups attached to the forward surface of the combustion chamber. The operation of the rocket is supposed to be about as follows. The fuel and oxygen tanks are filled, their relative capacities corresponding closely to those required for the ideal combustion of methyl alcohol with oxygen. Compressed air from small bottles then forces calcium permanganate into hydrogen peroxide, accompanied by an exothermic chemical reaction which results in the formation of superheated steam. The steam, of course, was produced solely for powering the pump turbine. The pumps transfer the oxygen directly to the burners, and the alcohol to them via the cooling jackets. Ignition is initiated electrically, and thereafter maintains itself as long as the fuel holds out and the turbine continues to turn. As soon as the jet builds up a reaction thrust equal to its weight the rocket takes off. Were the 8.5 tons burned in 70 sec., the exhaust would consist of 7.5 slugs per sec., which, moving at 6000 ft. per sec., would induce a reaction thrust of $\frac{6000 \times 7.5}{2000}$, or about 22.5 tons. The rocket is said to weigh 12 tons ready for launching, consequently a net 10.5 tons is available for acceleration. This would provide an initial acceleration of a little less than 1 g. As the fuel is consumed the rocket mass is diminished and the available thrust can propel the rocket at greatly increased acceleration. The combustion is said to propel this rocket about 25 miles high, after which its momentum carries it upward another 40 miles. U. S. Army postwar experimentation with those rockets increased the range to more than 100 miles altitude.

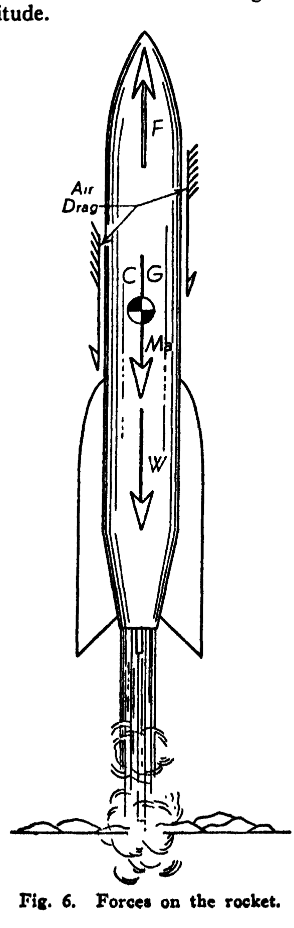

Fig. 6. Forces on the rocket.

The forces acting on a liquid fuel rocket aimed for vertical ascent are shown in Fig. 6. The exhaust jet produces a net reaction of F lbs., which, of course, must equal or exceed the sum of air drag D, and dead weight W. When F exceeds $D + W$, then $F - (D + W)$ is an accelerating force that can increase the velocity, u, of the rocket. An equation balancing the net thrust against inertia yields for vertical rocket acceleration $a = \frac{g}{W} \times [F - (D + W)]$ in which g is the acceleration of gravity. Supposed variations of some of these quantities with extreme altitude are shown by the accompanying graph.

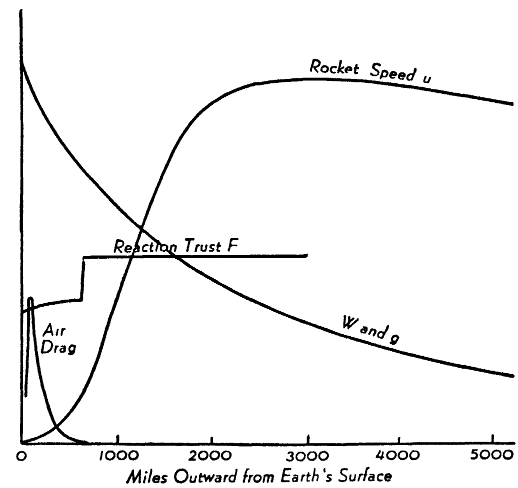

Fig. 7. Supposed variation of factors in rocket repulsion. (Low initial combustion rate to keep speed and air drag limited until the atmosphere is left behind.)

Rocket flights to a few miles of height above the earth's surface are today's wonder. (See **Atmosphere.**) Ascents to such heights that the gravitational field is noticeably weaker will probably come some day. Several books have been written which seriously weigh the pro's and con's of rocket flight into interplanetary space. From a former state of pessimism following analyses of requirements to be met in attempting a rocket-to-the-moon, there now appears a trend of thoughtful reasoning which admits the possibility. (F.T.M.)

ROCK-FLOUR. A peculiar and distinctive white mud the product of the grinding action of **glaciers.** When deposited in lakes rock-flour forms an important constituent of **varves**, or the type of annual cyclic stratification used by glacialogists in determining glacial time. When desiccated and transported by wind this material may form extensive deposits of **loess.** (R.M.F.)

ROCKS. In geologic usage, rock is the material composing the outer part or "crust" of the earth. It is a popular concept that the term rock is restricted to hard or firm substances. To a geologist, however, a body of clay or of volcanic ash is as truly rock as is a mass of hard granite. In general, a rock consists of one or more definite minerals. However, natural glass (**obsidian**), which has no definite composition and structure, makes large rock masses, as in Yellowstone National Park. Rocks composed of definite minerals may be either **simple** or **compound;** for example, the purest **marble** is formed entirely of the one mineral calcite, whereas **granite** consists of feldspar and quartz mixed in varying proportions, usually with minor quantities of mica and other accessory minerals.

All rocks are divided into three major classes, according to mode of origin. **Igneous rocks** are those that have been formed by cooling and solidification of molten masses derived from within the earth. Because

of their origin they are sometimes called the primary rocks. In part they are lavas and other products of volcanoes; other masses solidify slowly below the earth's surface to form granite and other crystalline types of igneous rock whose mineral content depends chiefly on the chemical composition of the parent molten mass. **Sedimentary rocks** consist of material that formed a part of pre-existent rocks, and that was moved from its former position, deposited by the action of water, the atmosphere, or glacier ice, and subsequently converted into rock. Examples are conglomerate, sandstone, and limestone. **Metamorphic rocks** are those that were originally igneous or sedimentary, but have been changed either in mineral composition or in texture, or in both, so that their original characters have been radically altered. **Slate,** formed by alteration of **shale,** and marble, derived from pre-existent **limestone,** are familiar examples. (C.R.L.)

ROCKWELL HARDNESS. **Hardness.**

ROCKY MOUNTAIN SPOTTED FEVER. **Rickettsial Diseases.**

RODENTIA. An order of gnawing **mammals** characterized particularly by the two chisel-like incisor teeth in each jaw. These teeth oppose each other and are worn down by use to maintain a keen enamel edge on the front, while the softer dentine slopes away inward. Most species are small but the **beavers** and **capybara** are moderately large animals. The rats and mice are the most familiar species, with the rabbits, squirrels, chipmunks and woodchucks scarcely less known. Because of their vegetarian habits and their destructive gnawing many rodents are serious crop pests, and as household nuisances they are all too common.

The **rabbits** and their allies are usually included under the Rodentia as a separate sub-order, the Duplicidentata, but are sometimes assigned to an order of their own, the Lagomorpha. (A.W.L.)

RODINAL. **Photography.**

ROEBUCK. Mammalia, Artiodactyla. *Caprealus.* The male of the roe **deer** of the Old World. The species is small and the antlers of the male reach a length of little more than a foot. They are rough, and in normal specimens have only three tines. The roe deer is a woodland species. (A.W.L.)

ROENTGEN RAYS. **X-Rays.**

ROLL, AIRPLANE. Roll is the angular displacement of an airplane about a longitudinal axis through its center of gravity. As a conventional airfoil is self-damping to roll, rolling instability is rare in aircraft. Roll is intentionally produced by the operation of **ailerons** which increase the effective camber of the wing on one side and decrease that of the other, thus unbalancing the lifting pressures and causing the existence of a rolling moment. The coefficient of rolling moment is defined as the moment directed by the product of span, wing area, and dynamic pressure. Rolls are used by pilots to neutralize "gustiness" and as part of the following common maneuvers—turns, slips, spins. (F.T.M.)

ROLLER. Aves, Coraciiformes. Birds (**Aves**) of several species found in Africa, the Oriental region, and Europe and Asia. They are brightly colored birds, named from their habit of turning over in flight. (A.W.L.)

ROLLER BEARING. **Bearings.**

ROLLER CHAIN. **Chain.**

ROLLER LEVELING. A method of flattening sheet metal by passing through a succession of bending rolls. A roller leveling machine consists of two parallel trains of small-diameter rolls mounted horizontally in a housing, one train above the other. Top and bottom rows are so off-set or staggered that the sheet passing through the leveler is flexed alternately up and down. The two layers of rollers are movable with respect to each other; so that by means of a screwdown the rollers may be made to mesh loosely or closely as desired, thus controlling the pressure exerted on the piece during the operation. On levelers with the proper amount of meshing of the rolls flatness may be obtained with essentially no increase in the length of the sheet, but the sheet is slightly cold worked by this plastic bending. Roller leveling helps to prevent **stretcher strains** in soft steel sheets. It does not ordinarily produce sheets as flat as **stretcher leveling,** and roller-leveled sheets are used primarily for fabricated articles which are to be stretched considerably, hence the original flatness has no bearing on the shape of the finished article. (R. S. BURNS.)

ROLLE'S THEOREM. Rolle's theorem is a mathematical result concerning the vanishing of the derivative of a function.

Let $f(x)$ be a **function** which vanishes at $x = a$ and at $x = b$, and which has a finite **derivative** $f'(x)$ at all points in the interval (a, b). Then $f'(x)$ vanishes at some point ξ between a and b. (L.L.S.)

ROLLING; ROLLING MILLS. Rolling is the process of reducing the cross-sectional area of pieces of metal by passing them between revolving cylinders called rolls. A rolling mill consists essentially of the rolls set in a suitable framework or housing to support them. These rolls are connected to a motor which transmits to them the power necessary to perform the reduction. Rolling mills roll metals to numerous intermediate and final shapes, such as blooms, billets, slabs, bars, rods, rails, structural sections, plates, sheets, and strip. Rolling may be performed either hot or cold, i.e., at elevated or at room temperatures.

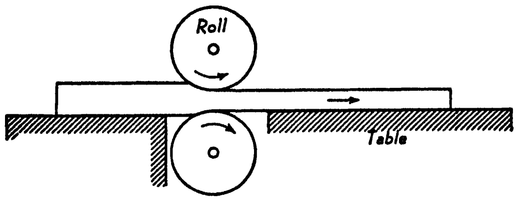
Perhaps the earliest definite description of rolling was given in 1495 by the Italian genius, Leonardo da Vinci, whose notebooks contain sketches of rolling mills for the production of sheet lead. Antoine Brulier, of France, in 1552 first adopted a rolling mill to the production of mint flats of uniform thickness in order to make coins of equal weight. This mill was so imperfect and its operation so expensive that its use was discontinued. Solomon de Caus, in 1615, describes a hand-driven mill for the rolling of lead plates for organ pipes.

About 1800, the cold rolling of metals was in general use for iron, steel, brass, and foil of various other metals. The cold rolling of iron and steel as an industry may be said to date from about 1830, because at that time we find records of the manufacture and use of steel reeds for weaving, wire for ladies' hats, hoops for hoop skirts, corset staves, clock springs, and shank steel for shoes.

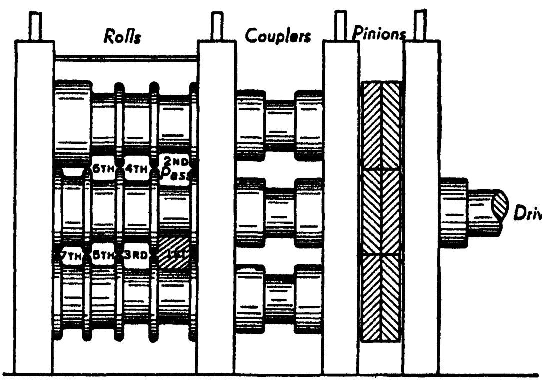
The earliest mills were driven by water power and later ones by steam. The steam engine, in turn, gave way to constant-speed electric motors which today have been supplanted by the highly flexible individual d-c motor.

In steel-mill practice the parts of a rolling mill are, in addition to cranes and other handling equipment, the soaking pits in which **ingots** are brought to rolling temperature, reheating furnaces, rolling mills, straightening and cooling tables, cut-off shears, coilers and decoilers for strip practice, and roll grinding machines. A stand in a rolling mill may be either 2, 3, or 4 high, depending on the number of rolls. In a 2-high stand there are two rolls, and if the work is to be passed a second time through the rolls, the direction of rotation

must be reversed, or the work may be passed back over the top roll for reinsertion in the mill. In a 3-high mill there are three rolls, the lower and upper turning in the same direction. A return pass can be made between the middle and upper rolls without reversing the drive. Several passes may be made in one stand as in the blooming mill illustrated.



Principle of the rolling mill.



Three-high blooming mill.

Because of the demands created by the automotive, refrigeration, and furniture manufacturers, progress in recent years has probably been most rapid in the production of flat rolled steel, i.e., sheets and strip. This particular phase of rolling, therefore, will be covered in more detail. The production of flat rolled steel products by what is commonly known as "sheet bar practice" prevailed in the early part of the 20th century. This practice consisted in rolling ingots into rectangular bars 8–12″ wide and from ⅜–3″ in thickness and then further reducing by cross-rolling into sheets.

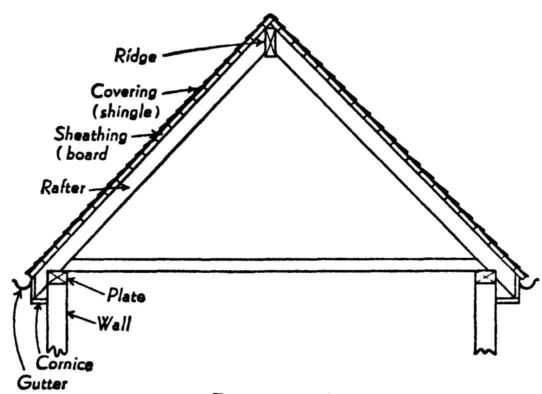
In 1924, strip was obtainable in widths up to 24″ and in lengths as long as demanded, and sheets were obtainable in widths as wide as were demanded (54″) but were limited in length and thickness. As a result of the development of continuous wide strip mills, cold rolled iron and steel sheets up to 90″ wide are available in either cut lengths or coils. The rolling equipment of a modern integrated steel mill now consists of a blooming mill which rolls ingots to slabs or billets, roughing mills, Universal mills and rod and section mills which further reduce these semi-finished products to bars, plates, rods, sections, etc., and continuous hot and cold strip mills which reduce slabs or bars to hot and cold rolled sheet and strip. Hot rolling of ingots to semi-finished products is performed at temperatures ranging from 2300° F. down to 2100° F. Hot rolling of these semi-finished products into other semi-finished and finished products is performed at temperatures between 2200 and 1300° F. In the production of cold-rolled sheet and strip and cold-drawn rods and bars of various dimensions, the oxide is removed from the hot-rolled product by **pickling** and these sections are further reduced on cold rolling mills.

Bars, sheet, and strip are cold rolled or cold finished to final dimensions for several reasons, the most important of which are:

1. To obtain the desired surface finish.
2. Improve dimensional tolerances.
3. To impart desired physical properties.
4. To make gauges lighter than can be produced on hot strip mills.

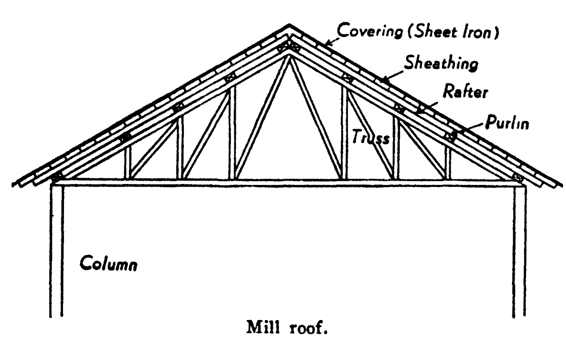
There are many different kinds of cold reduction mills. The one which enjoys by far the most general use is the conventional 4-high type in which there are two driven work rolls and two larger diameter rolls which back up or support the work rolls. Four-high mills are in use either in tandem or as reversing mills, wherein the strip is coiled on either side of the mill and run back and forth between the rolls until the desired thickness is obtained. Another type of reversing mill which is used to a lesser extent is the Steckel mill in which the work rolls are not driven and all power to perform the reduction is supplied through tension applied to the strip. There are many types of "cluster mills" wherein the supporting or back-up rolls are clustered around small work rolls to give them both vertical and horizontal rigidity. The use of small work rolls is beneficial from the standpoint of making large reductions, particularly on hard materials. (R. S. BURNS.)

ROOF. When a region is covered above to shed rain or snow, the covering is known as a roof. It is an essential feature of all buildings, sheds, etc. A roof consists of a weatherproof covering supported on a smooth surface which, in turn, is supported by certain structural mem-



Dwelling roof.

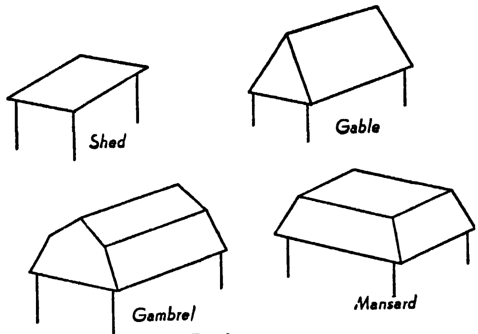
bers. In ordinary building construction, the roof covering is supported by a wood sheathing which is laid on rafters. The latter are structural members of wood which, in the case of ordinary dwellings, form the basic structural members of the roof, but which in the case of large roofs, are themselves laid on purlins (see **Bent**)



Mill roof.

which are supported by wood or steel trusses. The most common roof covers are slate, composition or wooden shingles, composition roofing paper, galvanized iron sheets (either smooth or corrugated), tinned sheets (smooth), and tile. The type of roof depends upon the expense which the owner is willing to incur in order to

secure permanence and also on the kind of building which the roof is to cover. Typical roofs are shown in the accompanying diagram. The loads to which these roofs



Roof types.

are subjected consist of dead load and live load. The dead load is the weight of the roof itself plus snow, and any structures that may be erected on the roof or suspended from it. The live load is wind or any movable loads which may be suspended from the roof, or which may roll over it. The dead weight varies with the composition of the roof, and the allowance for snow varies with the climate. Wind load varies both with the area and the slope of the roof. The steeper the slope, the greater the live load from wind. Pressure of wind against a vertical surface is approximately $0.0032v^2$, in which the velocity is given in m.p.h. This is resolved into pressure normal to the roof surface by one of the following formulae:

Normal pressure $= P \times \frac{2 \sin i}{1 + \sin^2 i}$ (Duchemin Formula)

Normal pressure $= P[\sin i]^{1.84 \cos i - 1}$ (Hutton Formula)

Normal pressure $= \frac{Pi}{45^\circ}$ (Ketchum Formula)

P = Vertical plate pressure in lbs. per sq. ft.
i = Roof angle in degrees.

The roof load is delivered to a plate which caps the bearing wall, or is carried to suitable foundation by means of vertical steel columns. The latter is favored in industrial buildings having large roofs supported by steel roof trusses. (F.T.M.)

ROOK. Aves, Passeriformes. A European bird (**Aves**), *Corvus frugilegus,* related to the crows. Its black plumage is glossed with purple and the face of the adult is usually naked and grayish. (A.W.L.)

ROOT MEAN SQUARE. The root mean square current or voltage is the effective value of the quantity in an **alternating-current circuit.** The defining equation for current is:

$$I = \sqrt{\frac{1}{T}\int_0^{T_2} i^2 dt}$$

where I is the root mean square current, T is the interval of integration and i is the current equation as a function of time t. A similar equation defines the voltage.

In statistics, the root mean square of the **variates** $x_1, x_2, \cdots, x_n$ is the **average** defined as

$$\text{R.M.S.} = \sqrt{\frac{x_1^2 + x_2^2 + \cdots + x_N^2}{N}}$$

and in a **frequency distribution** by $\sqrt{\frac{\Sigma x^2 f_x}{\Sigma f_x}}$. It is very seldom used. (L.R.Q., L.A.A.)

ROOT OF AN EQUATION. A root of an equation with one unknown is a value of the unknown which satisfies the equation, that is, which makes the two sides of the equation identical in value. (L.L.S.)

ROOT PRESSURE. **Ascent of Sap.**

ROOTS. In seed plants, the root is generally the first part of the plant to emerge from the germinating seed.

Commonly one thinks of the root as the part of a plant which is found in the ground. While this is true in the majority of cases, in some plants the roots are found in the air. So the common definition of the root is only partly correct.

On breaking through the seed coats of the germinating seed, the seed root, or hypocotyl, turns downward and soon puts out an abundance of minute hairs.

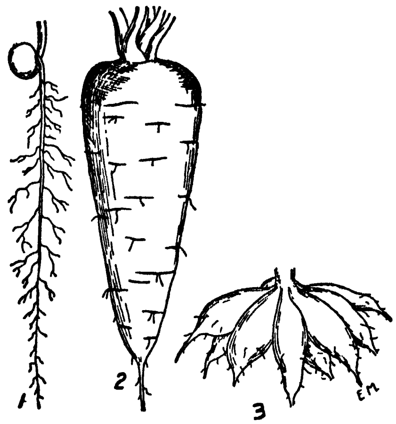
Root hairs penetrating the soil. Note the tiny rock particles, the bits of humus, the films of water, and the air spaces.

These serve the twofold purpose of attaching the hypocotyl firmly in the soil and of absorbing moisture and mineral solutions from the soil. The hypocotyl continues to grow into the soil, elongating and branching, and becomes the root.

Externally there are certain characteristics which distinguish a root from a stem, even when the latter grows underground. The root bears no leaves on its surface and is not separable into nodes and internodes, as is the case in the stem. The apex of the root is covered by a protective structure called the root-cap, a distinctive feature never found in stems. Just back of the tip, the surface of the root is usually provided with root hairs. Branching in roots is quite distinct from that in stems, the branch-roots appearing at irregular intervals; frequently these branch-roots are borne in longitudinal rows, a fact which is correlated with their origin. Branch-roots develop from the pericycle, a tissue deep in the root, and not from the sub-epidermal tissue as do stem branches. In many lower plants the root forks into two equal branches, a method of branching called dichotomous. In higher plants this does not occur.

Several types of roots are recognized. In many plants, the first formed, or primary, root continues to grow downward to form a long root which penetrates deep into the ground. Branch-roots arising from this are commonly much shorter, and of smaller diameter. Such a root is called a tap root, and the entire root system in such cases is known as a tap-root system. Familiar examples are found in the **dandelion,** burdock, and in **oak** trees. **Monocotyledonous** plants rarely show this form of branching. In them and in many other plants, the primary root soon loses its individuality, the secondary roots becoming larger, and forming an extensive root system, in which no single root is distinguished from the others by its larger size and more obvious downward growth. Such a system is called a fibrous root system, and the individual roots are known as fibrous roots. The common **plantain** has such a root

system. In many plants the roots become important places of storage of foods, the roots often being conspicuously enlarged because of this storage. Such roots are called fleshy roots. Their existence is of great value



Different kinds of roots 1, fibrous tap root of pea; 2, fleshy tap root of carrot; 3, fleshy fascicled roots of Dahlia.

to man, since many of them become important crop plants, as for example, carrots, parsnips, turnips and beets. In many plants, several roots are swollen with food so that a group or fascicle of storage roots is formed, as in the *Dahlia*.

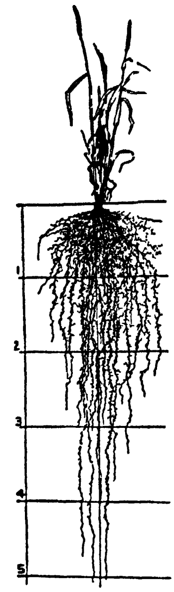
In many plants, especially in the tropics, the roots are formed in the air. Such aerial roots are often quite different from ordinary roots, being much coarser, less branched and lacking root hairs. In aerial roots the outer portion is frequently modified to a spongy tissue capable of absorbing moisture rapidly and retaining it tenaciously. This tissue, the velamen, is particularly well developed in epiphytic orchids. Other plants have aerial roots which extend either downward from the branches, or from the lower part of the stem. Such roots are called, respectively, prop roots or brace roots. The terms are often used interchangeably. These roots soon penetrate the surface of the ground and become like ordinary roots. The **Banyan** tree shows the downward-growing prop roots particularly well, while in the Screw-Pine and in **Corn** plants, brace roots are well-developed. They are especially conspicuous in the **Mangrove** plants, where they form an extensively branching system supporting the plant in the soft mud in which it grows. In many tropical plants, especially in those of large trees, the roots radiate out over the surface of the ground. Often these roots are conspicuously developed vertically, forming thin plates of considerable depth, but only a few inches thick; they are called buttress roots.

A type of modified roots—Aerial roots of poison ivy, *Rhus Toxicodendron.*

In **parasitic plants** the roots may be curiously modified or replaced by absorptive organs which penetrate the tissues of the host plant until they reach the conducting system, from which they obtain their nutrient supply. In some plants, roots are entirely lacking, their functions being taken over entirely by other parts of the plant. In the **saprophytic** Orchid, *Corallorhiza*, for example, the much-branched coarse underground stem, or rhizome, functions as a root; in the **Bladderworts,** *Utricularia*, floating in water, roots are entirely unnecessary and non-existent. In the **Spanish Moss,** *Tillandsia*, growing epiphytically in tropical and subtropical America, roots are entirely lacking, absorption occurring over the surface of the plant.

Commonly the extent of a root system is very much underestimated. Only when the entire plant is removed from the soil by careful and extensive digging is the great spread of the entire root system seen. Then it is found that the roots may penetrate the soil to a depth much greater than was supposed. In common Red Clover, for example, the roots may go downward to a depth of 8 or 9′, while in **alfalfa** depths of 15–20′ or more are found. The lateral spread of roots is also often very great. In the common Squash the lateral roots may extend outward 10–15′, while other roots of the same plane penetrate the soil to depths of 4–6′, forming a very extensive system. The nature of the soil, and especially the amount of oxygen present in it, are important factors in determining the amount of branching and the extent of the root system. In general, porous well-aerated soil favors extensive branching.

Roots do not seek water, as popularly supposed from the fact that they seem to grow toward water. This tendency is explained by the fact that roots respond very definitely to certain external factors, such as gravity. Most roots react positively to gravity, that is, are positively geotropic, growing directly downward into the soil. If a young plant is placed so that its root is horizontal, in a short time it will be found that this root has changed its direction of growth and is growing downward again.



Root system of wheat plant at blossoming time. Figures indicate depths in feet (*Weaver's Root Development of Field Crops, McGraw-Hill Book Co, Inc.*)

Many roots are also affected by light, from which they turn away, being negatively phototropic. Temperature also affects roots, so that a root encountering a region having a temperature more favorable for its growth will increase more rapidly than other roots. Entirely like this is the response of roots to favorable moisture conditions, which lead to greater growth of the roots extending in that direction. It is such phenomena which lead to the statement that roots seek water. Often they do seem to, especially when they penetrate joints in sewer pipes,

The root system of Iowa Silver Mine corn 36 days old. (*Weaver's Root Development of Field Crops, McGraw-Hill Book Co, Inc.*)

sometimes at distances of 30–60′ or more from the stem of the plant, and form great masses of much branched roots which may completely clog the sewer pipe, and become a source of great inconvenience and expense. Other factors such as the nature of the soil and its contained minerals, also influence the growth of roots.

The internal structure of the root is quite constant and distinct from that of the stem. In the tip of the

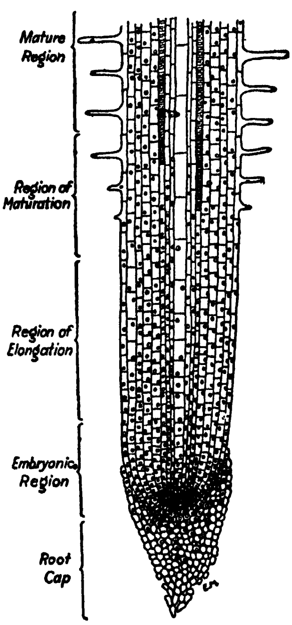
root an apical meristem, the promeristem, or zone of dividing cells is found. The cells of this region are more or less cubical in shape, thin-walled, and contain a dense protoplasm and a relatively very large nucleus. Because of this last characteristic, the root tip is a particularly suitable place to study nuclei during their divisions.

Over the apical end of the root, and covering the actively dividing cells is the root cap. This is a mass of loosely aggregated cells arising in various ways. In some plants the cells of the root cap are formed from the meristem cells in general. In **dicotyledonous** plants there is frequently a special layer of cells called the calyptrogen, covering the apical surface of the root. These cells divide and form cells which become the root cap. As the root elongates, the protoderm cells give rise to the epidermis of the root.

However formed, the root cap is continuously renewed throughout the life of the root, forming a protective cover over the tip. The outer and consequently older cells of this cap are loosely arranged. Their walls become considerably modified to form a mucilaginous mass, which greatly reduces the friction of the elongating root against the soil particles. This mucilaginous mass is often very conspicuous in the brace roots of corn.

Just back from the apical meristem of the root is the zone of elongation. In this region the cells show very characteristic changes. The most obvious of these is the increase in length which occurs in most of the cells. At the same time there appears in each cell a conspicuous central vacuole which enlarges greatly, the cytoplasm being pushed out to a thin peripheral layer in which is found the nucleus. In roots this elongating region is much shorter than is the corresponding region in the stem, a fact presumably correlated with the denser medium through which it grows. Usually it is less than a centimeter long.

As the root continues elongating the cells gradually change to form a third zone not sharply set off from the second. In this, the zone of maturation, the cells gradually assume their final form. Externally the most



Longitudinal section of onion root showing the regions of development.

conspicuous feature of this zone is the presence of the root hairs. A root hair is a slender outgrowth of an epidermal cell. In size they vary from 0.1 to 10 mm. long, with a diameter averaging about 0.01 mm.; the number of them formed on the root surface varies from 200 to 400 or more, so that they cause a tremendous increase in the surface of the root. The life of a root hair is not long, being commonly only a few days, after which it disappears. In a few cases root hairs may persist for 2 or 3 years, as in the Honey Locust or in certain **Composites.** In such cases they do not have the structure typical of root hairs, but are tough rather thick-walled objects. Usually the wall of a root hair is very thin and modified externally to a pectic substance which sticks closely to the soil particles and absorbs water readily therefrom. Within the wall is a thin peripheral layer of actively streaming **cytoplasm.** The central part of the hair is occupied by an evident **vacuole** which is continuous with that in the basal portion of the cell from which the hair protrudes.

As the root grows older and the cells composing it mature, a very definite structure appears. The outer portion is composed almost entirely of **parenchyma** cells, which are of irregular shape, loosely aggregated, and serve mainly for storage of materials.

The innermost layer of **cortical** cells is very distinct, forming the endodermis. In this layer, the walls of certain cells, as shown in the illustration, become thickened
